A ROBUST ALGEBRAIC MULTILEVEL DOMAIN DECOMPOSITION PRECONDITIONER FOR SPARSE SYMMETRIC POSITIVE DEFINITE MATRICES

HUSSAM AL DAAS† AND PIERRE JOLIVET‡

Abstract. Domain decomposition (DD) methods are widely used as preconditioner techniques. Their effectiveness relies on the choice of a locally constructed coarse space. Thus far, this construction was mostly achieved using non-assembled matrices from discretized partial differential equations (PDEs). Therefore, DD methods were mainly successful when solving systems stemming from PDEs. In this paper, we present a fully algebraic multilevel DD method where the coarse space can be constructed locally and efficiently without any information besides the coefficient matrix. The condition number of the preconditioned matrix can be bounded by a user-prescribed number. Numerical experiments illustrate the effectiveness of the preconditioner on a range of problems arising from different applications.

Key words. Algebraic domain decomposition, multilevel preconditioner, overlapping Schwarz method, sparse linear system.

1. Introduction. We are interested in solving the linear system of equations

\[ Ax = b, \]

where \( A \in \mathbb{R}^{n \times n} \) is a sparse symmetric positive definite (SPD) matrix and \( b \in \mathbb{R}^n \) is the right-hand side. On the one hand, despite their accuracy, direct methods [13] that are based on matrix factorizations become memory and computationally demanding for large-scale problems. Furthermore, establishing a high level of concurrency in their algorithm is challenging, which limits the effectiveness of their parallelization with many processing units, e.g., thousands of MPI processes. On the other hand, iterative methods, such as Krylov subspace methods, are attractive as they require less memory resources and parallelizing them is easier. However, their convergence depends on the coefficient matrix \( A \), the initial guess \( x_0 \), and the right-hand side \( b \). More precisely, the error at iteration \( k \) of the conjugate gradient method [21] satisfies

\[
\|x_k - x_*\|_A \leq 2\|x_0 - x_*\|_A \left( \frac{\sqrt{\kappa_2(A)} - 1}{\sqrt{\kappa_2(A)} + 1} \right)^k,
\]

where \( x_* \) is the exact solution and \( \kappa_2(A) \) is the spectral condition number of \( A \). Therefore, iterative methods are usually combined with preconditioners that modifies the properties of the linear system such that the convergence rate of the methods is improved. A variety of preconditioning techniques have been proposed in the literature, see the recent survey [36] and references therein. We focus in this work on preconditioners for SPD matrices. In terms of construction type, these preconditioners can be split into two categories. (1) Algebraic preconditioners: those do not require information from the problem besides the linear system, and their construction relies only on \( A \) and \( b \) [5, 22, 31, 35, 38]. (2) Analytic preconditioners: in order to construct them, more information from the origin of the linear system, e.g., matrix

assembly procedure, is required \cite{25, 26, 41}. Inferring how preconditioners modify the spectrum of iteration matrices provides another way to classify them. Again, two categories exist. (1) One-level preconditioners: those mostly rely on incomplete matrix factorizations, matrix splitting methods, approximate sparse inverse methods, and Schwarz methods \cite{38}. One-level preconditioners usually bound from above the largest eigenvalue of the preconditioned matrix. (2) Two-level and multilevel preconditioners: those are usually a combination of a one-level method and a coarse space correction. While the one-level part can bound from above the largest eigenvalue, the coarse space is used to bound from below the smallest eigenvalue such that the condition number of the preconditioned matrix is bounded \cite{2, 3, 4, 12, 15, 16, 18, 19, 28, 29, 31, 49, 42, 45}.

When it comes to overlapping DD, most one-level preconditioners and a few two-level/multilevel preconditioners are algebraic, while most two-level preconditioners are analytic. On the one hand, analytic two-level/multilevel preconditioners construct the coarse space efficiently without requiring computations involving the global matrix. On the other hand, existing algebraic two-level/multilevel preconditioners still require global computations involving the matrix $A$ that limit the setup scalability \cite{2, 16}. Furthermore, certain algebraic two-level preconditioners require complicated operations that may not be easy to parallelize. Therefore, we focus in this paper on two-level/multilevel preconditioners where the coarse space can be constructed locally. Certain algebraic multigrid (AMG) methods are examples of these preconditioners \cite{35}. Note that several AMG methods require unassembled matrices or the near-nullspace of the global matrix, which is known in some applications \cite{10, 44}. One could argue that these methods are thus not purely algebraic. Furthermore, their effectiveness has been proved only for certain classes of matrices. An algebraic two-level preconditioner for the normal matrix equations was recently proposed in \cite{4}.

In \cite{2}, the authors presented an algebraic framework to construct robust coarse spaces and characterized a class of local symmetric positive semi-definite (SPSD) matrices that allows to construct such coarse spaces efficiently. Since then, there have been several attempts to construct algebraic two-level preconditioners with a locally computed coarse space that are theoretically effective on any sparse SPD matrix, see, e.g., \cite{16} and references therein. Starting off with the subdomain matrices of $A$, the authors in \cite{16} define an auxiliary matrix $A_+$ such that $A - A_+$ is low-rank and a local SPSD splitting for $A_+$ is easily obtained. A robust algebraic two-level preconditioner for $A$ is then derived by a low-rank update of the robust algebraic two-level preconditioner of $A_+$. Despite the fact that the preconditioner proposed in \cite{16} is fully algebraic, using it in practice may not be very attractive since the low-rank update requires the solution of linear systems with $A_+$ involving a large number of right-hand sides that is nearly equal to the size of the coarse space of $A_+$, which is prohibitive for large number of subdomains. Therefore, we believe that the question of finding efficient locally constructed coarse spaces is still open.

When information such as the near-nullspace or the subdomain non-assembled matrices are available, analytic AMG or DD preconditioners are optimal. The preconditioner presented in this paper should be used when a robust black-box solver is needed.

The manuscript is organized as follows. We introduce the notation and review the algebraic DD framework in Section 2. Section 3 presents our main contribution in finding local SPSD splitting matrices associated with each subdomain fully algebraically in an inexpensive way and starting from local data. These matrices will be used to construct a robust two-level Schwarz preconditioner. Then, we briefly discuss the straightforward extension of our approach to a multilevel preconditioner.
Afterwards, we present in Section 4 numerical experiments on problems arising from different engineering applications. Concluding remarks and future lines of research are given in Section 5.

Notation. We end our introduction by defining notations that will be used in this paper. Let $1 \leq n \leq m$ and let $B \in \mathbb{R}^{m \times n}$. Let $S_1 \subset [1, m]$ and $S_2 \subset [1, n]$ be two sets of integers. $B(S_1, :)$ is the submatrix of $B$ formed by the rows whose indices belong to $S_1$ and $B(:, S_2)$ is the submatrix of $B$ formed by the columns whose indices belong to $S_2$. The matrix $B(S_1, S_2)$ is formed by taking the rows whose indices belong to $S_1$ and only retaining the columns whose indices belong to $S_2$. The concatenation of any two sets of integers $S_1$ and $S_2$ is represented by $[S_1, S_2]$. Note that the order of the concatenation is important. The set of the first $p$ positive integers is denoted by $[1, p]$. The identity matrix of size $n$ is denoted by $I_n$.

2. Domain decomposition. Throughout this section, we assume that $C$ is a general $n \times n$ sparse SPD matrix. Let the nodes $V$ in the corresponding adjacency graph $G(C)$ be numbered from 1 to $n$. A graph partitioning algorithm can be used to split $V$ into $N \ll n$ disjoint subsets $\Omega_i$ ($1 \leq i \leq N$) of size $n_i$. These sets are called nonoverlapping subdomains.

2.1. Abstract setting for two-level overlapping Schwarz methods. Defining first a one-level Schwarz preconditioner requires overlapping subdomains. Let $\Omega_{G_i}$ be the subset of size $n_{G_i}$ of nodes that are distance one in $G(C)$ from the nodes in $\Omega_i$ ($1 \leq i \leq N$). The overlapping subdomain $\Omega_i$ is defined to be $\Omega_i = [\Omega_i, \Omega_{G_i}]$, with size $n_i = n_{G_i} + n_i$. The complement of $\Omega_i$ in $[1, n]$ is denoted by $\Omega_{G_i}^c$. Associated with $\Omega_i$ is a restriction (or projection) matrix $R_i \in \mathbb{R}^{n_i \times n}$ given by $R_i = I_{n_i}(\Omega_i,:)$. $R_i$ maps from the global domain to subdomain $\Omega_i$. Its transpose $R_i^\top$ is a prolongation matrix that maps from subdomain $\Omega_i$ to the global domain.

The theory in this paper requires a decomposition of the graph of $C^2$. Hence, in addition to the previous subsets, we define the following ones. We denote $\Omega_{\Delta_i}$ the subset of size $n_{\Delta_i}$ containing nodes that are not in $\Omega_i$ and distance one in $G(C)$ from the nodes in $\Omega_{\Delta_i}$ ($1 \leq i \leq N$). The extended overlapping subdomain $\bar{\Omega}_i$ is defined to be $\bar{\Omega}_i = [\Omega_i, \Omega_{\Delta_i}, \Omega_{G_i}]$ and it is of size $\tilde{n}_i$. We denote the complement of $\bar{\Omega}_i$ in $[1, n]$ by $\Omega_{\Delta_i}^c$. Associated with $\bar{\Omega}_i$ is a restriction matrix $\bar{R}_i \in \mathbb{R}^{\tilde{n}_i \times n}$ given by $\bar{R}_i = I_{\tilde{n}_i}(\bar{\Omega}_i,:)$. $\bar{R}_i$ maps from the global domain to the extended overlapping subdomain $\bar{\Omega}_i$. Its transpose $\bar{R}_i^\top$ is a prolongation matrix that maps from the extended overlapping subdomain $\bar{\Omega}_i$ to the global domain.

The one-level additive Schwarz preconditioner [12] is defined to be

$$M_{\text{ASM}}^{-1} = \sum_{i=1}^{N} R_i^\top C_i^{-1} R_i, \quad C_i = R_i C R_i^\top.$$  

Applying this preconditioner to a vector involves solving concurrent local problems in the overlapping subdomains. Increasing $N$ reduces the sizes $n_i$ of the overlapping subdomains, leading to smaller local problems and faster computations. However, in practice, the preconditioned system using $M_{\text{ASM}}^{-1}$ may not be well-conditioned, inhibiting convergence of the iterative solver. In fact, the local nature of this preconditioner can lead to a deterioration in its effectiveness as the number of subdomains increases because of the lack of global information from the matrix $C$ [12, 15]. To maintain robustness with respect to $N$, a coarse space is added to the preconditioner (also known as second-level correction) that includes global
information.

Let $0 < n_C \ll n$. If $R_0 \in \mathbb{R}^{n_C \times n}$ is of full row rank, the two-level additive Schwarz preconditioner [12] is defined to be

$$M_{\text{additive}}^{-1} = \sum_{i=0}^{N} R_i^T C_{ii}^{-1} R_i = R_0^T C_{00}^{-1} R_0 + M_{ASM}^{-1}, \quad C_{00} = R_0 C R_0^T.$$  

Observe that, since $C$ and $R_0$ are of full rank, $C_{00}$ is also of full rank. For any full rank $R_0$, it is possible to cheaply obtain upper bounds on the largest eigenvalue of the preconditioned matrix, independently of $n$ and $N$ [2]. However, bounding the smallest eigenvalue is highly dependent on $R_0$. Therefore, the choice of $R_0$ is key to obtaining a well-conditioned system and building efficient two-level Schwarz preconditioners. Two-level Schwarz preconditioners have been used to solve a large class of systems arising from a range of engineering applications (see, for example, [18, 24, 30, 32, 40, 46] and references therein).

Following [2], we denote by $D_i \in \mathbb{R}^{n_i \times n_i}$ ($1 \leq i \leq N$) any non-negative diagonal matrices such that

$$\sum_{i=1}^{N} R_i^T D_i R_i = I_n.$$  

We refer to $(D_i)_{1 \leq i \leq N}$ as an algebraic partition of unity. In [2], Al Daas and Grigori show how to select local subspaces $Z_i \in \mathbb{R}^{n_i \times p_i}$ with $p_i \ll n_i$ ($1 \leq i \leq N$) such that, if $R_0^T$ is defined to be $R_0^T = [R_1^T D_1 Z_1, \ldots, R_N^T D_N Z_N]$, the spectral condition number of the preconditioned matrix $M_{\text{additive}}^{-1} C$ is bounded from above independently of $N$ and $n$.

### 2.2. Algebraic local SPSD splitting of an SPD matrix

We now recall the definition of an algebraic local SPSD splitting of an SPD matrix given in [2] and generalized in [3].

An algebraic local SPSD splitting of the SPD matrix $C$ with respect to the $i$-th subdomain is defined to be any SPSD matrix $\tilde{C}_i \in \mathbb{R}^{n \times n}$ that satisfies the following

$$0 \leq u^T \tilde{C}_i u \leq u^T C u, \quad \text{for all } u \in \mathbb{R}^{n},$$  

$$R_{c^{\text{rel}}} \tilde{C}_i = 0.$$  

We denote the nonzero submatrix of $\tilde{C}_i$ by $\tilde{C}_{ii}$ so that

$$\tilde{C}_i = R_i^T \tilde{C}_{ii} R_i.$$  

Associated with the local SPSD splitting matrices, we define a multiplicity constant $k_m$ that satisfies the inequality

$$0 \leq \sum_{i=1}^{N} u^T \tilde{C}_i u \leq k_m u^T C u, \quad \text{for all } u \in \mathbb{R}^{n}.$$  

Note that, for any set of SPSD splitting matrices, $k_m \leq N$.

The main motivation for defining splitting matrices is to find local seminorms that are bounded from above by the $C$-norm. These seminorms will be used to determine a subspace that contains the eigenvectors of $C$ associated with its smallest eigenvalues.
3. Local SPSD splitting matrices. In this section we show how to construct local SPSD splitting matrices of a sparse SPD matrix efficiently using only local subdomain information.

3.1. From normal equations matrices to general SPD matrices. In [4], the authors presented how to compute local SPSD splitting matrices for the normal equations matrix \( C = B^\top B \) where \( B \in \mathbb{R}^{m \times n} \). Considering the case \( B = A \), we have \( C = A^2 \). Thus, provided the theory developed in [4], we can compute local SPSD splitting matrices of \( A^2 \) efficiently. Using the permutation matrix \( P_i = I(\Omega_{II}, \Omega_{\Gamma i}, \Omega_{\Gamma\Delta i}, \Omega_{c\Delta i}, \cdot) \), we can write

\[
P_iAP_i^\top = \begin{pmatrix}
A_{II} & A_{I\Gamma} & A_{I\Delta} \\
A_{\Gamma I} & A_{\Gamma\Gamma} & A_{\Gamma\Delta} \\
A_{\Delta I} & A_{\Delta\Gamma} & A_{\Delta\Delta}
\end{pmatrix},
\]

and

\[
\tilde{C}_i = \tilde{R}_i^\top X_i^\top X_i \tilde{R}_i
\]

is a SPSD splitting of \( A^2 \), where \( X_i \) is given as

(3.1) \[ X_i = R_i\tilde{A}_i^\top = \begin{pmatrix}
A_{II} & A_{I\Gamma} \\
A_{\Gamma I} & A_{\Gamma\Gamma}
\end{pmatrix} \]

Remark 3.1. All terms from (3.1) stem from the original coefficient matrix \( A \), in the sense that there is no connection with the underlying discretization scheme or matrix assembly procedure. In a parallel computing context, e.g., if \( A \) is distributed following a contiguous one-dimensional row partitioning among MPI processes, all terms may be retrieved using peer-to-peer communication between neighboring processes.

Lemma 3.2 demonstrates how to obtain a local SPSD splitting of \( A \) with respect to the extended overlapping subdomains given a SPSD splitting of \( A^2 \).

Lemma 3.2. Let \( \tilde{C}_i \) be a local SPSD splitting of \( C = A^2 \), and let \( \tilde{A}_i \) be the square root SPSD matrix of \( \tilde{C}_i \) such that \( \tilde{A}_i^2 = \tilde{C}_i \). Then, \( \tilde{A}_i \) is a local SPSD splitting of \( A \) with respect to the extended overlapping subdomain \( \tilde{\Omega}_i \).

Proof. First, observe that for any vector \( u \in \mathbb{R}^n \),

\[
u^\top (A^2 - \tilde{A}_i^2)u = u^\top (A + \tilde{A}_i)(A - \tilde{A}_i)u.
\]

Since \( A + \tilde{A}_i \) is SPD, we can write \( A + \tilde{A}_i = W_i^\top W_i \), and we have

\[
u^\top W_i(A - \tilde{A}_i)W_i^{-1}u = v^\top W_i^{-1}W_i^\top W_i(A - \tilde{A}_i)W_i^{-1}u
\]

\[
= v^\top W_i^{-1}W_i(A - \tilde{A}_i)v
\]

\[
= v^\top (A + \tilde{A}_i)(A - \tilde{A}_i)v
\]

\[
= v^\top (A^2 - \tilde{A}_i^2)v
\]

\[
\geq 0,
\]

where \( v = W_i^{-1}u \). Since \( W_i(A - \tilde{A}_i)W_i^{-1} \) and \( A - \tilde{A}_i \) have the same eigenvalues, we conclude that \( A - \tilde{A}_i \) is SPD. The locality of \( \tilde{A}_i \) stems from the locality of \( \tilde{C}_i \). \( \square \)
We note that the SPSD splitting $\tilde{A}_i$ obtained from the SPSD splitting of $A^2$ is local with respect to the extended overlapping subdomain $\tilde{\Omega}_i$. A Schur complement technique can be applied to obtain the locality to the subdomain $\Omega_i$. Lemma 3.3 presents how to obtain a local SPSD splitting matrix of $A$ with respect to the subdomain $\Omega_i$ from the local SPSD splitting of $A$ with respect to the extended overlapping subdomain $\tilde{\Omega}_i$.

**Lemma 3.3.** Let $\tilde{A}_i = \tilde{R}_i^\top \tilde{A}_{ii} \tilde{R}_i$ be a local SPSD splitting of $A$ with respect to the extended overlapping subdomain $\tilde{\Omega}_i$. Let $\tilde{A}_{ii}$ be written as a $(2, 2)$ block matrix such that the $(1, 1)$ block corresponds to the overlapping subdomain $\Omega_i$ and the $(2, 2)$ block corresponds to $\Omega_{\Delta_i}$, i.e.,

$\tilde{A}_{ii} = \begin{pmatrix} X_{i,11} & X_{i,12} \\ X_{i,21} & X_{i,22} \end{pmatrix},$

and let

$\tilde{A}_{ii} = X_{i,11} - X_{i,12}X_{i,22}^{-1}X_{i,21},$

where we assume that $X_{i,22}$ is SPD. Then, $\tilde{A}_i = R_i^\top \tilde{A}_{ii} R_i$ is a SPSD splitting of $A$ with respect to the subdomain $\Omega_i$.

**Proof.** We have

$\tilde{A}_{ii} = \begin{pmatrix} X_{i,11} & X_{i,12} \\ X_{i,21} & X_{i,22} \end{pmatrix} = \begin{pmatrix} X_{i,11} - X_{i,12}X_{i,22}^{-1}X_{i,21} \\ X_{i,21} \end{pmatrix} + \begin{pmatrix} X_{i,12}X_{i,22}^{-1}X_{i,21} & X_{i,12} \\ X_{i,21} & X_{i,22} \end{pmatrix}.$

Since $X_{i,22}$ is SPD and $\tilde{A}_{ii}$ is SPSD, $X_{i,11} - X_{i,12}X_{i,22}^{-1}X_{i,21}$ is SPD. Therefore,

$0 \leq u^\top \tilde{A}_{ii} u = u^\top R_i^\top \tilde{A}_{ii} R_i u \leq u^\top \tilde{R}_i^\top \tilde{A}_{ii} \tilde{R}_i u \leq u^\top Au.$

**Remark 3.4.** Since the SPSD splitting will be used to construct a preconditioner, the assumption in Lemma 3.3 that $X_{i,22}$ is SPD can be obtained by shifting its diagonal elements by a small value such as $\|X_{i,22}\|_2 \varepsilon$, where $\varepsilon$ is the floating-point machine precision. One can also shift the diagonal values of the matrix $\tilde{A}_{ii}$ by a small value $\|\tilde{A}_{ii}\|_2 \varepsilon$ so that the Schur complement can be well defined.

In the following section, we explain how to compute the local SPSD splitting matrices efficiently.

### 3.2. Practical construction of local SPSD matrices

The construction of robust two-level overlapping Schwarz preconditioners is based on computing the coarse space projection operator $R_0$. Using the local SPSD splitting matrices of $A$, $R_0$ can be chosen as the matrix that spans the space

$Z = \bigoplus_{i=1}^N R_i^\top D_i Z_i,$
where $Z_i$ is defined to be

$$Z_i = \text{span}\{u \mid D_iA_{ii}D_iu = \lambda \tilde{A}_{ii}u, \text{ and } \lambda > 1/\tau\},$$

where $\tau > 0$ is a user-specified number. The condition number of the preconditioned matrix $M_{\text{direct}}^{-1}A$ is bounded from above by $(k_c + 1) \left( 2 + (2k_c + 1) \frac{2\pi}{\tau} \right)$, where $k_c$ is the number of colors required to color the graph of $A$ such that any two neighboring subdomains have different colors and $k_m$ is the multiplicity constant that satisfies (2.2).

Solving the generalized eigenvalue problem in (3.3) using iterative solvers such as the Krylov–Schur method [43] requires solving linear systems of the form $\tilde{A}_{ii}u = v$. The matrix $\tilde{A}_{ii}$ is the Schur complement of the matrix $A_{ii} = (X_i^T X_i)^{-1}$, where $X_i = R_i A R_i^T$. Let $X_i = U_i \Sigma_i V_i^T$ be the economic singular-value decomposition of $X_i$ and let $V_i^\perp$ be an orthonormal matrix whose columns form a complementary basis of the columns of $V_i$, i.e., $[V_i, V_i^\perp]$ is an orthogonal matrix. Note that $V_i^\perp (V_i^\perp)^T = I_{\tilde{n}_i} - V_i V_i^T$. Using Remark 3.4, $\tilde{A}_{ii}$ can be chosen as

$$\tilde{A}_{ii} = V_i \Sigma_i V_i^T + \sigma_{1i} \varepsilon I_{\tilde{n}_i} = V_i \Sigma_i V_i^T + \sigma_{1i} \varepsilon [V_i, V_i^\perp][V_i, V_i^\perp]^T = V_i (\Sigma_i + \sigma_{1i} \varepsilon I_{\tilde{n}_i} V_i^T + \sigma_{1i} \varepsilon (V_i^\perp)^T = V_i (\Sigma_i + \sigma_{1i} \varepsilon I_{\tilde{n}_i}) V_i^T + \sigma_{1i} \varepsilon (I_{\tilde{n}_i} - V_i V_i^T),$$

where $\sigma_{1i}$ is the largest singular value of $X_i$. One way to solve the linear system $\tilde{A}_{ii}u = v$ is thus to solve the augmented linear system

$$\tilde{A}_{ii} \begin{pmatrix} u \\ y \end{pmatrix} = \begin{pmatrix} v \\ 0 \end{pmatrix}.$$ 

Given the singular-value decomposition of $\tilde{A}_{ii}$, the solution $u$ can be obtained efficiently. Indeed, the inverse of $\tilde{A}_{ii}$ is

$$\tilde{A}_{ii}^{-1} = V_i (\Sigma_i + \sigma_{1i} \varepsilon I_{\tilde{n}_i})^{-1} V_i^T + \sigma_{1i} \varepsilon^{-1} (I_{\tilde{n}_i} - V_i V_i^T).$$

In our current implementation, the singular-value decomposition is computed concurrently using LAPACK [6]. This implies that the sparse matrix $X_i$, see (3.1), is converted to a dense representation. Then, $\tilde{A}_{ii}$ is never assembled, and instead, the action of its inverse is applied in a matrix-free fashion using (3.4). Since these operations are local to each subdomain, they remain tractable. However, it could be beneficial to leverage the lower memory-footprint of iterative sparse singular-value solvers, e.g., PRIMME_SVDS [48]. To the best of our knowledge, no such solver may be used to retrieve the complete economic singular-value decomposition of a sparse matrix.

Since the construction of the two-level method is fully algebraic, one can successively apply the same approach on the coarse space matrix to obtain a multilevel preconditioner in which, the condition number of each preconditioned matrix is bounded from above by a prescribed number. Note that if the matrices $\tilde{A}_{ii}$ for $i = 1, \ldots, N$ are formed explicitly as in (3.2), we can use the strategy that we proposed in [3] to construct a multilevel preconditioner with the same properties.
4. Numerical experiments. In this section, we present a variety of numerical experiments that show the effectiveness and efficiency of the proposed preconditioner. First, we compare it against state-of-the-art algebraic multigrid preconditioners including AGMG [34, 35], BoomerAMG [14], and GAMG [1]. Then, we include numerical experiments where the proposed preconditioner is used to solve coarse problems from other multilevel solvers, thus emphasizing the algebraic and robust traits of our method. Except for AGMG which is used through its MATLAB interface, all these experiments are performed using PETSc [7]. In particular, the proposed preconditioner is a natural extension of the PCHPDDM infrastructure [24] which we use to solve the concurrent generalized eigenvalue problems from (3.3) via SLEPc [20], and then to define our multilevel preconditioner by selecting the appropriate local eigenmodes depending on the user-specified value of τ. With respect to Remark 3.1, we use the PETSc routine MatCreateSubMatrices, see https://petsc.org/release/docs/manualpages/Mat/MatCreateSubMatrices.html. Instead of using \( M^{-1}_{\text{additive}} \) as defined in (2.1), we will use \( M^{-1}_{\text{deflated}} \), defined as

\[
M^{-1}_{\text{deflated}} = R_0^\top C^{-1} R_0 + M^{-1}_{\text{RAS}}(I_n - C R_0^\top C^{-1} R_0),
\]

where \( M^{-1}_{\text{RAS}} \) is the well-known one-level restricted additive Schwarz method [9]. The choice of \( M^{-1}_{\text{deflated}} \) over \( M^{-1}_{\text{additive}} \) is motivated by previous results from the literature [45], which exhibit better numerical property of the former over the latter. Table 1 presents the set of test matrices from the SuiteSparse Matrix Collection [11] that are used first. They represent a subset of the matrices from the collection which satisfy both criteria “Special Structure equal to Symmetric” and “Positive Definite equal to Yes”. We highlight the fact that our proposed preconditioner can handle unstructured systems, not necessarily stemming from standard PDE discretization schemes, by displaying some nonzero patterns in Figure 1.

4.1. The algebraic two-level case. In this section, we present a numerical comparison between our proposed preconditioner and three algebraic multigrid solvers: AGMG, BoomerAMG, and GAMG. Even though matrices from Table 1 are SPD, all three AMG solvers encounter difficulties in solving many of the associated linear systems with random right-hand sides. On the contrary, our algebraic two-level preconditioner is more robust and always reach the prescribed tolerance of \( 10^{-8} \).

Note that a simple one-level preconditioner such as \( M^{-1}_{\text{RAS}} \) with a minimal overlap of one does not converge for these problems. The outer Krylov method is the right-preconditioned GMRES(30) [39]. For preconditioners used within PETSc (all except AGMG), the systems are solved using 256 MPI processes and are first renumbered by ParMETIS [27]. For our DD method, a single subdomain is mapped to each process, i.e., \( N = 256 \) in (2.1). Furthermore, exact subdomain and second-level operator Cholesky factorizations are computed. In the last column of Table 2, the size of second-level is reported. One may notice that the grid complexities fluctuate among matrices. Indeed, for small-sized problem s3rmt3m3, the grid complexity is \( \frac{5.357 + 5.321}{5.357} = 1.99 \), while for problem parabolic_fem, it is \( \frac{5.26 \times 10^5 + 21.736}{5.26 \times 10^5} = 1.04 \).

4.2. The nested-level case. Since our proposed preconditioner is fully algebraic, we now use it recursively to solve the second-level operator from the previous section using yet another two-level method instead of using an exact Cholesky factorization. This thus yields an algebraic three-level preconditioner. HPDDM has the capability of automatically redistributing coarse operators on a subset of MPI processes on which the initial coefficient matrix \( A \) is distributed [23]. We still use 256
**Table 1**

Test matrices taken from the SuiteSparse Matrix Collection.

| Identifier | n       | nnz(A) | condest(A) |

MPI processes for the fine-level decomposition, then use four processes for the second-level decomposition, and the third-level operator is centralized on a single process. The outer solver is now the flexible GMRES(30) [37]. Second-level systems are this time solved with the right-preconditioned GMRES(30), with a higher tolerance set to $10^{-4}$, compared to the outer-solver tolerance of $10^{-8}$. We investigate problems s3rmt3m3 and parabolic_fem which are the two extremes from the previous section in terms of grid complexity. Iteration counts are reported in Table 3. One may notice that the number of outer iterations is exactly the same as in the fifth column of Table 2, meaning that the switch to an inexact second-level solver does not hinder the overall convergence. Also, the number of inner iterations is small, so our proposed preconditioner applied to the second-level operator is indeed robust. Eventually, as we decrease the number of subdomains for the second-level decomposition, the grid coarsening improves as well, especially for small-sized problem s3rmt3m3.

In another context, we use our proposed preconditioner to solve coarse systems yielded by two other multilevel preconditioners. The following three-dimensional problems are discretized by FreeFEM [17] using 4,096 MPI processes. First, we use GenEO [41] to assemble a two-level analytic preconditioner for a scalar diffusion equation using order-two Lagrange finite elements. The number of unknowns is $4.17 \cdot 10^6$, and the second-level operator generated by GenEO is of dimension $n_C,2 = 60,144$. It is redistributed among 512 processes, and our preconditioner constructs a third-level operator of dimension $n_C,3 = 12,040$. Then, we use GAMG to assemble a four-level quasi-algebraic (the near-nullspace is provided by the discretization kernel)
preconditioner for the system of linear elasticity using order-two Lagrange finite elements. The number of unknowns is $3.06 \cdot 10^7$. The coarse operator from GAMG grid hierarchy is of dimension $n_{C,2} = 14,880$. It is redistributed among 256 processes using the telescope infrastructure [33] and our preconditioner constructs a final-level operator of dimension $n_{C,3} = 5,120$. Unlike what is traditionally done with smoothed-aggregation AMG [47], we do not transfer explicitly the near-nullspace from GAMG coarse level for setting up our preconditioner. These results are gathered in Table 4. Again, one may notice that the fast and accurate convergence of the inner solves (third column) does not hinder the overall convergence (second column). For both the scalar diffusion equation $\nabla \cdot \kappa \nabla$ and the system of linear elasticity, highly heterogeneous material coefficients are used, see Figure 2a and Figure 2b, respectively.

Furthermore, as in subsection 4.1, note that using a simple one-level preconditioner such as $M_{RAS}^{-1}$ with a minimal overlap of one for solving coarse systems from Tables 3 and 4 does not yield accurate enough inner solutions, thus preventing the outer solvers from converging. Coupling GAMG with our preconditioner is a good assessment of the composability of PETSc solvers [8], for the interested reader, we provide next in Figure 3 the exact options used to setup such a multilevel solver.

5. Conclusion. We presented in this paper a fully algebraic and locally constructed multilevel overlapping Schwarz preconditioner that can bound from above the condition number of the preconditioned matrix given a user-defined number. The construction of the preconditioner relies on finding local SPSD splitting matrices of the matrix $A$. Computing these splitting matrices involves the computation of the right singular vectors of the local block row matrix which might be considered costly on the fine level. However, the locality of computations and the robustness of the
Table 4

Hybrid multilevel preconditioner: Outer iterations is the FGMRES iteration count, Inner iterations is the average GMRES iteration count to solve coarse systems, \( n \) is the size of the linear system, \( n_{C,2} \) is the size of the coarse-level operator assembled by either GenEO (for problem diffusion) or GAMG (for problem elasticity), \( n_{C,3} \) is the size of the second-level operator assembled by our algebraic preconditioner to solve the aforementioned coarse systems.

| Identifier | Outer iterations | Inner iterations | \( n \) | \( n_{C,2} \) | \( n_{C,3} \) |
|------------|------------------|------------------|------|-------|-------|
| diffusion  | 11               | 5                | 4,173,281 | 60,144 | 12,040 |
| elasticity | 8                | 11               | 30,633,603 | 14,880 | 5,120  |

Fig. 3. PETSc command-line options for coupling GAMG and the proposed preconditioner.

preconditioner provide a very powerful and scalable preconditioner that can be used as a black-box solver especially when other black-box preconditioners fail to achieve a desired convergence rate. Our implementation is readily available in the PETSc library. Again, the proposed preconditioner is not meant to replace analytic multilevel preconditioners such as smoothed-aggregation algebraic multigrid and GenEO. When these work, they will be more efficient algorithmically. However, employing the proposed preconditioner to solve the corresponding coarse problems proved to be effective and efficient. As a future work, we would like to investigate less expensive constructions of SPSD matrices for specific classes of SPD matrices that arise from the discretization of PDEs.

Acknowledgments. This work was granted access to the GENCI-sponsored HPC resources of TGCC@CEA under allocation A0090607519. The authors would like to thank J. E. Roman for interesting discussions concerning the solution of (3.3).
