Methanol poisoning can cause neurological complications, including visual disturbances (1), bilateral putaminal hemorrhagic necrosis (2), parkinsonism (3), cerebral edema, coma, or seizures (4). Therefore, methanol has strictly restricted use, with reference values of Biological Exposure Indices (BEI) intended as guidelines for evaluation of potential hazards (5). Methanol poisoning cases were reported as being mainly due to accidental oral ingestion (6,7) including suicidal attempts (8). However, recently there have been outbreaks of methanol poisoning via non-oral exposure at industrial sites in Korea (9,10). Besides, a hazard issue has been raised about methanol in automobile washer in Korea (11). We present in this study 3 patients who had severe neurological complications resulting from methanol poisoning via non-oral exposure in the electronics industry.

The first patient was a 27-year-old woman who was admitted in January 2016 with sudden onset dyspnea. The day before admission, she complained of visual dimness in both eyes and severe nausea. She had no past medical or drug history. Additionally, she had no past medical or drug history. She had severe neurological complications resulting from methanol poisoning. In order to manage it adequately, as well as to prevent it, physicians should recognize that methanol poisoning by non-oral exposure can cause neurologic complications.

Methanol poisoning results in neurological complications including visual disturbances, bilateral putaminal hemorrhagic necrosis, parkinsonism, cerebral edema, coma, or seizures. Almost all reported cases of methanol poisoning are caused by oral ingestion of methanol. However, recently there was an outbreak of methanol poisoning via non-oral exposure that resulted in severe neurological complications to a few workers at industrial sites in Korea. We present 3 patients who had severe neurological complications resulting from non-oral occupational methanol poisoning. Even though initial metabolic acidosis and mental changes were improved with hemodialysis, all of the 3 patients presented optic atrophy and ataxia or parkinsonism as neurological complications resulting from methanol poisoning. In order to manage it adequately, as well as to prevent it, physicians should recognize that methanol poisoning by non-oral exposure can cause neurologic complications.
was used to cool down the phone parts. Randomly collected air samples from 5 spots in this factory were found to contain methanol in the range of 1,030.1 ppm to 2,220.5 ppm, which exceeded the industrial threshold limit value (Time Weighted Average [TWA] 200 ppm; Short Term Exposure Limits [STEL] 250 ppm) (10). In addition, protection devices including masks and gloves were not provided, and the exhaust ventilation system was not operated.

Although her mental state became alert on the fourth day after admission, she complained of persistent blurred vision in both eyes. Her visual acuity test showed finger counting at 20 cm for her right eye and at 30 cm for her left eye. Her color vision test showed 0/24 for her right eye and 2/24 for her left eye. Fundus examination (Fig. 2A and 2B) and optical coherence tomography (OCT) indicated both optic nerves were edematous. In addition, she manifested hypomimia, hypophonia, monotonous and slurred speech, bradykinesia, and truncal ataxia (Supplementary Video 1). Her neurologic sequelae were not improved when discharged on the tenth day after admission. At outpatient clinic, 22 days after symptoms onset, she manifested markedly improved vision, facial expression, speech, and bradykinesia, but still had truncal ataxia (Supplementary Video 2).

The second patient was a 28-year-old woman who was admitted in February 2016 with acute mental changes. The day before admission, she complained of visual dimness in both eyes, and the next day presented disorientation. She had been working at a small cellular phone factory in Bucheon for 9 days. He also worked removing alcohol-smelling solvent and dust on the surface of cellular phone parts using an air-gun. His initial mental state was drowsy and vital signs were stable except for tachypnea with metabolic acidosis (Table 1). Because of unrecovered metabolic acidosis despite medical treatment, she was admitted in intensive care unit and continuous renal replacement therapy (CRRT) was performed. Despite improved metabolic acidosis with CRRT treatment, she showed stuporous mentality on the third day after admission. Spinal tapping was performed and showed negative results. As electroencephalography (EEG) suggested non-convulsive status epilepticus (Table 1), intravenous loading dose of antiepileptic drug was administered. Brain MRI showed abnormal signal intensity in the bilateral putamen and frontal cortices (Fig. 1D, 1E, and 1F). It turned out that similar to the first patient, she worked in removing alcohol-smelling solvent and dust using an air-gun, and she poured the solvent into drums. Toxin analysis from collected urine disclosed methanol concentration of 0.813 mg/L; however, it was collected after CRRT for 2 days. Workplace inspection revealed 99.9% methanol was used to cool the phone parts. In addition, workers used methanol without proper protectors.

Although her mental state became alert on the tenth day after admission, she manifested hypophonia, prominent bradykinesia, and gait ataxia. Her mini mental state examination score was 22/30 due to decreased attention and orientation. In addition, she was unable to see the shape of objects in front of her, read letters, or count fingers. Fundus examination revealed bilateral optic atrophy (Fig. 2C and 2D). Her parkinsonian symptoms were responsive to dopaminergic agents. However, her vision loss was not improved even when she was discharged 1 month later.

The third patient was a 25-year-old man who was admitted in December 2015 with acute mental change on the day of admission. Before admission, he had been working in another small cellular phone factory in Bucheon for 9 days. He also worked removing alcohol-smelling solvent and dust on the surface of cellular phone parts using an air-gun. His initial mental state was comatose and laboratory findings indicated metabolic acidosis with respiratory compensation (Table 1). He manifested anisocoric pupil size and no direct pupillary light reflex in his left eye, but with preserved indirect light reflex. In the emergency room, he showed generalized tonic-clonic seizure for a few minutes. Because of comatous mentality and unrecovered metabolic acidosis, he was intubated and admitted in intensive care unit, and CRRT was performed. Workplace inspection revealed 99.9% methanol was used to cool the phone parts without proper personal protectors. Randomly collected air samples in the factory contained methanol in the range of 228.5 to 417.7 ppm.

Although the alertness recovered on the fourth day after admission, his awareness was impaired. Fundus examination (Fig. 2E and 2F) and OCT showed bilateral optic atrophy. Visual evoked potential demonstrated no potential in his left eye and poor wave forms in his right eye. At outpatient clinic, 1 month later, he still expressed consistent inattention and was only capable of obey-
Fig. 1. Brain MRI images. (A, B, C) For patient 1, brain MRI performed on the day of admission showed diffusion restrictions in the bilateral putamen and anterior insular cortices in diffusion weighted imaging (A), high signal intensities in T2 weighted imaging over the same regions (B), and focal hemorrhage was not detected in susceptibility weighted imaging (C), which may have been due to toxic metabolic encephalopathy. (D, E, F) For patient 2, brain MRI performed on the fifth day after admission showed diffusion restriction in the bilateral putamen and frontal cortices in diffusion weighted imaging (D), high signal intensities in T2 weighted imaging over the same regions (E), and focal hemorrhage in the left putamen in susceptibility weighted imaging (F). (G, H, I) For patient 3, brain MRI performed 2 months after symptom onset showed low signal intensity in the bilateral putamen, frontal cortices, and subcortices in diffusion weighted imaging (G), high signal intensities in the bilateral putamen, frontal cortices and subcortices, and insular cortices in T2 weighted imaging (H), and focal hemorrhage in the bilateral putamen and frontal subcortices in susceptibility weighted imaging (I).

MRI = magnetic resonance image.
Fig. 2. Images of fundus examination. (A, B) Patient 1 with both edematous optic nerves (arrowheads). (C, D) Patient 2 with bilateral pale optic disks (arrows). (E, F) Patient 3 showing bilateral pale optic disks (arrows).
The third patient, probably due to the extensive lesions in the bilateral putamen, manifested frontal release signs and frontal lobe dysfunction. Parkinsonism has been reported (3) as a neurological sequela of acute methanol poisoning, and severe degrees of poisoning are associated with cerebral edema, coma, or seizures (4). The first patient suffered from truncal ataxia, whereas the second patient manifested parkinsonism that was relieved by dopaminergic agents. We could find non-convulsive status epilepticus by EEG in the second patient and generalized convulsive seizure event in the third patient (Table 1).

These cases presented severe neurological complications resulting from industrial outbreaks of methanol poisoning via inhalation and dermal exposure. Indeed, methanol poisoning via non-oral exposure can cause severe neurologic complications as presented above. In order to manage methanol poisoning adequately, as well as to prevent it, it should be recognized promptly by physicians.

Ethics statement

The study protocol was approved by the Institutional Review Board of Ewha Womans University Mokdong Hospital (IRB No. 2016-07-060). Informed consent was confirmed (or waived) by the IRB.

ACKNOWLEDGMENT

We thank Key Hwan Lim, MD, PhD of Department of Ophthalmology, Ewha Womans University College of Medicine and Dong-Ryeol Ryu, MD, PhD of Department of Internal Medicine, Ewha Womans University College of Medicine.

Supplementary Video 1. Patient 1 neurological examination 6 days after symptom onset. She manifested blurred vision in both eyes severe enough not to be able to distinguish objects, hypomimia, hypophonia, monotonous and slurred speech, bradykinesia, and truncal ataxia. There were no resting and action tremor, although there were some limitations due to phlebitis in the left arm and leg caused by intermittent intravenous needle injection.

Supplementary Video 2. Patient 1 follow up neurological examination 22 days after symptom onset. She manifested markedly improved vision, enough to read letters. Her facial expression, speech, and bradykinesia were also improved compared to initial presentation, but still had truncal ataxia.
