Keywords: electronic cigarettes, cigarettes, non-smokers, metals, biomarkers

Abstract:

Objectives: To determine if urinary biomarkers of effect and potential harm are elevated in electronic cigarette users compared to non-smokers and if elevation correlates with increased concentrations of metals in urine.

Study Design and Setting: This was a cross-sectional study of biomarkers of exposure, effect, and potential harm in urine from non-smokers (n=20), electronic cigarette users (n=20), and cigarette smokers (n=13). Participant’s screening and urine collection were performed at the Roswell Park Comprehensive Cancer Center and biomarker analysis and metal analysis was performed at the University of California, Riverside.

Results: Metallothionein was significantly elevated in the electronic cigarette group (3761 ± 3932 pg/mg) compared to the non-smokers (1129 ± 1294 pg/mg, p=0.05). 8-OHdG (8-hydroxy-2'-deoxyguanosine) was significantly elevated in electronic cigarette users (442.8 ± 300.7 ng/mg) vs non-smokers (221.6 ± 157.8 ng/mg, p=0.01). 8-isoprostane showed a significant increase in electronic cigarette users (750.8 ± 433 pg/mg) vs non-smokers (411.2 ± 287.4 pg/mg, p=0.03). Linear regression analysis in the electronic cigarette group showed a significant correlation between cotinine and total metal concentration; total metal concentration and metallothionein; cotinine and oxidative DNA damage; and total metal concentration and
oxidative DNA damage. Zinc was significantly elevated in the electronic cigarette users (584.5 ± 826.6 µg/g) compared to non-smokers (413.6 ± 233.7 µg/g, p=0.03). Linear regression analysis showed a significant correlation between urinary zinc concentration and 8-OHdG in the electronic cigarette users.

Conclusions: This study is the first to investigate biomarkers of potential harm and effect in electronic cigarette users and to show a linkage to metal exposure. The biomarker levels in electronic cigarette users were similar to (and not lower than) cigarette smokers. In electronic cigarette users, there was a link to elevated total metal exposure and oxidative DNA damage. Specifically, our results demonstrate that zinc concentration was correlated to oxidative DNA damage.

What is the key question?
• Is increased electronic cigarette usage associated with elevated metal exposure and if such exposure can cause biological harm?

What is the bottom line:
• Biomarkers of exposure (cotinine and metals), effect (metallothionein), and potential harm (8-isoprostane and 8-OHdG) were elevated in electronic cigarette users and were similar to concentrations in cigarette smokers; also increased electronic cigarette usage (as
measured by cotinine) was correlated with elevated urinary metal concentrations, which were correlated with oxidative DNA damage.

**Why read on:**

- This is one of the first studies to demonstrate a correlation between biological harm and electronic cigarette usage, suggesting the metal constituents (in particular zinc) in electronic cigarette aerosol can cause oxidative DNA damage. Given the recent deaths and pulmonary illnesses related to electronic cigarette usage, it is important for readers to know about the potential health effects related to electronic cigarette usage.

**Strengths and Limitations:**

- This was a cross-sectional study with gender and age-matched populations to compare urinary biomarker levels and metal concentrations in electronic cigarette users versus cigarette smokers and non-smokers.

- This is the first study to demonstrate electronic cigarette users are exposed to increased concentrations of potentially harmful levels of metals (specifically zinc) that were correlated to elevated oxidative DNA damage.

- This study is based on a relatively small population (n=53) and small number of biomarkers and should be expanded.
In the electronic cigarette and cigarette smoker groups, participants were not all using the same products and had different numbers of puffs/day.

Introduction:
Cigarette smoking causes more than 480,000 deaths annually in the United States and is the leading cause of preventable death\(^1\). Electronic cigarettes, which grew in usage over 900% between 2011-2015, do not burn tobacco and may be a safer product\(^2\). However, there are limited scientific data to prove that electronic cigarettes are actually less harmful than combustible tobacco products, although they may be harmful in different ways. To the contrary, some previous research has demonstrated that electronic cigarette aerosols contain potentially harmful chemicals, such as acrolein; formaldehyde and benzene\(^3\); cytotoxic flavor chemicals, such as diacetyl and cinnamaldehyde\(^4,5\); metals and ultrafine particles including tin, chromium and nickel nanoparticles\(^6,7\); and free radicals\(^8\). Moreover, some electronic cigarette refill fluids and aerosols showed cytotoxicity when tested in vitro\(^9,10\), an effect that has been linked to metals in the refill-fluid\(^6\). An in vitro study demonstrated that isolated human alveolar macrophages exposed to electronic cigarette vapour induces inflammation and reduces phagocytosis leaving the patient more susceptible to pulmonary infections\(^11\). Moreover, recent case reports have attributed electronic cigarette use to several adverse health effects, such as respiratory diseases\(^12\), increased risk
for cardiovascular disease, and impaired wound healing after surgery. Several previous studies on electronic cigarettes have evaluated biomarkers of exposure in blood, urine, and saliva, but none has yet examined and quantified biomarkers of effect and potential harm in relation to metals in electronic cigarette users.

This study compares urinary biomarkers of exposure, effect, and potential harm in non-smokers, conventional cigarette smokers, and electronic cigarette users and accounts for the effect of gender and age on biomarker expression. Based on the above studies, we hypothesized that there would be an increase in the level of biomarkers of effect and potential harm in electronic cigarette users compared to non-smokers and a decrease compared to cigarette smokers. The urinary biomarker of effect, metallothionein, is a protein that responds to and protects against metal toxicity and free radical stress. Urinary biomarkers of potential harm were two markers of oxidative stress: (1) 8-isoprostane, a prostaglandin formed by fatty acid peroxidation, and (2) 8-OHdG, a product of DNA oxidation. Urinary biomarkers of exposure were: (1) cotinine, a nicotine metabolite to measure smoking or vaping usage, and (2) total concentration of 11 urinary metals, which are present in electronic cigarette aerosol and are known to associate with metallothionein. Regression analyses were performed to identify relationships between biomarkers of exposure (cotinine and metals), effect (metallothionein), and potential harm (8-OHdG). To isolate the observed oxidative effects to a specific metal, regression analyses were performed...
performed between the urinary concentrations of individual metals and 8-OHdG.

**Materials and Methods**

**Subjects:** The urine samples were from participants who were non-smokers, cigarette smokers, and electronic cigarette users. Participants were recruited through local media and flyers posted in various locations around the Buffalo, New York area. Potential participants were provided with a brief description of the study and had an opportunity to ask questions about the study procedures. All potential participants were screened over the phone for inclusion and exclusion criteria. The exclusion criteria included concurrent use of smokeless tobacco, pipes, or cigars; alcohol or illicit drug dependence within the past six months or current illicit drug use (including marijuana; self-reported); psychiatric illness; and use of Nicotine Replacement Therapy (NRT). Information about medication and vitamins/antioxidants/metal usage was not collected. All eligible subjects who had been asked to come to the clinic for screening were given an informed consent form to read and sign. Copies of the signed consent forms were given to the research subject and were also stored in a secure location, along with the participant’s research chart. Informed written consent was obtained from each participant prior to their participation. Eligible participants were then asked to come to Roswell Park Comprehensive Cancer Center for a one-time visit, which lasted approximately 1 hour. Spot urine samples were collected during this on-site
A total of 53 participants were gender and age matched and selected for biomarker analysis. Because age may affect the basal expression level of biomarkers, the subjects were separated into those ≤40 years old and ≥41 years old, with the groups containing 23 and 30 samples, respectively. Out of these age-separated samples, participants were selected from the non-smoker, cigarette smoker, and electronic cigarette user groups. Each group had approximately equal male and female samples. Using a one-way ANOVA and a Tukey’s multiple comparison test, there were no significant differences in the ages of the younger participants or in the ages of the older participants; however, the ages of the younger and older groups were significantly different from each other. There were negligible levels of 4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) in the non-smokers (2.8 ± 6.3 pg/mg of creatinine) and electronic cigarette users (13.3 ± 18.6 pg/mg of creatinine) indicative of no tobacco use, in contrast to the cigarette smokers (105.7 ± 87.4 pg/mg of creatinine) who had significantly elevated NNAL (Supplementary Figure 1). In the non-smokers, no samples had levels of cotinine ≥1.0 ng/mg (Supplementary Figure 2), confirming smoking abstinence. The demographics of the 53 participants who provided urine samples were organized by age, gender, and smoking group (Table 1).
Table 1. Demographics of the 53 participants included in this study separated by smoking group, age, and gender. All smoking groups were gender and age matched.

| Sample ID | Sex  | Age  | Average |
|-----------|------|------|---------|

| 35B       | Female | 61 | 51.8 ± 8.5 |

**Biospecimen Collection:** Spot urine samples were collected from participants in a previous study\(^6\), and cotinine, NNAL, and creatinine concentrations were determined at the Center for Disease Control (CDC) and the Roswell Park Comprehensive Cancer Center (RPCCC), respectively.
Aliquots of 45 ml of fresh urine samples were transferred to 50-ml Falcon tube then centrifuged and immediately frozen at -20°C and stored at the RPCCC laboratory. Prior to shipping, samples were thawed, and 1.5 ml aliquots were transferred to smaller tubes and shipped frozen to University of California, Riverside (UCR) for biomarker analysis. The biomarker study was approved under IRB protocol HS-12-023 from UCR.

**Selection of Biomarkers:** Biomarkers were selected by studying previous literature pertaining to urinary biomarkers in smokers\(^21,22,23,24,25\). The selection criteria for our panel of urinary biomarkers was based on our goal to analyze metal exposure and oxidative stress (Table 2). To evaluate exposure, cotinine and metals were measured in urine samples. Metallothionein, which increases when metal exposure is elevated, was used as a biomarker of effect. Conventional cigarettes and electronic cigarettes generate free radicals that cause cellular oxidative stress\(^8,26,27\). Therefore, oxidative damage was evaluated in the three study groups by measuring urinary 8-isoprostane (a biomarker of lipid peroxidation) and 8-OHdG (a biomarker of DNA oxidation). Cigarette smoke and electronic cigarette aerosols contain a mixture of metals\(^6,7,28\) that could lead to an increased production of metallothionein (a metal exposure and ROS scavenging biomarker), which is a cysteine-rich protein that functions in metal binding\(^25\). All selected biomarkers described above have been shown to be specifically associated with clinically relevant outcomes and diseases (Table 2).
Table 2. Clinical diseases associated with biomarkers measured in this study.

| Biomarker Type | Associated Diseases                                                                 | References                                      |
|----------------|------------------------------------------------------------------------------------|------------------------------------------------|
| Exposure       | Selenium: Nausea, vomiting, "garlic breath", nail loss, hair loss, cardiovascular disease, cardiac arrest, cancer | MacFarquhar 2010, See 2006, Rayman 2012         |

|                | 8-Isoprostane: Coronary artery disease, atherosclerosis, interstitial lung disease, non-small cell lung cancer, breast cancer | Vassalle 2004, Morrow 2005, Montuschi 1998, Stathopoulos 2014, Rossner Jr 2006 |

Urinary Creatinine Concentrations: Spot urine samples were used since biomarkers would not necessarily be stable in samples collected over 24 hours. Because spot urine samples were used, it was necessary to normalize the data to creatinine, which is relatively stable in concentration over time. Creatinine concentrations in urine were analyzed at the RPCCC clinical
laboratory in Buffalo. There were no significant differences in creatinine concentrations in relation to gender or age (Supplementary Figure 3).

**Biomarker of Exposure (Cotinine, NNAL and Metal Concentration)**

**Analysis:** Cotinine and NNAL were measured using previously published\textsuperscript{29,30} and fully validated methods. Eleven elements/metals (antimony, cadmium, copper, indium, lead, nickel, rubidium, selenium, silver, titanium, and zinc) in urine samples were measured by inductively coupled mass spectrometry (ICP-MS) and used to calculate total urinary metal concentration. The 11 metals were selected for analysis because they have all been identified in electronic cigarette aerosols and are known to associate with metallothionein. There was no significant elevation of the total 11 metals in the smoking groups, though it is slightly elevated in the electronic cigarette group (Supplementary Figure 4). Details of metal analysis are given in the Supplementary Information.

**Biomarkers of Effect and Potential Harm Analysis Using ELISA:** Each ELISA kit was quality tested for accuracy and reproducibility using urine samples collected in house. Samples were tested in duplicate on three different days, and the biomarker concentration was normalized to creatinine. A range of sample dilutions was tested to determine the optimal dilution for quantification of each biomarker from the kits’ standard curves. For all ELISA kits, the coefficient of variation for the three independent
experiments was ≤15%, except for metallothionein, which was ≤20%. Any urine sample with a biomarker concentration outside the lowest or highest limit of quantification was excluded for statistical analysis. In all subsequent ELISA analyses, biomarkers were run in duplicate wells for each urine sample.

Following a 1:4 dilution in buffer, urine samples were analyzed to determine 8-isoprostane concentration using the Urinary 8-Isoprostane ELISA kit (Detroit R&D, MI, USA). The concentration of 8-OHdG was determined using a DNA Damage (8-OHdG) ELISA Kit (Stress Marq Biosciences, Victoria, Canada), following a 1:20 dilution. Urine samples were analyzed for metallothionein using a Human Metallothionein ELISA Kit (LifeSpan BioSciences, WA, USA), following a 1:20 or 1:40 dilution in sample diluent.

**Statistical Analysis:** Two urine samples from the electronic cigarette group had abnormally high creatinine concentrations (≥3 mg/mL) as detected by a statistical outlier test and were removed from further analysis. For each urine sample, the biomarker concentration was normalized to its respective creatinine concentration. Because the normalized biomarker concentration data were not normally distributed, a Box-Cox transformation was performed after which a 3-way ANOVA was applied in MiniTab 17.0 (MiniTab Inc, PA, USA) using gender, age, and smoking group as factors. Outliers were removed if they had a large standardized residual (≥2.0 or ≤-2.0). In all the 3-way ANOVA models, the 2-way and 3-way interactions were not significant,
and our final model included age, gender, and smoking group. Post-hoc tests were used to compare different age groups, gender groups, and smoking groups. When the smoking group was analyzed independently (disregarding gender and age), a Dunnett’s post-hoc test was used with the electronic cigarette group as the main comparison group, and the comparisons were electronic cigarette users vs. non-smokers and electronic cigarette users vs. cigarette smokers. All linear correlation analyses were performed using the Linear Regression Analysis ($R^2$ and p-value reported) in PRISM 7.0 (GraphPad, CA, USA). All graphs reported in this manuscript were made in PRISM 7.0.

**Patient and Public Involvement:** No patients were involved in the research planning or design, nor were they involved in any aspect of the study besides urine collection. There are no plans to directly disseminate the results of the research to study participants. The dissemination of results will be achieved through publication or press release.

**Results**

**Biomarker of Effect**

Metallothionein, a biomarker of effect (due to metal and reactive oxygen species exposure), in the electronic cigarette group (3761 ± 3932 pg/mg) was significantly elevated when compared to the non-smokers group (1129 ± 1294 pg/mg, p=0.05), and these concentrations were similar to the
cigarette smokers group (4096 ± 4320 pg/mg, p=0.95) (Figure 1A). There were no differences in age or gender.

**Biomarkers of Potential Harm (Oxidative Stress)**

A significant elevation in urinary levels of the biomarker of DNA oxidation, 8-OHdG, occurred in electronic cigarette users (442.8 ± 300.7 ng/mg) vs. non-smokers (221.6 ± 157.8 ng/mg, p=0.01) (Figure 1B). There was no significant difference between electronic cigarette users (442.8 ± 300.7 ng/mg) and cigarette smokers (388 ± 235 ng/mg, p=0.75). Age affected 8-OHdG levels; those ≥41 years old (413.4 ± 256.4 ng/mg) had significantly elevated 8-OHdG compared to those ≤40 years (241.2 ± 214.1 ng/mg, p=0.02) (Figure 1C). There was no effect on gender.

The lipid peroxidation biomarker, 8-isoprostane, showed a significant increase in electronic cigarette users (750.8 ± 433 pg/mg) vs. non-smokers (411.2 ± 287.4 pg/mg, p=0.03) (Figure 1D). There was no significant difference between electronic cigarette users (750.8 ± 433 pg/mg) and cigarette smokers (784.2 ± 546.1 pg/mg, p = 0.96). Moreover, the ≥41-year-old population (777.6 ± 481.5 pg/mg) was significantly elevated in 8-isoprostane compared to those ≤40 years (392.6 ± 246.9 pg/mg, p=0.002) (Figure 1E). In addition, 8-isoprostane was significantly elevated in females (741.8 ± 489.3 pg/mg) vs. males (484.9 ± 345, p=0.04) (Figure 1F).

**Biomarkers of Exposure are Correlated with Oxidative DNA Damage in E-Cigarette Users**
Results of linear regression analyses performed on the non-smokers, cigarette smokers, and electronic cigarette users are presented in Fig 2 for the following correlations: (1) cotinine and total metal concentration (Fig 2A-C), (2) total metal concentration and metallothionein (Fig 2D-F), (3) cotinine and 8-OHdG (Fig 2G-I), and (4) total metal concentration and 8-OHdG (Fig 2J-L). There were no significant correlations in the non-smokers (Fig 2A, D, G, and J). In the cigarette smokers group, only total metal concentration and 8-OHdG were significant (Fig 2K, p=0.0003). In the electronic cigarette users group, all linear regression analyses were significant: cotinine and total metal concentration (Fig 2C, p=0.02), total metal concentration and metallothionein (Fig 2F, p=0.04), cotinine and 8-OHdG (Fig 2I, p = 0.02), and total metal concentration and 8-OHdG (Fig 2L, p = 0.007).

Selenium and Zinc were Elevated in Electronic Cigarette Users

Two of the 11 metals that were analyzed were significantly elevated in the electronic cigarette group. Selenium concentrations (Fig 3A) were significantly elevated in the electronic cigarette users (54 ± 20.6 µg/g) compared to non-smokers (41.8 ± 14.1 µg/g, p=0.04) and cigarette smokers (39.7 ± 17.3 µg/g, p=0.05). Zinc concentrations (Fig 3B) were significantly elevated in electronic cigarette users (584.5 ± 826.6 µg/g) compared to non-smokers (413.6 ± 233.7 µg/g, p=0.03). Zinc in the electronic cigarette users
was not significantly elevated when compared to cigarette smokers (470.7 ± 223.6 µg/g, p=0.17).

**Zinc was Correlated with Oxidative DNA Damage in Electronic Cigarette Users**

Regression analysis were performed to compare urinary concentrations of selenium and zinc to 8-OHdG in the non-smokers, cigarette smokers, or electronic cigarette users (Fig 4). There were no significant correlations for selenium versus 8-OHdG (Fig 4A-C). In the electronic cigarette users only, zinc was significantly correlated to 8-OHdG (p=0.0066) (Fig 4F) In non-smokers and cigarette smokers, zinc was not correlated to 8-OHdG (Fig 4A, B).

**Discussion:**

Consistent with our hypothesis, our study shows for the first time that biomarkers of effect and potential harm were elevated in the urine of the electronic cigarette users compared to non-smokers. Moreover, in electronic cigarette users, the levels of biomarkers of effect and potential harm were positively correlated with biomarkers of exposure to nicotine and metals. Importantly, electronic cigarette participants in our study did not report using other tobacco products and were not dual users of electronic cigarettes and conventional cigarettes. Before entering our study, all electronic cigarette users who were previous cigarette smokers had abstained from
smoking cigarettes for a minimum of six months, and abstinence was confirmed by undetectable NNAL (Supplemental Fig 1). Previous literature has shown that abstinence from cigarette smoking was concurrently linked to a decrease in levels of 8-isoprostane and 8-OHdG, which returned to non-smokers levels\(^3\). Taken together, the above information supports the conclusion that the elevation of 8-isoprostane and 8-OHdG in urine was associated with electronic cigarette use specifically. Surprisingly, we did not find a significant reduction in biomarkers of effect and potential harm between electronic cigarette users and cigarette smokers. This observation may be explained by the fact that electronic and conventional cigarettes and their aerosols have anatomical, chemical, and particulate differences, which may contribute to physiological harm in separate ways.

Cigarette smoke and electronic cigarette aerosol contain a mixture of metals and free radicals\(^6,7,8,28,32\) that could be contributing to the oxidative harm in our participants. The metals in electronic cigarette aerosols come mainly from the metal components in the atomizer and the e-fluid that is heated in the atomizer\(^7,33\). Metal concentration in urine was positively correlated with cotinine concentration, indicating that metals were elevated with increased aerosol exposure.

Metal increase in urine is further supported by the observed elevation in metallothionein, which acts as a heavy metal-binding protein and also protects cells from oxidative stress by scavenging ROS\(^25\). Metallothionein normally binds physiological metals, such as zinc and copper, but can also
bind xenobiotic heavy metals such as cadmium, silver and arsenic\textsuperscript{25,34} that are present in cigarette smoke\textsuperscript{35} and electronic cigarette aerosols\textsuperscript{7}.

Metallothionein can also associate with at least 20 different elements/metals\textsuperscript{19,20}, and 11 of these have been found in cigarette smoke\textsuperscript{28,36} or e-cigarette aerosol\textsuperscript{6,7,18} and were present in the urine of our participants.

The increase in metallothionein in the electronic cigarette user group was positively correlated with increasing metal concentration in their urine and was likely a response to metals inhaled by the electronic cigarette users. In cigarette smokers, metallothionein was not significantly correlated with increasing metal concentration, suggesting other factors such as ROS may be contributing to its activation. Also, cigarette smoke can have a different composition of metals than e-cigarette aerosol\textsuperscript{6,7,18,28,36}, which were not selected for in our 11 metal analysis, and therefore the total metal concentration in smokers was not correlated to cotinine concentration.

Elevation of toxic metals can induce oxidative stress\textsuperscript{37,38}. In the electronic cigarette group, there was a significant correlation between total metals and oxidative DNA damage. A similar correlation was observed for the cigarette smokers. Lipid oxidation was not significantly correlated with metal concentration in either the electronic cigarette or cigarette smokers groups. There are multiple isoprostanes and isoprostane metabolites formed in-vivo during oxidative conditions\textsuperscript{39}, and we measured only 8-isoprostane, which may account for the lack of correlation between lipid oxidation and metal concentration. In contrast, during DNA oxidation the guanine residue is
highly oxidized compared to the other nucleic bases, leading to the
formation of a single DNA oxidation product (8-OHdG), which makes
correlation to oxidative stress straightforward.

Both zinc and selenium, which were significantly elevated in the
electronic cigarette user group, are present in electronic cigarette aerosols,
usually higher concentrations than most other elements\textsuperscript{6,7}. However, only
zinc concentration was correlated with oxidative DNA damage in the
electronic cigarette group. While zinc is required for normal human health,
its elevation above normal levels has been associated with oxidative stress\textsuperscript{40}.

Our data provide the first evidence that electronic cigarette usage increases
the risk of zinc exposure, which in turn causes oxidative DNA damage in humans. Selenium is also a required trace element that can cause harm
when elevated\textsuperscript{41}. While its elevation in electronic cigarette users was not
linked to increased oxidative stress, future work may find that it has other
adverse health effects.

Oxidative damage can lead to gradual harm of all organ systems\textsuperscript{42} and
if left unchecked can culminate in diseases such as atherosclerosis, coronary
heart disease, pulmonary fibrosis, acute lymphoblastic leukemia, and lung
cancer\textsuperscript{43}. Of particular concern, increases in both 8-isoprostane and 8-OHdG
were significantly greater in the older populations, suggesting that
conventional cigarette users who give up smoking and switched to electronic
cigarettes may be at greater risk for oxidative damage than young people
who have not smoked previously. In the case of 8-isoprostane, females were
more affected than males, suggesting that women should not be encouraged by physicians to use electronic cigarettes, especially when pregnant. There were no significant differences in the elevated concentrations of oxidative harm biomarkers between electronic cigarette users and cigarette smokers, suggesting their organ systems are exposed to similar levels of oxidative damage.

**Conclusions:**

Our data show for the first time that electronic cigarette use, which correlates with metal intake, leads to an elevation in metallothionein in the urine. The usage of e-cigarettes causes an increase in oxidative stress as measured by 8-OHdG and 8-isoprostane. E-cigarette users were exposed to elevated levels of selenium and zinc. The intake of metals (specifically zinc) is further correlated with increased oxidative damage to DNA. These data indicate that electronic cigarette use is not harm free and that prolonged use with elevation of oxidative stress may lead to disease progression. Given these observations, physicians should use caution in recommending the use of electronic cigarettes to their patients and should be alert to possible adverse health outcomes associated with electronic cigarette use. The biomarkers used in this study may be valuable in clinical practice when evaluating the health of electronic cigarette users.

Footnotes:

**Contributors:** SSC, CH, MG, PT were responsible for the study concept and design. SSC, MW and ANR performed the experiments for data collection. MG collected and shipped the urine samples to our lab. JL acted as a statistician. SMB helped design the use of the ICP-MS in TWL’s lab and the analysis of the metal data. SSC, MW, CH, JL, MG, PT drafted the manuscript, and all authors read and provided comments on the manuscript. SSC, MW, and PT reviewed the data and take responsibility for the integrity and accuracy of the data. The corresponding author attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted. SSC and PT are the guarantors.

**Funding:** This study was supported by the National Institute on Drug Abuse and the National Cancer Institute of the National Institutes of Health (awards R01DA037446 and P30 CA016056, respectively) and FDA Center for Tobacco Products (CTP) and by an award from the Roswell Park Alliance Foundation.
The content is solely the responsibility of the authors and does not necessarily represent the official views of the funding agencies.

Disclosures: Dr. Goniewicz reports grants from Pfizer (2011 GRAND [Global Research Awards for Nicotine Dependence] recipient) and personal fees from Johnson & Johnson (as a member of the advisory board) outside the submitted work. Authors not named here have disclosed no conflicts of interest.

Ethics Approval: The study was approved by Roswell Park Comprehensive Cancer Center IRB (protocol number I 247313). The biomarker measurement study was approved under IRB protocol HS-12-023 from UCR.

Data Sharing: No additional data are available.

Transparency: The study guarantors affirm that this manuscript is an honest, accurate, and transparent account of the study being reported; that no important aspects of the study have been omitted; and that any discrepancies from the study as planned (and, if relevant, registered) have been explained.

Figure Legends
Figure 1. Urinary metallothionein (pg/mg of creatinine), 8-OHdG (ng/mg of creatinine), 8-isoprostane (pg/mg of creatinine), are significantly elevated in e-cigarette users compared to non-smokers. A. Metallothionein levels among the different smoking groups. B. 8-OHdG concentration in the different smoking groups. C. 8-OHdG concentration in the younger and older populations. D. 8-isoprostane levels among the different smoking groups. E. 8-isoprostane levels in the younger and older populations. F. 8-isoprostane levels in males and females. Bars are the means and standard deviations for each group. * p = < 0.05; ** p = <0.01.

Figure 2. Correlation between total metals and cotinine, metallothionein and total metals, 8-OHdG and cotinine, and 8-OHdG and total metals in urine. A-C. Linear regression analysis comparing total metal (µg/g of creatinine) and cotinine concentration (ng/mg of creatinine) in urine of the non-smokers, cigarette smokers, and e-cigarette user groups. D-F. Linear regression analysis comparing metallothionein concentration (pg/mg of creatinine) and total metal concentration (µg/g of creatinine) in urine in the non-smokers, cigarette smokers, and e-cigarette users groups. G-I. Linear regression analysis comparing 8-OHdG (ng/mg of creatinine) and cotinine (ng/mg of creatinine) concentration in urine of the non-smokers, cigarette smokers, and electronic cigarette user groups. J-L. Linear
regression analysis comparing 8-OHdG (ng/mg of creatinine) and total metal
(µg/g of creatinine) concentration in urine of the non-smokers, cigarette
smokers, and electronic cigarette user groups. N/A = not applicable since
levels of cotinine in non-smokers was negligible.

**Figure 3.** Urinary selenium (µg/g of creatinine) and zinc (µg/g of
creatinine) concentrations are significantly increased in the
electronic cigarette users. A. Selenium concentrations in the different
smoking groups. B. Zinc concentrations in the different smoking groups. Bars
are the means and standard deviations for each group. * p = < 0.05.

**Figure 4.** Zinc concentrations (µg/g of creatinine) are significantly
correlated to oxidative DNA damage in the electronic cigarette
users. A-C. Linear regression analysis comparing selenium (µg/g) of
creatinine and 8-OHdG (ng/mg of creatinine) in urine of the non-smokers,
cigarette smokers, and e-cigarette user groups. D-F. Linear regression
analysis comparing zinc (µg/g of creatinine) and 8-OHdG (ng/mg of
creatinine) in urine in the non-smokers, cigarette smokers, and e-cigarette
users groups.

**Supplementary Figure 1.** NNAL concentration (pg/mg of creatinine)
among the different smoking groups. Significant elevation of NNAL (a
biomarker of tobacco exposure) was seen in the cigarette smokers. Bars are
the means and standard deviations for each group. * p = < 0.05; **** p = < 0.0001.

** Supplementary Figure 2. Cotinine concentration (ng/mg of creatinine) in the different smoking groups.** Cotinine concentration is elevated in the cigarette smokers and e-cigarette users compared to non-smokers. There is no difference between the cigarette smokers and e-cigarette users. Bars are the means and standard deviations for each group. ** p = < 0.01; **** p = < 0.0001.

** Supplementary Figure 3. Urinary creatinine concentration (mg/mL) in different genders and age populations.** A. Creatinine concentrations in males and females. B. Creatinine concentrations in the younger and older population. There were no significant differences between genders or age groups. Bars are the means and standard deviations for each group.

** Supplementary Figure 4. The total concentration of 11 metals (µg/g of creatinine) in each smoking group.** There were no significant differences in the total metals concentrations in any of the smoking groups. Bars are the means and standard deviations for each group.
