Hedgehog signaling has been linked to cell proliferation in a variety of systems; however, its effects on the cell cycle have not been closely studied. In the vertebrate retina, Hedgehog’s effects are controversial, with some reports emphasizing increased proliferation and others pointing to a role in cell cycle exit. Here we demonstrate a novel role for Hedgehog signaling in speeding up the cell cycle in the developing retina by reducing the length of G1 and G2 phases. These fast cycling cells tend to exit the cell cycle early. Conversely, retinal progenitors with blocked Hedgehog signaling cycle more slowly, with longer G1 and G2 phases, and remain in the cell cycle longer. Hedgehog may modulate cell cycle kinetics through activation of the key cell cycle activators cyclin D1, cyclin A2, cyclin B1, and cdc25C. These findings support a role for Hedgehog in regulating the conversion from slow cycling stem cells to fast cycling transient amplifying progenitors that are closer to cell cycle exit.

combinant Sonic Hedgehog (Shh) stimulates proliferation of mouse retinal precursor cells in vitro [Jensen and Wallace 1997; Levine et al. 1997]. In agreement with this, overactivation of the Hh cascade in Patched heterozygous mice leads to persistence of proliferative cells at the periphery of the post-embryonic retina, causing this region to resemble the CMZ of lower vertebrates [Moshiri and Reh 2004]. Additionally, in post-hatch chicks, intraocular injection of Shh stimulates proliferation in the peripheral retina [Moshiri et al. 2005]. Cycloamine, a pharmacological inhibitor of the Hh coreceptor Smoothened (Smo), inhibits CMZ proliferation [Moshiri et al. 2005], and conditional ablation of Shh expression in the peripheral mouse retina results in decreased cell cycling and down-regulation of cyclin D1 [Wang et al. 2005]. Finally, Hh signaling has recently been shown to be essential for chick retinal regeneration, most likely through stimulation of progenitor cell proliferation [Spence et al. 2004]. These data support the idea that Hh signaling promotes proliferation.

Neumann and colleagues, however, studying retinal development in the zebrafish, reached different conclusions [Stadler et al. 2004]. These authors showed that Shh, which is secreted by the first-born retinal ganglion cells (RGC), drives a wave of differentiation, and that interference with Shh signaling blocks this progression [Neumann and Nusslein-Volhard 2000]. Moreover, Syu mutants, which lack Shh, show increased proliferation through inhibition of p57Kip2 and consequent failure of cell cycle exit [Shkumatava and Neumann 2005]. PKA activation, which inhibits Hh signaling, or smo loss of function also leads to defects in retinoblast cell cycle exit in zebrafish [Masai et al. 2005].

Given these discordant results, the question that naturally arises is: What does Hh actually do in the retina? Does it inhibit the cell cycle in zebrafish and activate it in mice and chicks? Or is there a deeper function of Hh that is similar across these species, with contradictory interpretations arising because of differences in the assays used? At which step(s) does Hh affect cell proliferation along the road from stem cell to differentiated cell? The expression patterns of Hh signaling components in the developing retina and the CMZ of Xenopus laevis [Perron et al. 2003] led us to investigate these questions in this model organism, which is particularly accessible for studying retinal development in vivo. We found that blocking the Hh pathway reduces the number of retinal progenitors that take up bromodeoxyuridine [BrdU], consistent with its proposed function as a mitogen. However, this effect results from slower cell cycle kinetics rather than from an increase in cell cycle withdrawal. Moreover, blocking Hh signaling delays cell cycle exit. Conversely, Hh overexpression accelerates the cell cycle and leads to premature cell cycle exit. Flow cytometry experiments and in vivo analysis of cell cycle kinetics provide evidence that Hh stimulates G1/S and G2/M transitions. In situ hybridization experiments revealed that the phosphatase Cdc25C, cyclin B1, cyclin D1, and cyclin A2 are regulated by Hh in the Xenopus retina, providing potential targets mediating the effects of Hh on the cell cycle duration.

By combining different experimental approaches in different animals, and examining the effects of Hh signaling at various stages of retinogenesis, we have been able to show that the distinct phenotypes seen in different species could actually reveal aspects of an underlying role for Hh in controlling transition from a slow cycling “stem” cell to a faster cycling “transit amplifying” progenitor cell.

**Results**

**Hh signaling affects retinal progenitor proliferation in the CMZ**

The expression of Hh pathway genes in the Xenopus CMZ [Perron et al. 2003] suggests that Hh signaling may have a role in proliferation. To test this, two-cell-stage embryos were injected with Shh mRNA, allowed to develop until stage 40–41, and injected with BrdU. As Shh causes patterning defects in the ventral retina [Perron et al. 2003; Lupo et al. 2005], we focused our attention on the dorsal CMZ. Compared with controls, the CMZ of Shh-overexpressing embryos contained a significantly higher number of BrdU-positive cells [Fig. 1A–G].

If Hh promotes proliferation, interfering with this pathway should inhibit BrdU incorporation in the CMZ. Incubation of Xenopus embryos with cycloamine, which blocks the Smo receptor [Cooper et al. 1998; Incardona et al. 1998], strongly represses the expression of Hh transcriptional targets X-Patched-1 and Gli1, consistent with its ability to inhibit Hh signaling to a significant degree [Fig. 1H,H; Perron et al. 2003]. As previously described [Perron et al. 2003], cycloamine-treated stage 40 embryos presented typical patterning defects resulting from reduced Hh signaling; that is, mild cyclopic phenotypes, reduced eye size, and impaired RPE differentiation. They also showed a reduction in the number of BrdU-labeled cells in the CMZ [Fig. 1J–P]. To confirm this result, both blastomeres of two-cell-stage embryos were injected with anti-Smo morpholino (Mo) oligonucleotides or control Mo. Injected embryos displayed eye defects similar to those seen in cycloamine-treated embryos (data not shown). The specific blockade of the Hh cascade by anti-Smo Mo was further assessed by the observation of decreased X-Patched-1 expression [Fig. 1Q,R]. Similar to cycloamine, anti-Smo Mo significantly reduced BrdU incorporation in the CMZ [Fig. 1S–Y].

**Hh signaling regulates cell cycle kinetics in retinal precursor cells**

In order to understand how Hh works to control proliferation, it is necessary to establish a system in which the cell cycle of proliferating retinal cells can be investigated. At earlier optic vesicle stages of retinal development, most or all of the cells are proliferating, as indi-
cated by the ubiquitous uptake of BrdU, following a 3-h BrdU pulse at stage 25 [Fig. 2A,B]. We therefore considered this as a source of cycling progenitors that could be accessible to flow cytometric analysis of the cell cycle. Since the onset of Hh expression within the retina appears after stage 25 (Perron et al. 2003), we first examined whether retinal precursors at this stage respond to the extraocular source of Hh (Ekker et al. 1995). We found that the Hh targets X-Ptc-1 and Gli1 are expressed in the retinal neuroepithelium, suggesting that the pathway is active within the neural retina at this stage (Supplementary Fig. S1). We then injected cyclopamine-treated embryos with BrdU at stage 25 and fixed retinal cells after 1.5 h. The proportion of BrdU-positive cells decreased from 62% in controls to 48% in cyclopamine-treated retinas (Fig. 2C–E).

In a population of asynchronous cycling cells, the fraction of cells in a given phase of the cell cycle is proportional to the length of that phase, relative to the total length of the cell cycle [Nowakowski et al. 1989]. Thus, changes in BrdU incorporation do not necessarily reflect a change in the proportion of proliferating cells. They may instead be caused by alterations in the relative lengths of the different phases of the cell cycle. To distinguish between these two possibilities, we first evaluated the mitotic index in the retinal neuroepithelium of stage 24–25 embryos, using the mitotic marker phosphohistone H3 (P-H3). We found a significantly higher percentage of mitotic cells per section (5.49% vs. 2.07%) in Shh-overexpressing optic vesicles, suggesting that Hh increases the proportion of the cell cycle occupied by the M phase [Fig. 2F–J]. A similar in vivo experiment was performed following cyclopamine treatment. However, the high variability in the number of P-H3-labeled cells per retinal section prevented us from observing a clear difference compared with controls. In order to overcome statistical issues that come from counting sections on slides, we turned to flow cytometry, which allowed us to count a much higher number of cells per experiment. We found a reduction of ∼20% in M-phase-positive cells in retinas from cyclopamine-treated embryos compared with controls (Fig. 2K–P). Thus, assuming that at stage 25 all cells are cycling, the modifications observed in the percentage of BrdU and P-H3-labeled cells suggest that Hh modifies cell cycle kinetics, either by extending the duration of both S and M phases or by reducing the duration of G1 or G2.

**Hh inhibition lengthens G1 and G2 phases of the cell cycle**

To analyze the distribution of cell cycle phases, the DNA content of retinal cells was measured. At stage 25, when almost all cells are still proliferating, cyclopamine treatment caused a reproducible accumulation of retinal precursors in G1 [41% vs. 36% in controls]. This effect was more obvious at stage 30, where a corresponding decrease in the S-phase proportion could also be observed.
(Fig. 3A,B). These results have the same limitations as the above BrdU and P-H3 results—namely, that they are informative only about the duration of cell cycle phases relative to each other. In order to follow more closely the progression of retinal precursors through the cell cycle, we adapted the BrdU/DNA bivariate flow cytometric technique (Dolbeare et al. 1983) to the retina. BrdU is injected in stage 25 embryos; retinas are then fixed and dissociated and analyzed for both BrdU incorporation and DNA content. With no time interval between BrdU injection and fixation, only S-phase cells should be BrdU-positive. An interval, however, allows BrdU-positive cells to progress to subsequent phases of the cell cycle, and hence the proportions of the BrdU-labeled cells in the different cell cycle phases can give an indication of the rate of cell cycle traversal. In the following experiments, we allowed a 1.5-h injection–fixation interval. We separated the cells in six different groups, according to their cell cycle phase and their level of BrdU incorporation (1.5-h BrdU pulse), in retinal neuroepithelium from stage 25 control (n = 13,187 cells) or cycloamine-treated (n = 23,459 cells) embryos, p < 0.001 (binomial test). (F–I) Retinal sections from stage 25 embryos injected with GFP RNA or GFP plus Shh RNAs, immunostained with antibodies against GFP (not shown) and phospho-Histone H3 (P-H3). Dotted lines delineate neural retinas. Note that Shh-overexpressing optic vesicles are substantially thinner compared with control ones, probably due to early morphogenetic defects. Bar, 30 µm. (J) Quantification of the proportion of mitotic cells in the neuroepithelium of injected embryos. The area of each section was measured. The mean number of cells per section was then inferred from the counting of Hoechst-positive nuclei in a restricted area of each section, and was used to calculate the percentage of P-H3-labeled cells per section. Values are given as mean ± SEM. (*** p < 0.001 [Student’s t-test]. (K–P) Bivariate flow cytometric analysis of P-H3/DNA-stained retinal cells from control or cycloamine-treated embryos at stage 25 (K–M) and stage 30 (N–P). (K) At stage 25, the proportion of P-H3-labeled cells decreases from 1.55% (K, 2845 cells) in control to 1.20% in cycloamine-treated embryos (L, 6671 cells), but this is not significant presumably because of low cell numbers. (P) At stage 30, the percentage of mitotic cells is significantly reduced from 1.07% in control (N, 32,476 cells) to 0.89% in cycloamine-treated embryos (O, 18,763 cells). Error bars represent 95% confidence intervals. (*) p < 0.05 (one-tail binomial test).

treated retinas compared with controls (Fig. 3K), indicating a longer G2-phase duration. Similar results were obtained in the CMZ of stage 38 embryos following a 2-h BrdU pulse (Supplementary Fig. S3A).

Hh pathway activation accelerates G1 and G2

If cyclopamine lengthens G1 and G2, activation of the Hh pathway may specifically accelerate these phases. Analysis of DNA content showed an increase in the proportion of cells in S phase, and a decrease in G1 in Hh-overexpressing retinas (Fig. 4A,B), consistent with this hypothesis. However, as mentioned above, Hh overexpression leads to patterning defects in the ventral retina. In order to minimize this potential complication, we took advantage of an inducible Gli1 construct, VP16Gli1zfGR (Takabatake et al. 2002). RNA encoding VP16Gli1zfGR was injected in two-cell-stage embryos, and its activity was induced from stage 25 to stage 32 by addition of dexamethasone (DEX). BrdU was injected at stage 32, and the retinas were collected 2.5 h later for flow cytometric analysis. Overall, BrdU incorporation was significantly increased compared with controls (Fig. 4C). Using BrdU/DNA bivariate analysis as above, we found that in contrast to the loss-of-function experiments, stimulation of Gli target genes resulted in a shortening of both G1 and G2 phases (Fig. 4D–H). The rate of entry into S phase (ΔG1) significantly increased from 14.9% in the GFP controls to 46.8% in VP16Gli1zfGR-induced retinas, while the proportion of G2/M BrdU-negative cells decreased from 36.4% to 24.7% (Fig. 4H). As in the cyclopamine experiments, the duration of S phase (see ΔS and π + G2M) was not altered (Fig. 4H). Therefore, we conclude that Hh signaling is sufficient to accelerate G1 and G2 phases.

Cell cycle components are affected by Hh signaling

To examine whether Hh could achieve its effects on the cell cycle by changing core cell cycle component expression, we focused on the main cyclins expressed in the retina: cyclins A2, B1, and D1 (Ohnuma et al. 2002a; Vernon and Philpott 2003). The expression of these genes was examined by in situ hybridization in control and
cyclopamine-treated Xenopus embryos at stages 30/32 and 38/39. Cyclin D1 expression was slightly reduced in the retinas of cyclopamine-treated embryos [Fig. 5I–L], in accordance with previous findings (Kenney and Rowitch 2000; Wang et al. 2005). We also found that cyclin A2 and cyclin B1 expression was significantly repressed upon cyclopamine treatment [Fig. 5A–H]. The decrease in cyclin A2 expression was minor, whereas the decrease in cyclin B1 expression was much stronger. Finally, we found that the expression of the Cdc25C phosphatase, which activates G2/M transition, was strongly inhibited in the retina of cyclopamine-treated embryos [Fig. 5M–P]. These results are not likely to be secondary to changes in the size of the CMZ as expression of the CMZ marker XRx1 (Perron et al. 1998) did not significantly differ between control and cyclopamine-treated retinas [Fig. 5Q,R].

To investigate whether opposite effects on cell cycle components could be observed following activation of the Hh pathway, we injected embryos with RNA encod-
ing VP16Gli1zfGR (Supplementary Fig. S4). DEX was added for 8 h at stage 23. As expected, activation of the construct led to a significant increase in X-Ptc1 expression compared with the uninduced embryos. As the VP16Gli1zfGR construct is slightly leaky (Fig. 4H), uninduced VP16Gli1zfGR embryos exhibited an intermediate intensity of X-Ptc1 staining compared with control embryos treated with DEX. Increased expression was also detectable for all the cyclins and cdc25 in uninduced VP16Gli1zfGR-injected embryos compared with control ones. We could not detect any further up-regulation for cyclin B1 and cdc25 following the 8-h induction period. Cyclin D1 expression, however, was significantly enhanced, while Cyclin A2 expression was slightly increased. The changes in cell cycle length may thus be due to the influence of Hh signaling on the expression of cell cycle machinery.

Hh inhibition results in prolonged proliferation during retinal neurogenesis

The effects of Hh signaling on the expression of cell cycle stimulators and on the rates of cell cycle transition pose the question of whether Hh is also able to keep cells proliferating for longer during histogenesis by increasing cell cycle re-entry rates. To investigate this, we measured the proportion of BrdU-labeled cells at various stages of retinal neurogenesis in cyclopamine-treated embryos [Fig. 6A–E]. At stage 31, when many cells in the central retina are still cycling, cyclopamine treatment significantly reduced the percentage of BrdU-labeled cells in the retina, as expected from slower cell cycle kinetics [42.12% ± 1.71 vs. 52.18% ± 2.28 in control retinas]. At later stages, however, a significant increase could be observed upon Hh signaling inhibition [55.70 ± 2.58 cells per section vs. 49.51 ± 1.47, at stage 34; and 19.11 ± 1.39 cells per section vs. 12.1 ± 0.98, at stage 36], suggesting that, as neurogenesis progresses, the proportion of proliferating cells declines more slowly in cyclopamine-treated retinas compared with controls [Fig. 6A]. Consistent with this, the number of mitotic cells in the central retina was higher in stage 38 cyclopamine-treated embryos compared with control ones [Supplementary Fig. S3C]. Interestingly, stage 38 provides a window into several steps of retinogenesis; that is, “late retinogenesis” in the central retina and “early retinogenesis” in the CMZ (Harris and Perron 1998). In cyclopamine-treated stage 38 embryos, while the number of M-
phase cells is increased in the central retina, there is a significant reduction of P-H3-labeled cells in the CMZ, as expected from the altered cell cycle kinetics (Supplementary Fig. S3B).

To examine the timing of cell cycle exit more directly, we performed birthdating experiments that allow the evaluation of the timing of cell cycle exit of each differentiated cell type (Fig. 6F). BrdU was injected at regular intervals so that it would be constantly available from stage 32 to stage 41, and therefore mark all cells born in that period. As a delay in cell cycle exit should be more readily observed for cells normally born before stage 32, we focused our analysis on RGCs, the first-born cells in the retina [Holt et al. 1988]. We found a significant increase in the proportion of BrdU-labeled RGCs in cyclopamine-treated embryos compared with controls [Fig. 6G–K], showing that RGCs from Hh activity-deficient retinas exit the cell cycle on average later than control RGCs. Therefore, the observed switch in the proportion of BrdU-positive cells during retinogenesis reflects the fact that cell cycle kinetics slow down on the one hand, which tends to decrease the proportion of BrdU-labeled cells, while on the other hand, delayed cell cycle exit results in an increased proportion of proliferating cells.

The smaller eye size of cyclopamine-treated embryos suggests that the prolonged proliferation of retinal progenitors may be overridden by increased cell death, as observed in the zebrafish [Masai et al. 2005; Shkumatava and Neumann 2005]. Indeed, we found that retinal cell survival was consistently impaired at stage 39/40 upon Hh inhibition, as inferred from the increased number of TUNEL-positive cells [Fig. 6L]. However, the number of apoptotic cells in the retinas of cyclopamine-treated embryos was either indistinguishable or only slightly increased compared with controls, from stage 24 to stage 37. These findings show that Hh signaling may play a role in retinal cell survival after the period of neurogenesis has finished, but exclude a role for apoptosis in our observed proliferation effects during retinogenesis.

Hh overexpression leads to precocious cell cycle exit

If blocking Hh signaling delays cell cycle withdrawal, Hh activation should accelerate cell cycle exit. To test this idea, we lipofected stage 18 retinas with Bhh-CD2, which encodes a fusion Banded Hh protein linked to the human CD2 surface antigen [Brown et al. 1987]. The CD2 domain anchors the fusion protein to the plasma membrane, allowing a cell-autonomous activation of the Hh pathway in addition to nonautonomous effects. Lipofected embryos were injected with BrdU either at stage 32 or 35 and allowed to recover for 3 h before fixation (Fig. 7A–C). At stage 32, we found that the proportion of BrdU-positive cells in Hh-overexpressing clones was higher than in controls, consistent with accelerated cell cycle kinetics. By stage 35, however, the proportion of BrdU-labeled cells was significantly lower than controls (Fig. 7D). To test whether this could be related to precocious cell cycle exit, we performed birthdating experiments by injecting BrdU from stage 32 to stage 41. The proportion of cells born after stage 32 was significantly reduced in Bhh-CD2 lipofected cells, indicating that Hh-overexpressing cells not only cycle faster, but also exit the cell cycle earlier. This is particularly striking for Müller glia (normally the last cell type born in the retina), as the percentage of Müller cells born before stage 32 increased to 29% in Bhh-CD2 lipofected retinas compared with 4% in controls (Fig. 7E). Similar birthdating results were obtained following lipofection and activation of the inducible VP16Gli1zfGR-expressing construct [33% of BrdU-negative Müller cells in VP16Gli1zfGR clones vs. 13% in the control; χ² test, p = 0.001].

Hh functions as a regulator of cell cycle kinetics during zebrafish retinogenesis

Our direct measurements of the effects of Hh signaling on cell cycle exit in *Xenopus* are in accordance with reports showing that in the zebrafish retina Hh promotes cell cycle withdrawal. However, our finding that Hh accelerates the cell cycle of *Xenopus* retinal progenitors also supports previous work performed in chicks and mammals showing a mitogenic function of the Hh pathway. We therefore thought it was important to investigate whether Hh signaling affects cell cycle kinetics in the zebrafish in the same way as it does in *Xenopus*. To examine this possibility, we repeated our BrdU/DNA flow cytometric analysis in wild-type zebrafish embryos.
and in embryos mutant for the Hh coreceptor Smo {smu mutants}. Embryos were injected with BrdU for 1.5 h at 26 hours post-fertilization (hpf). At this stage, which just precedes the beginning of retinal neurogenesis, almost all cells are still cycling. Consistent with the *Xenopus* results, we found that BrdU labeling of retinal precursor cells is decreased from 66% in wild type to 53% in *smu* retinas (Supplementary Fig. S5A). Cell cycle kinetics parameters differed between *smu* and wild-type retinas in the same way as between cyclopamine-treated and control *Xenopus* retinas (Supplementary Fig. S5B–E). Both G1 and G2 phases exhibited an increased duration, as assessed by the proportion of BrdU-negative G2/M cells (πG2M* = 6% in wild type vs. 11% in *smu* mutants) and the rate of entry into S phase (ΔG1 = 36% in wild type vs. 22% in *smu* mutants) (Supplementary Fig. S5E). These results thus highlight a conserved role for Hh signaling in the control of retinal precursor cell cycle kinetics.

**Discussion**

In this study different experimental strategies, including histological assessment of proliferation and flow cytometry, were used with both gain- and loss-of-function approaches to examine the role of Hh signaling in the cell cycle of retinal cells in two vertebrate species. The results were consistent with a conserved function of Hh in the control of cell cycle kinetics, through the regulation of G1 and G2 length in retinal precursor cells. Examination of multiple stages of *Xenopus* retinogenesis revealed additional effects of Hh on cell cycle exit. Hh-overexpressing fast cycling cells tend to exit the cell cycle early, while slow dividing cells with blocked Hh signaling exhibit delayed cell cycle withdrawal [Fig. 8]. Hh signaling regulates the expression of key cell cycle regulators, which may account for these effects.

Most studies of proliferation use static analysis of BrdU incorporation and assume that the percentage of BrdU-positive cells reflects the fraction of actively dividing cells. We aimed for a more dynamic monitoring of the transitions through the cell cycle and by so doing revealed quite a different picture from what had been described before. Hh signaling does, indeed, promote cell cycle progression, consistent with its previously described action as a mitogen [Jensen and Wallace 1997; Levine et al. 1997; Moshiri and Reh 2004; Spence et al. 2004; Moshiri et al. 2005; Wang et al. 2005]. However, this is followed by central retinal progenitor depletion due to premature cell cycle exit. Conversely, Hh inhibition decreases the rate of cell cycling by extending the durations of G1 and G2 and at the same time maintains the proliferative cohort for longer, consistent with results in zebrafish mutants [Masai et al. 2005; Shkumatava and Neumann 2005]. Our data may therefore explain many of the apparent differences reported for the role of Hh in retinal development in different vertebrate species. Hh does not solely direct cell cycle exit, as zebrafish studies had previously suggested, because during early neurogenesis BrdU incorporation in both zebrafish and *Xenopus* retinas actually decreases in the absence of Hh, along with decreased cell cycle speed. Similarly, Hh does not favor proliferation versus differentiation per se, as had been suggested by the mouse and chick results, since, along with stimulating S- and M-phase entry, it also brings cells closer to cell cycle withdrawal. Our techniques highlight the fact that the same assay, in this case BrdU incorporation or P-H3 staining, can yield opposite results at different stages, even though the underlying action of the signaling cascade under consideration may be constant.

Our results not only provide a unifying basis for Hh function in different systems, but also shed light onto previously unexplained findings. For example, a previous study examining early zebrafish retinogenesis found decreased mitotic staining in *syu* retinas at 34 hpf [Stenkamp et al. 2002], consistent with our interpretation but at odds with the previously proposed Hh role in zebrafish. Levine et al. [1997] found that addition of recombinant Shh in rodent retinal cell cultures only transiently increases BrdU incorporation and total cell number, which, given our data, likely reflects initial faster cell division followed by premature cell cycle withdrawal. A few previous results, admittedly, are not directly interpretable with our model. Moshiri et al. [2005] did not observe any significant difference in cell cycle duration between control and Shh-treated dissociated retinal precursors in vitro. This may reflect the necessity of preserved intercellular contacts for Hh to act as a regulator of cell cycle speed as previously proposed [Jensen

![Figure 8](image-url)
and Wallace 1997). Wang et al. (2005) found a precocious birth of RGCs after knocking out Shh in the peripheral mouse retina, whereas we found that RGCs in cyclopamine-treated Xenopus embryos tend to have later birth dates. The discrepancy may arise from the use of different experimental strategies, that is, global inhibition of Hh signaling, which might change the whole environment, versus targeted loss of function in a subpopulation of retinal progenitors. Alternatively, it may reflect a distinct function of Shh in the control of ganglion cell fate (Zhang and Yang 2001; Spence et al. 2004). Clearly, there are likely to be cell-specific and context-dependent effects of Hh signaling in different situations.

We show that Hh is both necessary and sufficient to induce G1 and G2 acceleration. Recent reports have hinted that this effect may be more general during neural development. Cayuso et al. (2006) found that in the chick spinal cord, Shh inhibition increases the G0/G1 fraction in a mixture of post-mitotic and cycling cells. Our results, from stages when all retinal progenitors are still cycling, suggest that this effect reflects a specific increase in the duration of G1. Additionally, Lien et al. (2006) found that the S-phase fraction in the mouse cerebral cortex increases upon Hh activation, which in light of our results can be explained by a decreased duration of G1 and G2.

These cell cycle accelerating effects of Hh may be brought about because the expression of key cell cycle stimulators is influenced by Hh signaling. Cyclin D1 regulates G1/S transition, and, consistent with a slower G1 transition, its expression is decreased upon Hh inhibition, as already reported in the mouse retina (Wang et al. 2005) and other areas of the vertebrate central nervous system (Kenney and Rowitch 2000). The most striking repression by cyclopamine is found for cyclin B1 and cdc25C, crucial regulators of G2/M transition. These represent key candidates for Hh effects on G2 length duration. The related cdc25B phosphatase was recently found to be a target of Hh signaling in the neural tube (Benazeraf et al. 2006). Finally, expression of cyclin A2, the closest Xenopus homolog to human cyclin A, involved in both S- and G2-phase progression (Collins and Garrett 2005), is also significantly reduced upon Hh blockade. Of note, cyclopamine-treated retinas show decreased expression of the G1-specific cyclin D1 and the G2-specific cyclin B1, despite containing a higher proportion of G1- and G2-phase cells, suggesting that the expression changes are a cause, rather than a consequence, of the proliferation defects. In addition, our short-term gain-of-function analysis is consistent with cyclin D1 being a potential direct target of Hh signaling in the retina, although further investigations will be necessary to address this issue for cyclin A2, cyclin B1, and cdc25. Work in the Drosophila eye has also implicated Hh in the activation of cyclin D, cyclin A, and cdc25 (string) (Heberlein et al. 1995; Duman-Scheel et al. 2002, Vrailas and Moses 2006). But why does Hh also lead to early cell cycle exit? One possibility is that this effect is not directly dependent on Hh signaling, but is a consequence of the changes in cell cycle kinetics. Alternately, Hh may directly activate the cell cycle exit program through modulation of cyclin-dependent kinase inhibitors expression as proposed in zebrafish (Shkumatava and Neumann 2005).

In the post-embryonic Xenopus retina, the sources of Hh are the ganglion cell layer and the RPE. These regions are juxtaposed to dividing CMZ precursors that presumably cycle fast according to their labeling following a short BrdU pulse and their high expression level of cell cycle activators (Ohnuma et al. 2002a). In contrast, cells in the outermost edge of the CMZ that are not in direct contact with a Hh source remain BrdU-negative after a short pulse and express low levels of cell cycle activators (Ohnuma et al. 2002a), suggesting slower cell cycle kinetics. Thus, proximal to the source are fast dividing cells almost ready to exit the cell cycle, and distal to the source are slow cycling cells that are far from becoming post-mitotic. It is therefore tempting to speculate that the proliferative properties of CMZ stem cells and precursors are controlled by gradients of Hh signaling. In line with this idea, we have previously shown that the expression of Ptc and Gli1, two known Hh target genes, is detectable in the CMZ region of active proliferation but only faintly detectable in the more peripheral stem cell niche, where Gli3 is highly expressed (Perron et al. 2003). In the absence of Hh signaling, Gli3 is processed into a repressor form (Kasper et al. 2006), which may account for the slower cell cycle kinetics in these most peripheral CMZ stem cells. Consistent with this hypothesis is the recent demonstration that transfection of a repressor form of Gli3 in the chick neural tube causes a severe decrease of proliferation and an increase in the G0/G1-phase fraction (Cayuso et al. 2006). We therefore propose that Hh signaling transforms retinal stem cells into faster cycling progenitor cells. Some familial and sporadic brain cancers have been shown to derive from inappropriate sustained activation of the Hh pathway in stem cells or progenitors (Varga et al. 2001; Palma and Ruiz i Altaba 2004). Our work suggests that Hh signaling may contribute to tumor initiation and progression by transforming quiescent or slow cycling cancer stem cells into fast dividing amplifying cells.

Materials and methods

**Embryos and cyclopamine treatment**

*X. laevis* embryos were obtained by hormone-induced egg laying and in vitro fertilization by conventional methods. Cyclopamine treatment (100 μM, Tebu Bio and TRC) was started from the blastula stage except in Supplementary Figure S2 (from stage 24) and performed as previously described (Perron et al. 2003). Smurf2<sup>−/−</sup> zebrafish mutants (Varga et al. 2001) were obtained by crossing heterozygous mutants raised at 28.5°C and selected according to their external phenotype. Experiments were carried out with wild-type and heterozygous siblings as controls.

**Constructs**

The full-length coding region of X-bhh was subcloned from the X-bhh T7TS plasmid (Ekker et al. 1995) cut with SpeI, and...
inserted into a pCS2 vector (a gift from D. Turner) following Xbal linearization. The coding region of CD2 [a gift from N. Brown] lacking the signal sequence was subcloned into pCS2 vector cut with ClaI and XhoI, after PCR amplification. The N-terminal region (devoid of C-terminal cleavage product) of X-bhh was subcloned into a pCS2-CD2 vector cut with BamHI and ClaI, after PCR amplification. The oligonucleotides used are available upon request. The pSP64T VP16Gli1zfGR construct, encoding a glucocorticoid-inducible Gli1 chimeric morphant, has been described previously (Takahata et al. 2002). The VP16Gli1zfGR coding region was cut from the pSP64T vector using HindIII/KpnI and was subcloned into a pCS2 vector cut with HindIII/AscI. The construct is induced with 4 µg/mL DEX (Sigma) in the embryo medium.

In vitro RNA synthesis and microinjections
Capped GFP and X-Shh (Ekker et al. 1995) RNAs were prepared from CS2 plasmids after NotI digestion, and VP16Gli1zfGR RNAs from a pSP64T plasmid after KpnI digestion. Transcription was performed using the mMessage mMachine kit (Ambion). RNAs were injected in a volume of 5 nl at a concentration of 100–150 pg/nl into two or one of two blastomeres of embryos at the two-cell stage. GFP RNA (100 pg) coinjection was used to visualize injected cells. Morpholino (Mo) injections were performed as indicated by the manufacturer (Genetools). The following antisense Mo oligonucleotide against X-Smo was designed (sequence complementary to AUG is underlined): CATGGAAGAGACTCTTTGAGAAATGA. A standard Mo was used as a control (Genetools).

In vivo lipofection
pCS2-GFP, pCS2-X-bhh-CD2, and pCS2-VP16Gli1zfGR were transfected at stage 18 into the presumptive region of the retina as previously described [Holt et al. 1990; Ohnuma et al. 2002b].

BrdU incorporation
BrdU (10 mM; Roche) was injected intra-abdominally for various durations, as indicated in the text. For birthdating analysis, embryos were lipofected at stage 18 and injected every 6–10 h from stage 32 to stage 41.

Flow cytometry
Fifty dissected retinas per condition were pooled, transferred to serum-free medium on ice, resuspended either in Ca2+-free medium for 30 min or in Trypsin-EDTA (Invitrogen) for 15 min, mechanically dissociated into single-cell suspensions, and fixed in ice-cold 70% ethanol. For DNA content analysis, cells were stained with 40 µg/mL Propidium Iodide (PI; Sigma) in phosphate-buffered saline containing 10 µg/mL RNase. For the estimation of BrdU incorporation, cells were stained with Hoechst (Sigma). Detection of cell apoptosis was performed as described (Perron et al. 2003). Embryos were then vibratome sectioned (50 µm).

In situ hybridization
Digoxigenin-labeled antisense RNA probes were generated according to the manufacturer’s instructions [Roche]. Whole-mount in situ hybridization was carried out as previously described [Perron et al. 2003]. Embryos were then vibratome sectioned (50 µm).
