A trade-off between classical and quantum circuit size for an attack against CSIDH

https://doi.org/10.1515/jmc-2020-0070
Received Jun 05, 2019; accepted Jul 01, 2019

Abstract: We propose a heuristic algorithm to solve the underlying hard problem of the CSIDH cryptosystem (and other isogeny-based cryptosystems using elliptic curves with endomorphism ring isomorphic to an imaginary quadratic order \(\mathcal{O}\)). Let \(\Delta = \text{Disc}(\mathcal{O})\) (in CSIDH, \(\Delta = -4p\) for \(p\) the security parameter). Let \(0 < \alpha < 1/2\), our algorithm requires:
• A classical circuit of size \(2^{\tilde{O}(\log(|\Delta|)^{1-\alpha})}\).
• A quantum circuit of size \(2^{\tilde{O}(\log(|\Delta|)^{\alpha})}\).
• Polynomial classical and quantum memory.

Essentially, we propose to reduce the size of the quantum circuit below the state-of-the-art complexity \(2^{\tilde{O}(\log(|\Delta|)^{1/2})}\) at the cost of increasing the classical circuit-size required. The required classical circuit remains subexponential, which is a superpolynomial improvement over the classical state-of-the-art exponential solutions to these problems. Our method requires polynomial memory, both classical and quantum.

1 Introduction

Given two elliptic curves \(E_1, E_2\) defined over a finite field \(\mathbb{F}_q\), the isogeny problem consists in computing an isogeny \(\phi : E_1 \to E_2\), i.e. a non-constant morphism that maps the identity point on \(E_1\) to the identity point on \(E_2\). A hash function construction based on supersingular isogeny graphs was first proposed in [9], with a security based on the hardness of computing isogenies. An isogeny-based key-exchange was described by Couveignes [12], and its concept was independently rediscovered by Stolbunov [31].

Childs, Jao and Soukharev observed in [10] that the problem of finding an isogeny between two ordinary elliptic curves \(E_1\) and \(E_2\) defined over \(\mathbb{F}_q\) and having the same endomorphism ring could be reduced to the problem of solving the Hidden Subgroup Problem (HSP) for a generalized dihedral group. More specifically, if the endomorphism ring of the curves is isomorphic to an imaginary quadratic order \(\mathcal{O}\), then the problem of finding an isogeny between \(E_1\) and \(E_2\) can be reduced to the problem of finding an ideal \(a \subseteq \mathcal{O}\) such that \([a] \cdot E_1 = E_2\) where \(*\) is the action of the ideal class group \(\text{Cl}(\mathcal{O})\), \([a]\) is the class of \(a\) in \(\text{Cl}(\mathcal{O})\) and \(E_i\) is the iso-
morphism class of the curve $E_i$. Let $N := |\text{Cl}(\mathcal{O})|$. Using Kuperberg’s sieve [25], this task requires $2^O(\sqrt{\log(N)})$ queries to an oracle that computes the action of the class of an element in $\text{Cl}(\mathcal{O})$. Using the heuristic oracle of [4], the cost of the oracle can be brought down to $2^O(\sqrt{\log(N)})$, thus giving an overall complexity of $2^O(\sqrt{\log(N)})$ where $N = \sqrt{|\Delta|}$.

Although neither the CRS [12, 31] nor the CSIDH (a similar system [8] using supersingular curves defined over $\mathbb{F}_p$) cryptosystems are NIST candidates, it is natural to evaluate their security according to the methodology proposed by NIST for its standardization process [26]. In particular, Level I is defined in [26, Page 16] as follows: “any attack that breaks [this] security definition must require computational resources comparable to or greater than those required for key search on a block cipher with a 128-bit key (e.g. AES-128).” Hence, this corresponds to $2^{128}$ classical AES evaluations ($2^{143}$ classical gates, according to the document) or to $2^{87.5}$ quantum gates (with 2953 logical qubits), according to the counts given in [17] on the universal Clifford + T set. We point out that this “or” has no reason to be exclusive: a quantum adversary can also run massive classical computations.

Contributions.
We propose a different trade-off between classical and quantum circuits in the cryptanalysis of CRS and CSIDH relying on the resolution of the Hidden Shift Problem. Let $E_1$, $E_2$ be two elliptic curves and $\mathcal{O}$ be an imaginary quadratic order of discriminant $\Delta$ such that $\text{End}(E_i) \simeq \mathcal{O}$ for $i = 1, 2$. Then assuming Heuristic 1 for constant $0 < \alpha < 1/2$ and Heuristic 2, there is a quantum algorithm for computing $[a]$ such that $[a] \cdot E_1 = E_2$ requiring:

- A classical circuit of size $2^{\tilde{O}(\log(|\Delta|)^{1-x})}$.
- A quantum circuit of size $2^{\tilde{O}(\log(|\Delta|)^{x})}$.
- Polynomial classical and quantum memory.

Related Works.
After the publication of CSIDH, there has been a line of works on the quantum security of CRS and CSIDH. Some of these works concern the security of concrete CSIDH [8] parameters. These include [6] and [3], which give a quantum circuit for computing isogenies for the 512-bit CSIDH parameters. On the asymptotic side, which is our main focus here, both [4] and [19] present algorithms for computing isogenies with quantum (and classical) circuit size in $2^{\tilde{O}(\log(|\Delta|)^{1/2})}$ and polynomial space, which yields a subexponential quantum attack on CSIDH and CRS with polynomial quantum space. While these two previous works focused on isogeny computations, in this paper, we complement the analysis of the Hidden Shift resolution underlying the attack procedure common to all these works. With our trade-off, we can obtain a superpolynomial improvement on the size of the quantum circuit.

The rest of the paper is organized as follows: Section 2 contains background information on isogenies. Section 3 shows the connection between the Dihedral Hidden Subgroup Problem and the computation of isogenies. Section 4 give a high level description of the idea for the resolution of the Dihedral HSP. Section 5 introduces the concept of trading-off quantum gates for classical gates in the resolution of the Dihedral HSP. Section 6 describes a heuristic oracle compatible with the intended trade-off. Section 7 discusses the heuristic made for the validity of the oracle. Section 8 describes the challenges of a fault-tolerant implementation. Section 9 concludes and discusses the relevance of this result to the evaluation of the security with respect to NIST security levels.
2 Mathematical background

An elliptic curve $E$ defined over a finite field $\mathbb{F}_p$ of characteristic $p \neq 2, 3$ is a projective algebraic curve with an affine plane model given by an equation of the form $y^2 = x^3 + ax + b$, where $a, b \in \mathbb{F}_p$ and $4a^3 + 27b^2 \neq 0$. The set of points of an elliptic curve is equipped with an additive group law. Details about the arithmetic of elliptic curves can be found in many references, such as [30, Chap. 3].

Let $E_1, E_2$ be two elliptic curves defined over $\mathbb{F}_p$. An isogeny $\phi : E_1 \to E_2$ is a non-constant rational map defined over $\mathbb{F}_p$ (resp. over $\overline{\mathbb{F}}_p$) which sends the identity point on $E_1$ to the identity point on $E_2$. The degree of an isogeny is its degree as a rational map, and an isogeny of degree $\ell$ is called an $\ell$-isogeny. Moreover, $E_1, E_2$ are said to be isomorphic over $\mathbb{F}_p$, or $\mathbb{F}_p$-isomorphic, if there exist isogenies $\phi_1 : E_1 \to E_2$ and $\phi_2 : E_2 \to E_1$ over $\mathbb{F}_p$ whose composition is the identity. Two $\mathbb{F}_p$-isomorphic elliptic curves have the same $j$-invariant given by $j := 1728 \frac{a^3}{a^3 + 27b^2}$.

An order $\mathcal{O}$ in a number field $K$ such that $[K : \mathbb{Q}] = n$ is a subring of $K$ which is a $\mathbb{Z}$-module of rank $n$. A fractional ideal of $\mathcal{O}$, is a set of the form $a = \frac{1}{d}I$ where $I$ is an ideal of $\mathcal{O}$ and $d \in \mathbb{Z}_{>0}$. A fractional ideal $I$ is said to be invertible if there exists a fractional ideal $J$ such that $IJ = \mathcal{O}$. The invertible fractional ideals form a multiplicative group $\mathcal{I}$. Let $\mathcal{P}$ be the subgroup consisting of the invertible principal ideals. The ideal class group $\text{Cl}(\mathcal{O})$ is $\text{Cl}(\mathcal{O}) := \mathcal{I}/\mathcal{P}$. We denote by $[\mathcal{a}]$ the class of the fractional ideal $\mathcal{a}$ in $\text{Cl}(\mathcal{O})$. The ideal class group is finite and its cardinality $h_{\mathcal{O}}$ satisfies $h_{\mathcal{O}} \leq \sqrt{|\Delta| \ln(|\Delta|)}$ (see [11, §5.10.1]), where $\Delta$ is the discriminant of $\mathcal{O}$.

Let $E$ be an elliptic curve defined over $\mathbb{F}_p$. An endomorphism of $E$ is either an isogeny defined over $\mathbb{F}_p$ between $E$ and itself, or the zero morphism. The set of endomorphisms of $E$ forms a ring that is denoted by $\text{End}(E)$. For elliptic curves, $\text{End}(E)$ is either an order in an imaginary quadratic field (and has $\mathbb{Z}$-rank 2) or a maximal order in a quaternion algebra ramified at $p$ (the characteristic of the base field) and $\infty$ (and has $\mathbb{Z}$-rank 4). In the former case, $E$ is said to be ordinary while in the latter it is called supersingular. When a supersingular curve is defined over $\mathbb{F}_p$, then the ring of its $\mathbb{F}_p$-endomorphisms, denoted by $\text{End}_{\mathbb{F}_p}(E)$, is isomorphic to an imaginary quadratic order, much like in the ordinary case.

When $E$ is ordinary (resp. supersingular over $\mathbb{F}_p$), the class group of $\text{End}(E)$ (resp. $\text{End}_{\mathbb{F}_p}(E)$) acts transitively on isomorphism classes of elliptic curves having the same endomorphism ring. More precisely, the class of an ideal $\mathcal{a} \subseteq \mathcal{O}$ acts on $\mathcal{E}$ with $\text{End}(E) \simeq \mathcal{O}$ via an isogeny of degree $N(\mathcal{a})$ (the algebraic norm of $\mathcal{a}$). Likewise, each isogeny $\varphi : E \to E'$ where $\text{End}(E) \simeq \text{End}(E') \simeq \mathcal{O}$ corresponds (up to isomorphism) to a class in $\text{Cl}(\mathcal{O})$. From an ideal $\mathcal{a}$ and the $\ell$-torsion (where $\ell = N(\mathcal{a})$), one can recover the kernel of $\varphi$, and then using Vélu’s formulae [34], one can derive the corresponding isogeny. We denote by $[\mathcal{a}] \ast \mathcal{E}$ the action of the ideal class of $\mathcal{a}$ on $\mathcal{E}$. To evaluate the action of $[\mathcal{a}]$, we decompose it as a product of classes of prime ideals of small norm $\ell$, and evaluate the action of each prime ideal as an $\ell$-isogeny. This strategy was described by Couveignes [12], Galbraith–Hess–Smart [15], and later by Bröker–Charles–Lauter [7] and reused in many subsequent works.

3 Isogenies from solutions to the HSP

As shown in [5, 10], the computation of an isogeny between $E_1$ and $E_2$ defined over $\mathbb{F}_p$ such that there is an imaginary quadratic order with $\mathcal{O} \simeq \text{End}(E_i)$ for $i = 1, 2$ can be done by exploiting the action of the ideal class group of $\mathcal{O}$ on isomorphism classes of curves with endomorphism ring isomorphic to $\mathcal{O}$. This concerns the cases of ordinary curves, and supersingular curves defined over $\mathbb{F}_p$.

Assume we are looking for a such that $[\mathcal{a}] \ast \mathcal{E}_1 = \mathcal{E}_2$. This is precisely the hard mathematical problem of the CSIDH [8] and CRS [12, 29] cryptosystems. Let $A = \mathbb{Z}_{d_1} \times \cdots \times \mathbb{Z}_{d_s} \simeq \text{Cl}(\mathcal{O})$. We define $f : \mathbb{Z}_2 \times A \to \mathbb{F}_q$ by

$$f(x, y) := \begin{cases} [\mathcal{a}_y] \ast \mathcal{E}_1 & \text{if } x = 0, \\ [\mathcal{a}_y] \ast \mathcal{E}_2 & \text{if } x = 1, \end{cases} \quad (1)$$

where $[\mathcal{a}_y]$ is the element of $\text{Cl}(\mathcal{O})$ corresponding to $y \in A$ via the isomorphism $\text{Cl}(\mathcal{O}) \simeq A$. Let $H$ be the subgroup of $\mathbb{Z}_2 \times A$ such that $f(x, y) = f(x', y')$ if and only if $(x, y) - (x', y') \in H$. Then $H = \{(0, 0), (1, s), (0, s), (1, 0)\}$.
where \( \bar{s} \in A \) such that \([a_2] \ast \bar{E}_1 = \bar{E}_2\). The computation of \( \bar{s} \) can thus be done through the resolution of the Hidden Subgroup Problem in \( \mathbb{Z}_2 \ltimes A\).

Algorithm 1 Quantum algorithm for evaluating the action in \( \text{Cl}(\mathcal{O}) \)

**Input:** Elliptic curves \( E_1, E_2 \), imaginary quadratic order \( \mathcal{O} \) such that \( \text{End}(E_i) \simeq \mathcal{O} \) for \( i = 1, 2 \) such that there is \([a] \in \text{Cl}(\mathcal{O})\) satisfying \([a] \ast E_1 = E_2\).

**Output:** \([a] \)

1. Compute \( A = \mathbb{Z}_{d_1} \times \cdots \times \mathbb{Z}_{d_l} \) such that \( A \simeq \text{Cl}(\mathcal{O})\).
2. Find \( H = \{(0, 0), (1, s)\} \) by solving the HSP in \( \mathbb{Z}_2 \ltimes A \) with oracle (1).
3. return \([a_s]\)

### 4 Sieve algorithms for solving the HSP

**Kuperberg’s original algorithm**

Assume that we want to find a secret subgroup \( H = \{(0, 0), (1, d)\} \) in \( D_N := \mathbb{Z}_2 \ltimes \mathbb{Z}_N \) given a function (oracle) \( f : D_N \rightarrow X \) where \( X \) is a finite set. Additionally, we assume that \( N = 2^n \) for simplicity. Using a circuit implementing \( f \), we can prepare the state \( |\psi_{k}^{d,N}\rangle := \frac{1}{\sqrt{2}} \left( |0\rangle + e^{2 \pi i d/k} |1\rangle \right) \). We want to recover \( d \) from many states \( |\psi_{k}^{d,N}\rangle \) where \( k \) is distributed uniformly at random in \( \mathbb{Z}_N \). When we restrict ourselves to \( N = 2^n \), this task consists in recovering \( d \) bit by bit. To get the least significant bit of \( d \), we only need \( |\psi_{2^{n-1}}^{d,N}\rangle = \frac{1}{\sqrt{2}} \left( |0\rangle + (-1)^d |1\rangle \right) \).

As shown in [24], the repetition of this process yields all bits of \( d \). When \( N \) is not a power of 2, the process is terminated with a quantum phase estimation step.

To go from many \( |\psi_{k}^{d,N}\rangle \) with random \( k \) to \( |\psi_{2^{n-1}}^{d,N}\rangle \), Kuperberg’s sieve [24] proceeds by small iterations. Given two states \( |\psi_{k_1}^{d,N}\rangle, |\psi_{k_2}^{d,N}\rangle \) where \( k_1, k_2 \) share the same initial \( l \) bits, there is a simple procedure that computes \( |\psi_{k_1-k_2}^{d,N}\rangle \) with constant probability, thus killing \( l \) bits of the decomposition of the index \( k \). At the end of the process we end up with states of the form \( |\psi_{2^{n-1}}^{d,N}\rangle \) and \( |\psi_{0}^{d,N}\rangle \). As we saw above, the latter gives us the least significant bit of \( d \). The sieve starts with a set \( L_0 \) of states of the form \( |\psi_{k}^{d,N}\rangle \) with \( |L_0| = 2^{O(\sqrt{n})} \) and at each steps recombines all states sharing the same last \( m = \lceil \sqrt{n-1} \rceil \) bits. At each step of the way, the cardinality of the set gets divided by 4. At the end, \( L_m \) contains states of the form \( |\psi_{2^{n-1}}^{d,N}\rangle \) and \( |\psi_{0}^{d,N}\rangle \). The cost of the procedure is dominated by the creation of \( L_0 \) with takes \( 2^{O(\sqrt{n})} \) calls to the circuit implementing \( f \).

In CSIDH, \( \text{Cl}(\mathcal{O}) \) is cyclic with high probability, but this applies to non-cyclic groups [10, Appendix A]. Here, we consider the HSP in \( D_N \) with \( N = 2^n \).

**Low memory variants**

The main disadvantage of Kuperberg’s sieve is that the memory requirements are proportional to the gate complexity, which is in \( 2^{O(\sqrt{n})} \). That is a subexponential space complexity. Regev’s variant [27] offers a classical and quantum polynomial space complexity at the cost of a slight increase of the runtime. The idea is to only keep a polynomial amount of qubits at all time and to recombine to produce states of the form \( |\psi_{k}^{d,N}\rangle \) with initial bits of \( k \) being zero. Kuperberg also described a second Hidden Shift algorithm [25] that uses a different combination method. It has also a time cost in \( 2^{O(\sqrt{n})} \), and uses only a polynomial amount of qubits. It however has a classical memory requirement as large as the classical time.
5 Trade-off classical/quantum

Regev’s variant of Kuperberg’s sieve can be seen as an $n_1$-step process which is paused at each step to perform a classical brute-force enumeration of cost $2^{O(n_1)}$. Instead of balancing the classical and quantum effort, we propose to spend more effort performing the classical search to reduce the size of the quantum circuit. Let $n = n_1 n_2$, with $n_1 = O(n^a)$ and $n_2 = O(n^{1-a})$ for some $0 < a < 1$. The case $a = 1/2$ is essentially Regev’s variant [27].

Algorithm 2 Iteration of the sieve procedure based on [27]

Input: Integers $n_1, n_2$ and $n_2 + 4$ states of the form $|\psi^{d,N}_{k_i,n_1}|$ for random $k_i$ having their initial $tn_2$ bits equal to 0.

Output: $|\psi^{d,N}_{k,n_2}|$ for a random $k$ having its initial $(t+1)n_2$ bits equal to 0.

1: $\tilde{k} \leftarrow (k_1, \ldots, k_{n_2+4})$.
2: From $\otimes_{i=1}^{n_2+4} |\psi^{d,N}_{k_i,n_1}|$, get $\frac{1}{\sqrt{2^{n_2+4}}} \sum_{\tilde{b} \in \{0,1\}^{n_2+4}} e^{2\pi i n_1 \langle \tilde{k}, \tilde{b} \rangle} |\tilde{b} \rangle |(\tilde{b} \cdot \tilde{k}) \mod 2^{n_2}\rangle$.
3: Measure the second register to obtain $z \in \{0, \ldots, 2^{n_2} - 1\}$.
4: Compute the number $m$ of $\tilde{b} \in \{0,1\}^{n_2+4}$ such that $(\tilde{b} \cdot \tilde{k}) \mod 2^{n_2} = z$.
5: if $m \notin [2, 32]$ then return failure.
6: $\tilde{b}^1, \ldots, \tilde{b}^m \leftarrow$ the $m$ vectors that satisfy $(\tilde{b}^i \cdot \tilde{k}) \mod 2^{n_2} = z$.
7: $|\psi\rangle \leftarrow \frac{1}{\sqrt{2}} \left( |\tilde{0}\rangle + e^{2\pi i n_1 \langle \tilde{k}, \tilde{b}^i \rangle} |\tilde{1}\rangle \right)$ with a measurement on $\text{Span} (\tilde{b}^1, \tilde{b}^2)$.
8: return $|\psi\rangle$.

Proposition 5.1. Let $0 < a < 1/2$, then there is a quantum algorithm to solve the HSP in $D_N$ with a circuit satisfying:

- $2^{O(n^a)}$ calls to a circuit implementing $f$ are made.
- The number of quantum gates beside the oracle is in $2^{O(n^a)}$.
- The number of classical gates is in $2^{O(n^{1-a})}$.

Proof. As long as $n_2 \to \infty$, the main ingredients of the proof of the validity and run time of [27] still hold. Namely, a direct application of Chebyshev’s inequality shows that Step 5 (and therefore Algorithm 2) has a constant probability of success. Following the approach of [27], the algorithm to solve the HSP consists in the production of states $|\psi^{d,N}_{k,n_1}|$ for random $k$ with an oracle implementing $f$, and $2^{n_1}$ successive applications of Algorithm 2 to produce $|\psi^{d,2n_1}_{2n_1,n_2}|$. An application of the Chernoff bound shows that the number of calls to the oracle implementing $f$ that guarantees the success of the overall procedure is $n_2^{O(n_1)} = 2^{O(n^a)}$. Meanwhile, each brute force search of the number $m$ of vectors $\tilde{b} \in \{0,1\}^{n_2+4}$ such that $(\tilde{b} \cdot \tilde{k}) \mod 2^{n_2} = z$ is performed by a classical circuit of size $2^{O(n^{1-a})}$.

The quality of the trade-off depends on the cost of the oracle. Indeed, if the quantum circuit to implement the oracle $f$ is larger than $2^{O(n^a)}$ for the chosen $a$, then the size of the circuit to implement $f$ will dominate the number of quantum gates. This issue particularly impacts the resolution of the isogeny problem between elliptic curves whose endomorphism ring is isomorphic to an imaginary quadratic order (i.e. ordinary curves and supersingular curves defined over $F_p$).
6 The cost of the isogeny oracle

Let \( p_1, \ldots, p_u \) be prime ideals generating \( \text{Cl}(\mathcal{O}) \). Let \( \mathcal{L} \) be the lattice of relations between \( p_1, \ldots, p_u \), i.e. the lattice of all the vectors \( (f_1, \ldots, f_u) \in \mathbb{Z}^u \) such that \( \prod_i p_i^{f_i} \) is principal. In other words, the ideal class \( \prod_i p_i^{f_i} \) is the neutral element of \( \text{Cl}(\mathcal{O}) \). The high-level strategy for computing the action of \( [a] \in \text{Cl}(\mathcal{O}) \) on \( E_1 \) is the following: (i) Compute a basis \( B \) for \( \mathcal{L} \), (ii) Find a BKZ-reduced basis \( B' \) of \( \mathcal{L} \), (iii) Find \( (h_1, \ldots, h_u) \in \mathbb{Z}^u \) such that \( [a] = \prod_i h_i p_i^{f_i} \), (iv) Use Babai’s nearest plane method on \( B' \) to find short \( (h_1', \ldots, h_u') \in \mathbb{Z}^u \) such that \( [a] = \prod_i h_i' p_i^{f_i} \). (v) Evaluate the action of \( \prod_i h_i' p_i^{f_i} \) on \( E_1 \) by applying repeatedly the action of the \( p_i \) for \( i = 1, \ldots, u \). Step 1 is a precomputation. It takes quantum polynomial time. Step 2 can be performed as a precomputation requiring only classical gates.

**Heuristic 1** (With parameter \( 0 < \alpha < 1/2 \)) Let \( 0 < \alpha < 1/2 \) and \( \mathcal{O} \) be an imaginary quadratic order of discriminant \( \Delta \). There are \( (p_i)_{i<\alpha} \) for \( k = \log^{1-\alpha}(\|\Delta\|) \) split prime ideals of norm in \( \text{Poly}(\log(\|\Delta\|)) \) whose classes generate \( \text{Cl}(\mathcal{O}) \). Furthermore, each class of \( \text{Cl}(\mathcal{O}) \) has a representative of the form \( \prod_i p_i^{n_i} \) for \( |n_i| \leq e^{\log^a |\Delta|} \).

**Algorithm 3** Precomputation for the oracle

**Input:** Order \( \mathcal{O} \) of discriminant \( \Delta \) and \( 0 < \alpha < 1/2 \).

**Output:** Split prime ideals \( p_1, \ldots, p_s \) whose classes generate \( \text{Cl}(\mathcal{O}) \) where \( s = \log^{1-\alpha}(\|\Delta\|) \), reduced basis \( B' \) of the lattice \( \mathcal{L} \) of vectors \( (e_1, \ldots, e_s) \) such that \( \prod_i p_i^{f_i} \) is trivial, generators \( g_1, \ldots, g_l \) such that \( \text{Cl}(\mathcal{O}) = (g_1) \times \cdots \times (g_l) \) and vectors \( \vec{v}_i \) such that \( g_i = \prod_j p_j^{v_{ij}} \).

1. Find \( p_1, \ldots, p_s \) satisfying the conditions of Heuristic 1 with [4, Alg. 2].
2. \( \mathcal{L} \leftarrow \text{lattice of vectors } (e_1, \ldots, e_s) \text{ such that } \prod_i p_i^{f_i} \text{ is principal.} \)
3. Compute a BKZ-reduced matrix \( B' \in \mathbb{Z}^{s \times r} \) of a basis of \( \mathcal{L} \) with block size \( \log^{1-2\alpha}(\|\Delta\|) \).
4. Compute \( U, V \in \text{GL}_s(\mathbb{Z}) \) such that \( UB'V = \text{diag}(d_1, \ldots, d_r) \) is the Smith Normal Form of \( B' \).
5. \( l \leftarrow \min_{1 \leq i \leq S} \{|i| \mid d_i \neq 1\} \). For \( i \leq l \), \( \vec{v}_i \leftarrow i\text{-th column of } V \).
6. \( V' \leftarrow V^{-1} \). For \( i \leq l \), \( g_i \leftarrow \prod_{j \leq S} p_j^{v_{ij}} \).
7. return \( \{p_1, \ldots, p_s\}, B', \{g_1, \ldots, g_l\}, \{\vec{v}_1, \ldots, \vec{v}_l\} \).

**Lemma 6.1.** Let \( \mathcal{L} \) be an \( n \)-dimensional lattice with input basis \( B \in \mathbb{Z}^{n \times n} \), and let \( \beta < n \) be a block size. Then the BKZ variant of [18] used with Kannan’s enumeration technique [22] returns a basis \( \vec{B}_1, \ldots, \vec{B}_n \) such that \( \|\vec{B}_1\| \leq e^{\mathfrak{h}_{\|\mathcal{L}\|}} \mathfrak{h}_1(\mathcal{L}) \), using time \( \text{Poly}(n, \text{Size}(B)) \mathfrak{h}^{\frac{1}{2}+o(1)} \) and polynomial space.

**Proof.** See proof of [4, Lem. 1].

**Corollary 6.2.** Assuming Heuristic 1 for \( \alpha \), Algorithm 3 is correct, runs in time \( 2^{\mathfrak{h}(\log(\|\Delta\|))^{1-2\alpha}} \) and has polynomial space complexity. It returns a basis of \( \mathcal{L} \) whose first vector \( \vec{B}_1 \) satisfies \( \|\vec{B}_1\| \leq 2^{\mathfrak{h}(\log(\|\Delta\|)^{\gamma})} \).

We implement Algorithm 4 reversibly by using generic techniques due to Bennett [2] to convert any algorithm taking time \( T \) and space \( S \) into a reversible algorithm taking time \( T^{1+\epsilon} \), for an arbitrary small \( \epsilon > 0 \), and space \( O(S \log T) \). To bound the cost of Algorithm 4, we assume the following standard heuristic.

**Heuristic 2** (GSA) The basis \( B' \) computed in Algorithm 3 satisfies the Geometric Series Assumption (GSA): there is \( 0 < q < 1 \) such that \( \|\vec{B}_1\| = q^{1-1}\|\vec{B}_1\| \) where \( \left( \vec{B}_i \right)_{i \leq n} \) is the Gram-Schmidt basis corresponding to \( B' \).

**Proposition 6.3.** Assuming Heuristic 1 for \( 0 < \alpha < 1/2 \) and Heuristic 2, Algorithm 4 is correct and runs in quantum time \( 2^{\mathfrak{h}(\log(\|\Delta\|)^{\gamma})} \) with polynomial space.
Algorithm 4 Quantum oracle for implementing $f$ defined in (1)

**Input:** Curves $E_1, E_2$. Order $\mathcal{O}$ of discriminant $\Delta$ such that $\text{End}(E_i) \simeq \mathcal{O}$ for $i = 1, 2$. Split prime ideals $p_1, \ldots, p_s$ whose classes generate $\text{Cl}(\mathcal{O})$ where $s = \log^{1+\varepsilon}(|\Delta|)$, reduced basis $B'$ of the lattice $\mathcal{L}$ of vectors $(e_1, \ldots, e_s)$ such that $\prod p_i^{e_i}$ is trivial, generators $g_1, \ldots, g_l$ such that $\text{Cl}(\mathcal{O}) = \langle g_1 \rangle \times \cdots \times \langle g_l \rangle$ and vectors $\bar{v}_i$ such that $\bar{v}_i = \prod p_i^{e_i}$. Ideal class $[a_i] \in \text{Cl}(\mathcal{O})$ represented by the vector $y_i = (y_{1,i}, \ldots, y_{l,i}) \in \mathbb{Z}/d_1 \mathbb{Z} \times \cdots \times \mathbb{Z}/d_l \mathbb{Z} \simeq \text{Cl}(\mathcal{O})$, and $x \in \mathbb{Z}/2\mathbb{Z}$.

**Output:** $f(x, y)$.

1. $\bar{y} \leftarrow \sum_{i=1}^s y_i \bar{v}_i \in \mathbb{Z}^s$ (now $[a_i] = \prod p_i^{e_i}$).
2. Use Babai’s nearest plane method with the basis $B'$ to find $\bar{u} \in \mathcal{L}$ close to $\bar{y}$.
3. $\bar{y} \leftarrow \bar{y} - \bar{u}$
4. If $x = 0$ then $E \leftarrow E_1$ else $E \leftarrow E_2$.
5. for $i = 1, \ldots, s$
6. for $j = 1, \ldots, s$ do
7. $E \leftarrow [p_i] \ast E$.
8. end for
9. end for
10. return $\bar{E}$.

**Proof.** Each group action of Step 7 is polynomial in $\log(p)$ and in $N(p_i)$. Moreover, Babai’s algorithm runs in polynomial time and returns $\bar{u}$ such that

$$||\bar{y} - \bar{u}|| \leq \frac{1}{2} \sqrt{\sum_i ||\bar{b}_i||^2} \leq \frac{1}{2} \sqrt{n} ||\bar{b}'_1|| \in 2^\Theta(|\Delta|^{1/4}).$$

Therefore, the $y_i$ are in $2^\Theta(|\Delta|^{1/4})$, which is the cost of Steps 5 to 9. The main observation allowing us to reduce the search to a close vector to the computation of a BKZ-reduced basis is that Heuristic 1 gives us the promise that there is $\bar{u} \in \mathcal{L}$ at distance less than $2^\Theta(|\Delta|^{1/4})$ from $\bar{y}$.

Algorithm 5 Hybrid algorithm for finding the group action.

**Input:** Curves $E_1, E_2$, $0 < \alpha < 1/2$, order $\mathcal{O}$ such that $\text{End}(E_i) \simeq \mathcal{O}$ for $i = 1, 2, n_1, n_2$ with $N = 2^{1+n_1n_2}$ for $\text{Cl}(\mathcal{O}) \simeq \mathbb{Z}_N$.

**Output:** $X \in \mathbb{Z}_N \leftrightarrow [a] \in \text{Cl}(\mathcal{O})$ such that $[a] \ast E_1 \equiv E_2$.

1. Compute $p_1, \ldots, p_s, B', g, \bar{v}$ with Algorithm 3.
2. $b \leftarrow 0$, $n \leftarrow 0$, $X \leftarrow 0$, $f_n$ defined by (1).
3. while $n < 1 + n_1n_2$
4. Repeat Algorithm 5 using the oracle $f_n$ implemented with Algorithm 4 and using $p_1, \ldots, p_s, B', g, \bar{v}$ to compute $b \in \{0, 1\}$.
5. $X \leftarrow X + b2^n$, $n \leftarrow n + 1$, $f_n \leftarrow \{(x, y) \in D_{N/2^n} \mapsto f_{n-1}(x, 2y + b)\}$.
6. end while
7. return $X$.

**Corollary 6.4.** Let $E_1, E_2$ be two elliptic curves and $\mathcal{O}$ be an imaginary quadratic order of discriminant $\Delta$ such that $\text{End}(E_i) \simeq \mathcal{O}$ for $i = 1, 2$. Then assuming Heuristic 1 for $0 < \alpha < 1/2$, Algorithm 5 finds $[a]$, with $[a] \ast E_1 \equiv E_2$ using:

- A classical circuit of size $2^{\Theta(|\Delta|^{1/4})}$.
- A quantum circuit of size $2^{\Theta(|\Delta|^{1/4})}$.
- Polynomial classical and quantum memory.

Similar modifications to [24] and [10, Appendix A] extend this to arbitrary class groups.
7 Discussion on Heuristic 1

The idea behind Heuristic 1 is that the number of vectors of length $\log(|\Delta|)^{1-\alpha}$ with entries bounded by $e^{\log(|\Delta|)\alpha}$ is $|\Delta|$ while $|\text{Cl}(\mathcal{O})| = \sqrt{|\Delta|}$. If the class of $\prod_i p_i^{x_i}$ yielded by a vector $\vec{x}$ were known to be distributed uniformly at random in $\text{Cl}(\mathcal{O})$, then we would cover all of $\text{Cl}(\mathcal{O})$ with high probability. Unfortunately, the distribution of the classes of these ideals is not known (unless we consider products over the first $\log(|\Delta|)^{2+\epsilon}$ split primes [20], but this is incompatible with our restriction on $\alpha$). To support Heuristic 1, we drew 5000 elements of $\text{Cl}(\mathcal{O})$ for various $\mathcal{O}$ of increasing discriminant. At each discriminant size, we report the maximal exponent in the decomposition of the random classes with respect to the first $\log(|\Delta|)^{1-\alpha}$ split primes. We systematically observe that it is significantly lower than $e^{\log(|\Delta|)\alpha}$. In Table 1, we present the evolution of the maximal exponent for $\alpha = 0.4$ and $\text{Disc}(\mathcal{O}) = -p$ for $p$ the first prime greater than $2^i$ such that $-p$ is a fundamental discriminant and $i$ between 35 and 160. In Appendix A we present similar results for $\alpha = 0.1, \ldots, 0.5$ and smaller increments in the size of $\Delta$.

| $\log_2(|\Delta|)$ | $\log^{0.6}(|\Delta|)$ | Maximal exponent | $e^{\log^{0.6}(|\Delta|)}$ |
|---------------------|------------------------|-----------------|-----------------------------|
| 35                  | 7                      | 4               | 36                          |
| 60                  | 9                      | 8               | 85                          |
| 85                  | 12                     | 11              | 165                         |
| 110                 | 13                     | 19              | 287                         |
| 135                 | 15                     | 24              | 466                         |
| 160                 | 17                     | 30              | 718                         |

8 On fault tolerant implementations

All the asymptotic results regarding the proposed trade-off between classical and quantum circuits only apply to logical qubits. If we incorporate the cost of error correction, then the quantum circuit has to idle while the classical circuit searches for the number $m$ of vectors $\vec{b} \in \{0, 1\}^{n_2 + 4}$ such that $\langle \vec{b} \cdot \vec{k} \rangle \mod 2^{n_2} = z$. The logical gate representation of this circuit does not include the cost of idling, but in all realistic models of fault tolerant qubits, operations need to be performed on a qubit that is being stored while the classical computation is being done. There is currently an ongoing debate in the cryptographic community as to how to assign a cost-metric to a quantum algorithm given its representation in the logical quantum circuit-model of computation [3, 21]. One approach is the quantum circuit-size and the other is the product of the quantum circuit-width (#qubits) and the quantum circuit-depth (time taken). We have previously studied our tradeoff in light of the circuit-size metric. We now briefly make some remarks with regards to the latter, which is proposed as it captures the difficulties in performing quantum error-correction.

Regardless of the architecture chosen for quantum computers and method used to perform quantum error-correction, it is clear from theoretical error models regarding physical qubits that if we consider discrete timesteps, then applying single or two-qubit gates induce an error in the qubit with a significantly higher probability than if it were simply resting (or "idling") [13, 14, 23, 28, 33]. As the resources we must expend on error-correction is intrinsically linked to the probability of an error occurring, it is plain that the resources to protect an idle quantum state have the potential to be lower than those required to protect a quantum
state undergoing active manipulation. For one example of the proposed gaps and tradeoffs that can exist for different architectures, see [32, Tab 2]. In Table 2, we observe that the error rate while storing a qubit is lower than when applying gates in most system.

Table 2: Gates and Memory Errors (Table 3 of [32]).

| Error   | Superconductors | Ion Traps    | Quantum Dots | Photonics |
|---------|-----------------|--------------|--------------|-----------|
| Gate    | $1.00 \times 10^{-5}$ | $3.19 \times 10^{-9}$ | $9.89 \times 10^{-1}$ | $1.01 \times 10^{-T}$ |
| Memory  | $1.00 \times 10^{-5}$ | $2.52 \times 10^{-12}$ | $3.47 \times 10^{-2}$ | $9.80 \times 10^{-4}$ |

Furthermore, classical gates could be significantly faster in practice than quantum gates, thus reducing the quantum cost of idling. In fact, most recent resource estimations [1] can show that, given the current trajectory of quantum architectures, a quantum computation requires inherently a corresponding amount of classical computations. From the counts in [16] a Grover search for an AES-128 key requires $2^{106}$ classical computations, hence approximately $2^{20}$ classical computations per quantum gate.

Our tradeoff therefore allows for agility in cryptanalysis depending upon the eventual architecture of quantum computers and opens the door for improvements and further tradeoffs if smarter methods of performing the brute-force enumeration step are discovered. A simple example of a further trade-off would be to employ parallelism in this stage so that if $m$ classical processors are available, then the classical time would be proportional to $2^{O(n^{1-\alpha})/m + O(m)}$, thus reducing the time of quantum idling even more. A full examination of this work under current projections involving quantum error-correction is left for future work.

9 Conclusion

We proposed an asymptotic trade-off between the size of the classical and quantum circuits required to attack CSIDH. This angle is motivated by the fact that to use the full power of the NIST metric, we should authorize $2^{128}$ classical computations and $2^{87.5}$ quantum gates simultaneously. This work showed that such a hybrid attack could be performed with a quantum and a classical circuit that are both asymptotically smaller than the state-of-the-art. The study of the impact of this attack against the parameters for a specific security level (ex: Level I) is left for future work. In the case of CSIDH-512, the number of Clifford + T gates required to run a reversible CSIDH isogeny computation has been estimated in [3] to approximately $2^{111}$. This is costly, but if we adjust $\alpha$ such that $\log(|\Delta|)^{1-\alpha} = 128$ for $\log(|\Delta|) = 512$ (since $\log(|\Delta|) = \log(p)$ where $p$ is the security parameter), we get $\alpha = 0.22$. Then $\log(|\Delta|^{\alpha}) = 4$, which indicates that the size of the quantum circuit besides oracle calls might be moderate, thus leaving the door open for the relevance of our algorithms to the analysis of the NIST Level I security of CSIDH.

A Numerical data in support of Heuristic 1

In this section, we provide additional numerical data in support of the heuristic made in Section 7. For each $i \in 30, 35, \ldots, 160$ and $\alpha = 0.1, \ldots, 0.5$, we select the first prime $p \geq 2^i$ such that $\Delta = -p$ is a fundamental discriminant. For each discriminant, we compute the corresponding ideal class group and produce a reduced basis of the lattice of relations between the classes of the split primes $p_i$ of norm less than $\log^{1-\alpha}(|\Delta|)$. Then we draw 5000 ideal classes uniformly at random and compute a short decomposition over the split primes of norm less than $\log^{1-\alpha}(|\Delta|)$. To compute a short decomposition of $[\alpha]$, we solve an instance of the approximate Closest Vector Problem between a vector $\vec{x}$ such that $[\prod_p p_i] = [\alpha]$ and the lattice $L$ of relations. We solve approximate CVP by reducing the basis of $L$ with the BKZ algorithm and calling Babai’s nearest plane algorithm. We do not necessarily find the shortest $\vec{x}$, however, all our exponents are below the intended bound $e^{\log^\alpha(|\Delta|)}$. In each table, we show the largest exponent occurring in a decomposition next to $e^{\log^\alpha(|\Delta|)}$ for each $\Delta$. Our heuristic is systematically satisfied. Moreover, aside from the case $\alpha = 0.1$ where the intended bound is already very small (between 4 and 5), we observe that our heuristic seems in fact very conservative. For example, for $\log_2(|\Delta|) = 160$ and $\alpha = 0.5$, the maximal exponent recorded over 5000 short decompositions is 188 while the intended bound is $e^{\log^{0.5}(|\Delta|)} = 37462$.

Table 3: Maximal exponent in short decompositions (over 5000 random elements of the class group).

| $\log_2(|\Delta|)$ | $\log^{0.9}(|\Delta|)$ | Maximal exponent | $e^{\log^{0.9}(|\Delta|)}$ |
