A new algorithm for numerical integration of the rigid-body equations of motion is proposed. The
algorithm uses the leapfrog scheme and the quantities involved are angular velocities and orienta-
tional variables which can be expressed in terms of either principal axes or quaternions. Due to
specific features of the algorithm, orthonormality and unit norms of the orientational variables are
integrals of motion, despite an approximate character of the produced trajectories. It is shown that
the method presented appears to be the most efficient among all known algorithms of such a kind.

The method of molecular dynamics (MD) plays a prominent role in studying molecular liquids. All exis-
ting techniques appropriate to simulate such systems can be categorized in dependence on what type of parameters
are chosen to represent the rotational degrees of freedom and what kind of numerical algorithm is applied to inte-
grate the corresponding equations of motion.

In the molecular approach, the phase trajectories are considered in view of translational and rotational
dynamics. The translational dynamics is defined by motion of molecular centers of masses, whereas the orientational
dynamics can be determined in terms of Eulerian angles [1, 2], quaternions [3–8] or principal-axis vectors [4]. The
numerical integration within Eulerian angles is very inefficient due to singularities of the equations of motion [3, 5]. If the quaternions or principal-axis vectors are involved, additional efforts must be paid to conserve their unit norms or orthonormality.

The atomic approach [9] treats dynamics of the system in view of translational motion of individual atoms
which move under the potential-energy forces plus forces of constraints introduced to hold inter-atomic distances constant. This approach is believed to have good stability properties, because the usual Verlet algorithm can be applied here. Nevertheless, the atomic approach is so-
phisticated to implement for point molecules and when there are more than two, three or four atoms in the cases of linear, planar and three-dimensional molecules, respectively. Moreover, to reproduce the rigid molecular structure it is necessary to solve complicated systems of non-
linear (in general, six per molecule) equations at each time step of the integration [10].

It is a common practice to integrate orientational motion with the Gear predictor-corrector algorithm of a high-order [11]. Such an algorithm, being accurate at very small time steps, quickly becomes unstable with increasing the step size [10]. Translational motion is usually integrated with lower-order Verlet [12], velocity Ver-
let [13] and leapfrog [14] integrators, owing their simplicity and exceptional numerical stability. However, original versions of these integrators were constructed assuming that acceleration is velocity-independent and, therefore, they can not be applied directly to rotational dynamics. Analogous problems arise with translational motion in the presence of magnetic fields.

In order to remedy that situation, Fincham [15] has derived a rotational-motion version of the leapfrog algo-
rithm in which systems of four nonlinear equations per molecule for quaternion components are solved by iteration.
Ahlrichs and Brode have introduced a method [16] in which principal axes are considered as pseudo-particles and constraint forces are introduced to maintain their orthonormality. But the algorithm is within the Verlet framework and does not contain angular velocities explicitly. The quaternion dynamics with constraints was also formulated [17]. As a result, a new algorithm within the velocity Verlet framework has been generated. Re-
cently, the principal-axes scheme has been adapted to this framework as well [18]. Nevertheless, it was con-
cluded that the best numerical stability can be achieved in the atomic-constraint approach.

In this paper we propose a new leapfrog integrator of the rigid-body equations of motion. The main idea con-
ists in involving angular velocities, instead of angular momenta, into the integration. This leads to significant simplifications with respect to angular-momenta versions [15]. The algorithm seems to be the most efficient and simple, exhibiting excellent stability properties which are similar to those observed within the cumbersome atomic-constraint technique.

Consider a classical system with \( N \) rigid molecules composed of \( M \) point atoms. Translational motion of the system is described in the usual way, applying Newton’s law, whereas two first-order equations per molecule of the rotational dynamics can be obtained as follows. According to Euler equations [1], the rate of change in time of principal components, \((\Omega_X^i, \Omega_Y^i, \Omega_Z^i) = \Omega_i\), of angular velocity is

\[
J_\alpha \frac{d\Omega_\beta^i}{dt} = K_\alpha^i(t) + (J_\beta - J_\gamma) \Omega_\delta^i(t) \Omega_\gamma^i(t). \tag{1}
\]

Here \((\alpha, \beta, \gamma) = (X, Y, Z), (Y, Z, X)\) and \((Z, X, Y), K_\alpha^i\)
are principal components, $K_i = A_i k_i^2$, of the torque $k_i = \sum_{j,a,b} (r_{ij}^a - r_{ij}^b) \times f_{ij}^a b$ exerted on molecule $i$ with respect to its center of mass $r_i$ due to the site-site interactions $f_{ij}^b \equiv f(r_{ij}^a - r_i^b)$ with the other molecules, $J_a$ denote the principal moments of inertia, orientational variables were collected into the square orthonormal matrices $A_i$, the nine elements of each of which ($i$ in the laboratory frame, the position of atom $i$ and coordinates of three principal axes (XYZ) of the molecule $q_i$), where $\xi_i$ where $\xi$ is the unit quaternion norm (3).

The second equation follows from definition of angular velocity,

$$\frac{dA_i}{dt} = \begin{pmatrix} 0 & \Omega_{iY} & -\Omega_{iZ} \\ -\Omega_{iY} & 0 & \Omega_{iX} \\ -\Omega_{iZ} & -\Omega_{iX} & 0 \end{pmatrix} A_i \equiv W(\Omega_i)A_i,$$  \hspace{0.5cm} (2)

where the property $AA^\dagger = I$ of orthonormal matrices has been used, $W(\Omega_i)$ is a skewsymmetric matrix associated with angular velocity, i.e., $W^\dagger(\Omega_i) = -W(\Omega_i)$ and I designates the unit matrix. In an alternative representation the matrix $A_i \equiv A(q_i)$ is a function of the four-component quaternion $q_i = (\xi_i, \eta_i, \zeta_i, \chi_i)^+$ [4, 5]. The time derivatives of quaternions can be cast in the form

$$\frac{dq_i}{dt} = \frac{1}{2} \begin{pmatrix} 0 & \Omega_{iY} & -\Omega_{iZ} \\ -\Omega_{iY} & 0 & \Omega_{iX} \\ -\Omega_{iZ} & -\Omega_{iX} & 0 \end{pmatrix} q_i \equiv Q(\Omega_i)q_i,$$  \hspace{0.5cm} (3)

where $Q(\Omega_i)$ is a skewsymmetric matrix again and the unit quaternion norm $\xi_i^2 + \eta_i^2 + \zeta_i^2 + \chi_i^2 = 1$, which follows from the orthonormality of $A_i$, has been used.

In the case of translational motion, it is easy to derive the leapfrog algorithm [14]: $v_i(t+h) = v_i(t-\frac{h}{2}) + h a_i(t)$, $r_i(t+h) = r_i(t) + h v_i(t+\frac{h}{2})$, where $h$ denotes the time increment, $v_i = dr_i/dt$ is the center-of-mass velocity, $a_i(t) = \frac{1}{m} \sum_{j,a,b} f_{ij}^a (t)$ the molecular acceleration and $m$ the mass of a separate molecule. Recently, it has been shown that contrary to the conventional point of view, the order of truncation errors for this leapfrog is four rather than three for both coordinates and velocities due to a fortunate cancellation of uncertainties [19].

The problems with deriving a leapfrog algorithm for rotational motion are that angular accelerations (1) depend explicitly not only on spatial coordinates via molecular toques but also on angular velocities. Moreover, the time derivatives of orientational variables do not define angular velocities directly (see Eqs. (2) and (3)). These difficulties cannot be handled with a simple leapfrog in which position and velocity are known at different times. It is worth to underline that similar problems (even much more difficult) arise in the angular-momentum approach [15], Verlet and velocity Verlet frameworks [17, 18].

The basic idea of our approach lies in involving principal angular velocities into the integration process. Then, acting in the spirit of leapfrog scheme and using Euler equation (1), one obtains

$$\Omega_{\gamma}^{(n+1)}(t + \frac{h}{2}) = \Omega_{\gamma}^{(n)}(t - \frac{h}{2}) + \frac{h}{J_a} \left[ K_i(t) + (J_\beta - J_\gamma) \Omega_\beta^{(n)}(t)\Omega_\gamma^{(n)}(t) \right].$$  \hspace{0.5cm} (4)

While the molecular torques $K_i(t)$ can easily be evaluated via the coordinates $r_i(t)$ and $A_i(t)$ or $q_i(t)$, a propagation of the products of angular velocities in Eq. (4) to on-step levels of time is necessary. The obvious choice for this is

$$\Omega_{\gamma}^{(n+1)}(t) = \frac{1}{2} \left[ \Omega_{\gamma}^{(n)}(t + \frac{h}{2}) \Omega_\gamma^{(n)}(t - \frac{h}{2}) + \Omega_{\gamma}^{(n)}(t + \frac{h}{2}) \right].$$  \hspace{0.5cm} (5)

In view of (5), equation (4) constitutes a system of maximum three nonlinear equations per molecule for the unknowns $\Omega_\gamma(t + \frac{h}{2})$. The system is simple and can be solved in a quite efficient way by iteration, $n = 0, 1, \ldots$, taking $\Omega_\gamma^{(0)}(t + \frac{h}{2}) = \Omega_\gamma^{(n)}(t + \frac{h}{2})$ as an initial guess. We note that the order of truncation errors for angular-velocity evaluation (4) reduces to three, because approximation (5) is only second order accurate on $h$.

The evaluation of orientational variables can be realized by writing

$$S_i(t + h) = S_i(t) + h H_i S_i(t + \frac{h}{2})$$  \hspace{0.5cm} (6)

for principal-axis vectors ($S_i = A_i H_i \equiv W_i$) and quaternion ($Q_i \equiv Q(\Omega_i)$) representations, where Eqs. (2) and (3) have been used. The matrices $W_i \equiv W(\Omega_i)$ and $Q_i \equiv Q(\Omega_i)$ are calculated using already defined angular velocities $\Omega_i(t + \frac{h}{2})$, whereas orientational variables can be propagated to mid-step levels of time as

$$S_i(t + \frac{h}{2}) = \frac{1}{2} [S_i(t) + S_i(t + h)].$$  \hspace{0.5cm} (7)

Equation (6) together with (7) are, in fact, systems of linear equations with respect to elements of $A_i(t + h)$ and $Q_i(t + h)$, which, therefore, can be solved analytically. The result is

$$S_i(t + h) = (I - \frac{h}{2} H_i)^{-1} (I + \frac{h}{2} H_i) S_i(t) \equiv \Theta_i(t, h) S_i(t).$$  \hspace{0.5cm} (8)

More explicit expressions for the set $\Theta_i = \{ D_i, G_i \}$ of evolution matrices are: $D_i = I \left(1 - \frac{h^2}{12} \Omega_i^2\right) + h W_i + \frac{h^2}{2} P_i/[1 + \frac{h^2}{12} \Omega_i^2]$ and $G_i = I \left(1 - \frac{h^2}{12} \Omega_i^2\right) + h Q_i/[1 + \frac{h^2}{12} \Omega_i^2]$ in the cases of principal axes and quaternion representations, respectively, where $P_i$ is a symmetric matrix with the elements $\Omega_i(t + \frac{h}{2}) \Omega_i(t + \frac{h}{2})$ and $\Omega_i^2 \equiv \Omega_i(t + \frac{h}{2}).$
This completes the algorithm. It is interesting to remark that evaluation (8) exhibits the same fourth-order local accuracy on \( h \) as in the case of translational coordinates, despite the second order of interpolation (7). The reason for this results again from a cancellation of errors arising in coordinates and velocities during two neighbor time steps.

It can be verified easily that the matrix \((I - \lambda H)^{-1}(I + \lambda H)\) is orthonormal at arbitrary values of \( \lambda \), provided \( H^+ = -H \). Then, as follows from construction (8), the evolution matrices \( D_i \) and \( G_i \) are orthonormal as well. Therefore, if initially the orthonormality of \( A_i \) and unit norms of \( q_i \) are satisfied, they will be fulfilled perfectly at arbitrary times in future, despite the approximate character of produced trajectories. This fact can be considered as the main advantage of the algorithm derived that distinguishes it from all other singularity free algorithms, because no additional efforts are needed to preserve the rigid structure of molecules.

We now test our approach on the basis of MD simulations on liquid water. The simulations were performed in an NVE ensemble with \( N = 256 \) molecules at a density of \( N/V = 1 \) g/cm\(^3\) and at a temperature of 298 K using the TIP4P potential \( (M = 4) \) and reaction field geometry [20]. All runs were started from an identical well equilibrated configuration. The numerical stability was identified in terms of fluctuations of the total energy, \( \mathcal{E} = [(E - \langle E \rangle)^2]^{1/2}/\langle E \rangle \). The kinetic part of the energy was calculated at time \( t \) putting \( V(t) = \frac{1}{2}[V(t - \frac{h}{2}) + V(t + \frac{h}{2})] + \mathcal{O}(h^2) \) for \( V = \{v_i, \Omega_i\} \), where the main term \( \mathcal{O}(h^2) \) of uncertainties is in the self-consistency with the second order of global errors for our algorithm (one order lower than minimal order of truncation errors for coordinates and velocities).

As the atomic-constraint algorithm [9, 10] is intensively exploited and its performances are generally recognized, we have made comparative tests using this method and our advanced leapfrog algorithm within quaternion and principal-axes representations, which conserve the energy approximately with the same accuracy (the results for principal-axis variables and pseudo-particle formalism are not included in the figure to simplify graph presentation). Quite a few iterations (the mean number of iterations varied from 3 to 5 at \( h = 1/4 \) fs) was sufficient to find solutions to the system of nonlinear equations (4) with a precision of \( 10^{-12} \). This contributes a negligible small computation time additionally into the total time.

No shift of the total energy was observed for the atomic-constraint and our leapfrog techniques at \( h \leq 4 \) fs over a length of 10 000 steps. To reproduce features of an NVE ensemble quantitatively, it is necessary for the ratio \( \Gamma = \mathcal{E}/\Upsilon \) of the total energy fluctuations to the fluctuations \( \Upsilon \) of the potential energy to be no more than a few per cent. We have obtained the following results of \( \mathcal{E} \) at the end of the runs in our leapfrog approach: 0.0016, 0.0065, 0.015 and 0.029 %, corresponding to \( \Gamma \approx 0.29, 1.2, 2.7 \) and 5.2 % at \( h = 1, 2, 3 \) and 4 fs, respectively (for the system under consideration \( \Upsilon \approx 0.56\% \)). Therefore, the greatest time step considered (4 fs) is still suitable for precise calculations. The ratio \( \Gamma \) can be fitted with a great accuracy to the function \( C h^2 \) with a coefficient of \( C \approx 0.29 \) fs\(^{-2} \). This is completely in line with our theoretical prediction about a characteristic square growth of global errors and, as a consequence, \( \mathcal{E}(t) \) at \( t \gg h \). The square growth was observed in all other approaches, excepting the Gear algorithm. However, only the advanced leapfrog algorithm provides a minimum of \( C \) and total energy fluctuations.

The algorithm presented might become popular because of its great stability, simplicity to implement for arbitrary rigid bodies and its intrinsic conservation of rigid structures. These features should be considered as significant benefits of the algorithm with respect to all the rest approaches. It can easily be substituted into existing MD programs on rigid polyatomics. Moreover, since velocities appear explicitly, the algorithm can be extended to a thermostat version and to integration in the presence of magnetic fields. These problems will be discussed in a separate publication.
