Abstract

We provide an alternative approach to the decoherence-by-environment paradigm in the field of the quantum measurement process and the appearance of a classical world. In contrast to the decoherence approach we argue that the transition from pure states to mixtures and the appearance of macro objects (and macroscopic properties) can be understood without invoking the measurement-like influence of the environment on the pointer-states of the measuring instrument. We show that every generic many-body system contains within the class of microscopic quantum observables a subalgebra of macro observables, the spectrum of which comprises the macroscopic properties of the many-body system. Our analysis is based (among other things) on two ingenious papers by v. Neumann and v. Kampen. Furthermore we discuss the possibility of the emergence of interference among macro states via time evolution.
1 Introduction

In recent years environment induced decoherence has apparently acquired the status of a new paradigm in the context of the quantum measurement process, the appearance of a classical world, or the nature of superselection sectors (see, just to mention a few representative sources, [1], [2], [3], [4]). It is even sometimes erroneously claimed, that it solves the quantum measurement problem (cf. [5] and the reply by Adler [6]).

In our view the measurement problem consists of a deeper mystery, that is, how particular measurement values appear in a single measurement, and a problem which is of a somewhat lesser calibre, i.e. the transition of a superposition of states into a corresponding mixture within the ensemble picture interpretation of quantum mechanics. As papers about this field go into the hundreds, we refer the reader to the above mentioned reviews what concerns the decoherence approach, to [7] as to the older history of the quantum measurement process and to the recent [8] which discusses the more recent history of the subject. Our main concern in the following is not to write another review but develop an (in our view) coherent complementary approach to the above mentioned problems which is based on a deep (but seldomly cited) paper by v.Neumann, a later equally important paper by v.Kampen and prior work of the author (see [9], [10], [11], [12]). See also the brief comment of van Kampen in [13].

Remark: Only a small part of the content of [9] can be found in v.Neumann's famous book about the foundations of quantum mechanics. See [14] sect. V4 (p. 212ff) where macroscopic observables are introduced.

One of the reasons why [9] has been largely neglected in the context of the quantum measurement process is possibly that it is written in German and that it deals mainly rather with the ergodic problem. Furthermore, in the fifties (for reasons difficult to understand) it has been unjustly criticized as being 'empty' etc. (a quite ridiculous remark in our view). As to the reception history see the recent analysis by Lebowitz et al [15].

To describe the difference of our approach compared to the decoherence approach in a nutshell one may say: It goes without saying that no (macroscopic) object is completely isolated, i.e. is in a sense an open system. This does however not! imply that in an idealized but perhaps nevertheless reasonable description of nature, we are not allowed to either neglect these effects or incorporate them in some averaged statistical manner (as e.g. in the random phase approximation in statistical mechanics, cf. [16]).
The decoherence by environment philosophy claims that the entanglement with the environment is the crucial property while we will argue that e.g. the appearance of macroscopic objects can be alternatively understood in a more intrinsic manner without invoking the (in our view) rather contingent influence of some environment.

Remark: We note that a similar dichotomy exists for example in statistical mechanics and in particular in ergodic theory. That is, can ergodicity or statistical behavior only be understood by invoking some disorder assumption (coming from outside) or can it also be understood within closed many-body systems.

There appeared a couple of other investigations which follow a path similar to ours, i.e. seeking to provide an explanation for the behavior of quantum measurement instruments which deviates from the decoherence-by-environment philosophy. Papers we became aware of belong roughly to two classes. For one there are for example the papers by Sewell ([17],[18]). They are essentially written in the many-body point of view, described by us in the beginning of section 3 and which also serves as a basis of e.g. papers [11] and [12].

To the other class belong e.g. papers by Kofler et al ([19],[20],[21]). These papers address slightly different aspects, for example how classicality does emerge and use as one tool the Leggett-Garg inequality ([22]) which is about correlations in time instead of space. We will comment on possible time correlations of macrosystems below in the context of superposition of macrostates (cf. sect.6). Interesting ideas are also developed in [8]. The view of the authors of [8] concerning the decoherence philosophy is similar to our point of view.

But before we embark on the development of an alternative approach to the quantum measurement process and the concept of ‘classicality’ in the quantum context, we want to give a very brief description of the ideas of the decoherence-by-environment framework as formulated in e.g. [23].

2 The Decoherence by Environment Concept

In a nutshell, the idea is quite simple. In the ordinary presentation of the quantum measurement process (in the v.Neumann spirit) we start from the following chain of equations. Let $\Phi_0, \Phi_i$ be the (pure) states of the measuring apparatus, or rather of a subsystem (typically some macro system). Note however that in the decoherence approach they are frequently called pointer
states, the true nature of which is often not openly specified. Let \( \psi_i \) be the eigenstates of the quantum observable, \( A \), to be measured. We then have (with frequently \( \psi_i \Phi_i \) etc. as shorthand for \( \psi_i \otimes \Phi_i \) etc.) in a measurement of \( A \):

\[
\psi_i \Phi_0 \rightarrow \psi_i \Phi_i
\]

The superposition principle of quantum mechanics then yields:

\[
\left( \sum_i c_i \psi_i \right) \Phi_0 \rightarrow \sum_i c_i \psi_i \Phi_i
\]

Then follows the argument that the rhs of the last equation cannot be identified (even in the case of macro objects) with the corresponding mixture

\[
\sum_i |c_i|^2 P_{\psi_i \Phi_i}
\]

\( P_{\psi_i \Phi_i} \) being the projector on the state \( \psi_i \Phi_i \) irrespectively of the fact that usually \( (\psi_i \Phi_i | \psi_j \Phi_j) = \delta_{ij} \) is assumed. The reason is that in case some of the \( |c_i| \) happen to be equal, we observe a so-called basis-ambiguity (a mathematically coherent treatment can be found in [24], [25], [26]).

It is argued in e.g. [23] and elsewhere that in that cases there do exist other decompositions of the state vector \( \sum_i c_i \psi_i \Phi_i \) with respect to different bases, which in the decoherence philosophy can then be associated with different observables, so that a unique association of macroscopic pointer states and microscopic states (at first glance) does not seem possible.

Remark: We give a critical analysis of this point of view in the following sections.

It is said that this stage of the measuring process is only a premeasurement in so far as the state \( \sum_i c_i \psi_i \Phi_i \) is still a pure quantum state being observably different from a mixture! As a typical example the Stern-Gerlach experiment is frequently invoked where the two split beams can, in principle, be reunited again into a pure state. This (thought) experiment is frequently attributed to Wigner (see e.g. [2]). But it can already be found in the book by Ludwig ([27]) and in an even earlier interesting paper by Jordan ([28]).

The measurement process is, according to this philosophy, closed by an appropriate entanglement of the above state with the so-called environment. If \( \varepsilon_i \) are (in the ideal case) orthogonal states of the environment, it is claimed that we finally have

\[
\left( \sum_i c_i \psi_i \right) \Phi_0 \varepsilon_0 \rightarrow \sum_i c_i \psi_i \Phi_i \varepsilon_i
\]
which solves the basis ambiguity (see [24], [25], [26]).

As a typical example illustrating the basis ambiguity, the following situation is frequently invoked. The singulett state of two spin-one-half particles

\[ \frac{1}{\sqrt{2}} (|\uparrow\rangle(|\downarrow\rangle - |\downarrow\rangle|\uparrow\rangle)) \]

(5)
can be represented in e.g. the eigen basis of the x-component of the spin, i.e.

\[ \psi'_1 = \frac{(|\uparrow\rangle + |\downarrow\rangle)}{\sqrt{2}} , \quad \psi'_2 = \frac{(|\uparrow\rangle - |\downarrow\rangle)}{\sqrt{2}} \]

(6)
as

\[ -\frac{1}{\sqrt{2}} (\psi'_1 \psi'_2 - \psi'_2 \psi'_1) \]

(7)

Remark: Note that the exact compensation of the other cross terms come about because of the common prefactor \( \frac{1}{\sqrt{2}} \), i.e. the necessary and sufficient condition for a basis ambiguity mentioned above.

In the decoherence philosophy according to e.g. Zurek the second tensor product component may then be associated with some pointer that is (part of) a measurement instrument. It is then argued that in the three-orthogonal Schmidt-decomposition, \( \sum_i c_i \psi_i \Phi_i \varepsilon_i \), which is a delocalized state due to the structure of the environment states, \( \varepsilon_i \), one can locally regard the measurement outcome as a mixture, \( \sum_i |c_i|^2 P_{\psi_i \Phi_i} \), (by tracing over the environment) while the global state is still a pure vector state with the information spread into the environment. That is, the crucial point is that one remains globally in the regime of unreduced quantum states!

In our view, at least two of the conceptual ingredients are problematical. First, in case of e.g. the Stern-Gerlach experiment, which serves as kind of a paradigm, the (silver) atoms, carrying the spin degree of freedom, are frequently regarded as pointers (cf. e.g. [23]), or at least as a similar device. In our view, and in the original quantum measurement literature (see e.g. [29]), one would rather call such a subsystem a quantum probe in the context of quantum non-demolition measurements. A similar role is played by the photon in the quantum microscope. In general it may be subsumed under the catchword of shift of the cut between the micro and the macro world in the measurement process. To put it briefly, we have the impression that important subsystems like photo plates, magnets, and the like, which we would prefer to regard as essential parts of the measurement instrument are now simply called environment in the decoherence approach. This exactly happens in the paradigmatical Stern-Gerlach experiment.

In [23] the measurement interference is for example idealialized to a two-bit which path measurement. We think, the situation is not satisfactorily
analysed in parts of the decoherence literature. Either the detector is quantum, then the measurement interference is not! *closed* (almost by definition) and no decision is made. Or the decision is made irreversible, this can only happen if the detector is a macroscopic device like e.g. a photographic plate. In that case it is no longer a premeasurement as our following analysis shows. In any case, no environment is really involved in the process.

Second, it is claimed that the *pointer basis* (and ultimately the correct functioning as a measurement instrument) is established via the interaction of the pointer states with the environment. We must say that we are extremely sceptical, if this point of view is really correct and we will substantiate our scepticism below. We rather think that pointer basis and functioning as a measurement instrument are a priori fixed by the concrete setup of the instrument according to some pre-theory of measurement, typically incorporating pieces of classical and quantum physics. This we can at least learn from the analysis of concrete measurement situations ([29](#)) and the work of the founding fathers of quantum theory (cf. the beautiful discussion between Einstein and Heisenberg as described in [30](#)). A typical ingredient is usually some sub-system being in a meta-stable state (photo plate, Wilson chamber, spark chamber etc.).

Third, the ordinary environment is usually of a very contingent character and it is at least debatable to attribute pure quantum states to it, and, a fortiori, states which are assumed to play a role relative to the pointer states as do measuring instruments relative to the micro objects (in the words of Zurek in [2](#)). We would like to emphasize that the interaction of a measuring instrument with a micro object is a very special one while the interaction of a pointer with the environment is usually of the ordinary statistical type.

On the other hand, the influence of the environment has played an important role already in the classical literature about the quantum measurement process (cf. e.g., the lucid analysis of Heisenberg in his contribution to the Bohr-Festschrift [31](#)). He clearly states that an apparatus, not interacting with the exterior world, is a quantum system and cannot be used as a measuring instrument. It is, in his words, in a potential, i.e. a quantum state. It becomes a macro system via its contact with the environment (thus acquiring factual properties). Furthermore, the illustrations of concrete measuring instruments in the contribution to the Bohr-Einstein debate in [7](#), with their solid clamps and bolts clearly show that a strong contact with the environment is important.

As a last point, the influence of the environment is also incorporated in statistical mechanics. Starting from a global pure state (system plus environment) it is shown in e.g. [10](#) how one arrives via the *random phase*
approximation at a statistical state of the system. That is, it is not the influence of the environment which is denied by us but rather the ubiquity of the invoked measurement-like effect on the pointer states and its role for the appearance of a classical world.

3 Macro Observables from Quantum Theory

In this section we describe in a, as we think, coherent way how macro observables and macroscopic properties do emerge within the framework of quantum theory. The description is based on the highly original papers by v. Neumann and v. Kampen ([9], [10]), some related work of Ludwig ([32], [33]) and prior work of the author ([11], [12]).

Most of [32], [33], [11], [12] is written in the many-body-language approach to the measurement process with relations to phase transitions and super selection sectors. Papers written in a similar spirit are e.g. from the italian school (see for example [34]) or the papers by Sewell already mentioned above. A central problem discussed in these papers was the treatment of macroscopic systems as quantum systems, a problem which also troubled Legett (see e.g. [35]). We think, a transplantation of the above ideas of v. Neumann and v. Kampen into this measurement context will clarify some longstanding open questions. That is, we will show in the following how the macroscopic regime is embedded as a subtheory in general quantum physics.

In this section, for short, we will mainly discuss the ideas of v. Kampen. We start from a many-body wave function

$$\Psi(q) = \sum a_n \psi_n(q) e^{-iE_n t/\hbar}, \quad q = (q_1, \ldots, q_f)$$

with $\psi_n(q)$ the eigenfunctions of the microscopic Hamiltonian, $H$. It is not really necessary to discuss the distribution of spectral values of $H$ in any detail. We know that for $f \gg 1$ they are usually irregularly distributed in dense clusters (at least for ordinary many-body systems) and are also typically (highly) degenerated. We postpone the discussion of more particular systems (displaying e.g. so-called macroscopic quantum phenomena) to forthcoming work (cf. also the discussion in [35]). Put differently, there may exist particular many-body systems (or states) which have a more pronounced quantum nature, i.e. have a more regular spectrum, but in this paper we will concentrate on systems with the usual macroscopic properties. The crucial idea is the existence of what v. Neumann and v. Kampen call macroscopic observables (a possible construction is given in e.g. [9]), other
constructions are given in [33] or [11],[12]; we come back to this point below, in particular in the last section.

In the following we mainly use the notation of v.Kampen.

**Observation 3.1** There exist (almost) commuting observables in the representation space of the many-body system, denoted by $E,A,B,...$ ($E$ representing the macroscopic, i.e. coarse-grained energy operator) and a complete, orthonormal set of (approximate) common eigenvectors, $\Phi_{Ji}$, with the property

$$A \circ \Phi_{Ji} = A_J \cdot \Phi_{Ji} + O(\Delta A) \quad (9)$$

where $\Delta A$ is the measurement uncertainty of the macro observable $A$. It is always assumed that $\Delta A$ is macroscopically small but large compared to the quantum mechanical uncertainty $\delta A$. The approximate common eigenvectors come in groups, indexed by $J$ with $i$ labelling the vectors belonging to the group $J$.

The above equation is assumed to hold for all macro observables. The subspace, belonging to $J$ is called a phase cell. It is assumed that the eigenvalues $A_J$ are macroscopically discernible, i.e. they describe different macroscopic behavior. That is, quantum states belonging to the same phase cell have the same macroscopic properties but are microscopically different. This is, by the way, the same concept as the concept of phases and superselection sectors in the above mentioned many-body approach to the quantum measurement process. That is, the phase cells will go over into the latter concepts after a certain idealization (thermodynamical limit).

Remark: In order that an observable qualify as a macro observable, some properties have to be fulfilled (cf. e.g. [10]).

Typically a macro observable is the sum over few-body micro variables (cf. [33] or [12], see also the last section) like e.g.

$$A = c_f^{-1} \sum_{\text{partitions}} a(q_{i1},\ldots,q_{in}) , \quad f \gg n \quad (10)$$

with the sum extending over all partitions of $(1,\ldots,f)$ into $n$-element subsets and the constant $c_f$ is of the order $f$. It can be shown that such observables fulfill the above assumptions.

One can now represent an arbitrary state vector $\Psi(q)$ as a sum over this new basis, i.e.

$$\Psi(q) = \sum b_{Ji} \Phi_{Ji}(q) = \sum \Psi_J(q) \quad (11)$$
with $\psi_J := \sum_i b_J i \Phi_{J_i}$. In a next step we will introduce *coarse* observables $E, A, B, \ldots$ with the property

$$\mathcal{A} \Phi_{J_i} = A_J \Phi_{J_i} , \quad \mathcal{A} = \sum_J A_J \cdot P_J = \sum_J A_J P_J \quad (12)$$

with $P_J = \sum_i P_{J_i}$. I.e., the $\Phi_{J_i}$ are now exact common eigenvectors of the commuting set $\{ E, A, B, \ldots \}$.

**Remark:** Note that the existence of such observables is guaranteed by the explicit construction via the above spectral representation.

The expectation of e.g. $\mathcal{A}$ in the state $\Psi(q)$ is

$$\langle \Psi | \mathcal{A} | \Psi \rangle = \sum_J A_J \left( \sum_i |b_{J_i}|^2 \right) =: \sum_J A_J w_J \quad (13)$$

with $w_J$ the probability that the (macro) system is found in the phase cell $J$. Furthermore $\mathcal{A} \Psi = \sum A_J \Psi_J$

**Observation 3.2** The $w_J$ fix the macroscopic properties of the state $\Psi(q)$.

As to the technical details of the construction of such a set of macro observables see the above cited papers. We give only one technical property.

**Observation 3.3** With $A = c_f^{-1} \sum_k a_k$, $B = c_f'^{-1} \sum_{k'} b_{k'}$, $a_k, b_{k'}$ microscopic few-body observables, we have

$$[A, B] = c_f^{-1} \cdot (c_f')^{-1} \sum_{kk'} [a_k, b_{k'}] \approx 0 \quad \text{for} \quad f \gg 1 \quad (14)$$

Proof: Note that by assumption most of the $[a_k, b_{k'}] \approx 0$, that is, the set of terms, $[a_k, b_{k'}]$, being essentially different from zero is of cardinality $O(f)$ and that $c_f = O(f)$. Hence $c'_f \cdot c_f = O(f^2)$

A fortiori, a macro observable (almost) commutes with all micro observables in the large $f$-limit.

**Conclusion 3.4** Within the framework of true (many-body) quantum mechanics we found a subset of observables $E, A, B, \ldots$ which behave almost macroscopic, while the coarse observables $\{ E, A, B, \ldots \}$ exactly commute and have the common set of eigenvectors $\Phi_{J_i}$ which come in groups indexed by $J$. The macroscopic eigenvalues $E_J, A_J, B_J, \ldots$ are macroscopically discernible for $J \neq J'$ with $\Phi_{J_i}$ having the macroscopic properties belonging to the group of micro states indexed by $J$. 

8
In the above approach we assumed (for convenience) that the spectrum of the observables under discussion is discrete. In case we have an observable with continuous spectrum the approach only needs a few technical modifications. On the one hand, we can form observables with discrete spectrum from observables with continuous spectrum by appropriate coarse-graining. In a next step we can e.g. via rescaling construct macro observables with (almost) continuous spectrum. As example take certain position observables of some (macroscopic) subsystems (cf. for example the last section).

4 The Quantum Mechanical Measurement Process in the Light of the Preceding Analysis

Our notion of macro systems and macro observables emerges as a subtheory living on a second (coarse-grained) level relative to the underlying quantum level. Furthermore, the algebra of macro observables is a subalgebra of the full algebra of quantum observables. I.e., in the space of microscopic observables we (rigorously) construct a subspace of macro observables, \( \mathcal{A}_M \), the members of which almost commute while the corresponding coarse-grained observables, \( \overline{\mathcal{A}}_M \), exactly commute by construction. The measurement devices or the pointers are assumed to be essentially macroscopic, that is, pointer states or pointer observables are assumed to belong to this class. This point of view is in sharp contrast to the decoherence philosophy, where macroscopic pointer states are assumed to be fixed via interaction with the environment.

Observation 4.1 (Superposition Principle) With \( \Psi_1, \Psi_2 \) many-body quantum states of a measurement instrument or of some macroscopic part of it (pointer), which are assumed to have unique macroscopic properties, i.e. belonging to single but different phase cells, that is

\[
\Psi_1(q) = \sum_i b^1_{J_i} \Phi_{J_i} (q) \quad , \quad \Psi_2(q) = \sum_i b^2_{J_i'} \Phi_{J_i'} (q) \quad (15)
\]

we have

\[
\Psi := \Psi_1 + \Psi_2 = \sum_i b^1_{J_i} \Phi_{J_i} (q) + \sum_{i'} b^2_{J_i'} \Phi_{J_i'} (q) \quad (16)
\]

and (with \( A_J \) the eigenvalues of some \( \overline{\mathcal{A}}_M \))

\[
(\Psi | \overline{\mathcal{A}}_M | \Psi) = \left( \sum_i |b^1_{J_i}|^2 \right) \cdot A_J + \left( \sum_{i'} |b^2_{J_i'}|^2 \right) \cdot A_{J_i'} = (\Psi_1 | \overline{\mathcal{A}}_M | \Psi_1) + (\Psi_2 | \overline{\mathcal{A}}_M | \Psi_2) \quad (17)
\]
That is, within the realm of the smaller algebra $\mathcal{A}_M$ states like $\Psi_l$ or $\Psi$ behave as mixtures and not as pure states.

Note that in our approach the system is treated as a true quantum many-body system in the microscopic regime and at the same time as a macro system with respect to the smaller algebra $\mathcal{A}_M$. This answers (in our view) also some longstanding questions as to a possible threshold where quantum properties go over (in a presumed phase-transition-like manner) into macro properties. According to our analysis there is no such threshold. It is rather the many-body behavior as such which enables the selection of a subalgebra $\mathcal{A}_M$!

**Observation 4.2 (Schroedinger’s Cat)** The above result concerns superpositions of macro states being observably different, a catchword being Schroedinger’s Cat. In many discussions the wrong picture is invoked as if a superposition of dead and alive is something like a macroscopically blurred state. This impression is incorrect! What can be macroscopically observed is given by the class of macroscopic observables. But as we have shown, these observables annihilate the respective interference terms. Such interference terms could possibly only be observed in some super cosmos with the help of observables which connect macroscopically many degrees of freedom at a time (cf. the last section).

Remark: We want to briefly comment upon a typical misconception frequently occurring in the literature. In the discussion of the Schroedinger cat paradox the superposition of a dead and alive cat is typically invoked. But this will actually never happen. On an intermediate stage of the experiment the decay of e.g. a radioactive atom and the fate of the cat is connected by the proper action of a chain of various many-body devices setting ultimately free the poison. That is, the macro state of the cat happens to be well separated from the transition zone between micro and macro physics with which our discussion is concerned.

In a next step we want to show that the basis ambiguity problem becomes obsolete in our context.

**Observation 4.3** As all elements of $\mathcal{A}_M$ quasi-commute or rigorously commute in $\mathcal{A}_M$, there do not exist the so-called complementary observables.

This has the following effect. In e.g. the Stern-Gerlach experiment we can of course formally repeat the analysis of Zurek and generalize

$$1/\sqrt{2} \left( (\uparrow) (\downarrow) - (\downarrow) (\uparrow) \right) = -1/\sqrt{2} \left( \psi'_1 \psi'_2 - \psi'_2 \psi'_1 \right)$$

(18)
(cf. section 2) to
\[ \frac{1}{\sqrt{2}}((\uparrow)\Phi_2 - (\downarrow)\Phi_1) = -\frac{1}{\sqrt{2}}(\psi_1'\Phi_1' - \psi_2'\Phi_2') \] (19)
with \( \Phi_1, \Phi_2 \) some pointer states and
\[ \psi_1 = \frac{1}{\sqrt{2}}((\uparrow) + (\downarrow)) \quad , \quad \psi_2 = \frac{1}{\sqrt{2}}((\uparrow) - (\downarrow)) \] (20)
\[ \Phi_1' = \frac{1}{\sqrt{2}}(\Phi_1 - \Phi_2) \quad , \quad \Phi_2' = \frac{1}{\sqrt{2}}(\Phi_1 + \Phi_2) \] (21)
I.e., the superposition principle is taken for granted. However, there does not exist a macro observable, \( \mathcal{B}_M \), so that the new states, \( \Phi_i' \), are its eigenstates. That is, the \( \Phi_i' \) do not correspond to different macroscopic pointer positions but rather are general many-body states without distinct macroscopic properties. Macroscopically they rather represent mixtures of macro states (cf. observation 4.1)

More precisely, we have

Observation 4.4 With \( \Phi_J \) eigenstates of the coarse macro observable \( \mathcal{A} \), i.e. belonging to some phase cells \( \mathcal{C}_J \),
\[ \mathcal{A} \circ \Phi_J = A_J \cdot \Phi_J \] (22)
there does not exist another coarse observable \( \mathcal{B} \) with e.g.
\[ \mathcal{B} \circ (\Phi_1 + \Phi_2) = B_3 \cdot (\Phi_1 + \Phi_2) \] (23)
that is, with \( (\Phi_1 + \Phi_2) \) another macroscopic state with macroscopic properties. The state \( \Phi_1 + \Phi_2 \) rather represents a mixture with respect to \( \mathcal{A}_M \).

Proof:
\[ \mathcal{B} \circ (\Phi_1 + \Phi_2) = B_3 \cdot (\Phi_1 + \Phi_2) \] (24)
implies (by assumption and definition) that \( \Phi_1 + \Phi_2 \) is a macro state. As all the macro observables commute, it is also an eigen state of \( \mathcal{A} \) with
\[ \mathcal{A} \circ (\Phi_1 + \Phi_2) = A_3 \cdot (\Phi_1 + \Phi_2) \] (25)
But we have
\[ \mathcal{A} \circ \Phi_1 = A_1 \cdot \Phi_1 \quad , \quad \mathcal{A} \circ \Phi_2 = A_2 \cdot \Phi_2 \] (26)
with \( A_1 \neq A_2 \). Hence
\[ \mathcal{A} \circ (\Phi_1 + \Phi_2) \neq A_3 \cdot (\Phi_1 + \Phi_2) \] (27)
i.e., we get a contradiction, that is, \( \Phi_1 + \Phi_2 \) can never be a macro state with macroscopically definite properties.
Conclusion 4.5 The basis ambiguity does not exist for $\mathcal{A}_M$. We can of course represent some many-body state with respect to another basis but the macroscopic properties remain the same! They are encoded in the a priori fixed decomposition

$$\Psi = \sum b_{ji} \cdot \Phi_{ji}, \quad \mathcal{A}\Phi_{ji} = A_{ji} \Phi_{ji}$$

and are the consequence of the complex many-body spectrum and the reduced size of the algebra of macro observables. The entanglement with the environment does not play a role in this analysis.

In physical terms we can explain this result with the help of the Stern-Gerlach experiment, following Bohr’s dictum that the quantum mechanical measurement of two complementary observables as e.g. $\sigma_z$ and $\sigma_x$ need two different! and mutually exclusive experimental setups. That is, in order to measure the $z$-component one has to split the beam along the $z$-axis. This implies that the magnets have to be oriented accordingly. The same procedure with respect to the $x$-direction implies the respective orientation of the magnets parallel to the $x$-axis. That is, we have to apply a macroscopic rotation of the magnets (a many-body transformation).

Observation 4.6 This rotation cannot be described by means of a superposition of states of the magnets being oriented in the $z$-direction as was the case in microscopic quantum mechanics of some spin variable.

Conclusion 4.7 We can infer that the macroscopic pointer states are not determined via interaction (by decoherence) with the environment. They are obviously fixed a priori by the concrete experimental setup as described in the above example.

5 The Analysis of a Concrete Measurement Situation

We now want to give a concrete example illuminating the approach, described above. It was already essentially given in [11],[12]. We assume that the pointer of our measurement instrument is a macroscopic subsystem consisting of $N$ ($N \gg 1$) quantum particles (e.g. a solid state system or an avalanche in a Geiger-counter), being capable of performing approximately a coherent motion, depending on the micro state of the quantum system to be measured.
I.e., in a concrete individual measurement event, the pointer as a whole starts to move with a macroscopic momentum

$$\left( \Phi_i(t)|\hat{P}|\Phi_i(t) \right) \approx N \cdot \langle p \rangle_i$$ (29)

with \(\hat{P} = \sum_{i=1}^{N} \hat{p}_i\) the quantum mechanical total momentum observable, \(\Phi_i(t)\) a collective state of the pointer (induced by the contact with the micro object) and

$$\langle p \rangle_i := \left( \Phi_i(t)|N^{-1} \cdot \hat{P}|\Phi_i(t) \right)$$ (30)

the (approximately constant) mean-momentum per (quantum-) particle of the pointer. We assume that different measurement results imply \(\langle p \rangle_i \neq \langle p \rangle_j\) with the \(\langle p \rangle_i\) being in correspondence with microscopic values \(q_i\) of some quantum observable to be measured.

The center-of-mass observable of the pointer

$$\hat{R}_{CM} := \sum_i m_i \hat{r}_i / \sum_i m_i$$ (31)

then behaves as (with \(M := \sum_i m_i\))

$$(\hat{R}_{CM})_i(t) := \left( \Phi_i(t)|\hat{R}_{CM}|\Phi_i(t) \right) \approx \text{const.} + t \cdot \langle p \rangle_i \cdot N/M$$ (32)

**Observation 5.1**

i) For \(N \gg 1\) and \(\langle p \rangle_i \neq \langle p \rangle_j\) the states \(\Phi_i(t), \Phi_j(t)\) become (almost) orthogonal for macroscopic \(t\).

ii) In our simple model the values \(\{\langle p \rangle_i\}\) label different phase cells (or sectors) with (almost) sharp eigen values of the macro observables \(N^{-1} \cdot \sum_i \hat{p}_i\) or \(\hat{R}_{CM}\).

iii) An arbitrary microscopic state vector of our pointer system is a superposition of the above sector states, i.e.

$$\Psi = \sum_{Ji} b_{Ji} \Phi_{Ji}$$ (33)

with \(i\) labelling the different vectors belonging to the same phase cell described by \(\langle p \rangle_J\).
6 Interference among Macro States

In this section we want to analyse the possibility of the observation of interference effects among macroscopically distinct macro states. We addressed this problem already in [11] and [12]. We have shown in the preceding analysis that this cannot happen at a fixed time, \( t \), in the regime of macro observables, \( A_M \) or \( \overline{A}_M \). If one goes into the technical details one observes that one (crucial) property, in order to qualify as a macro observable, is the following

**Observation 6.1** With \( N \) the number of microscopic constituents of a macroscopic (many-body) system \( (N \gg 1) \), we see that typical microscopic quantum mechanical observables are so-called few-body observables. I.e.

\[
\hat{a}(x_{i1}, \ldots, x_{in})
\]

(34)

denotes a microscopic \( n \)-particle observable, correlating \( n \ll N \) microscopic constituents at a time. A typical many-body observable which qualify as a macroscopic observable can then be written as

\[
\hat{A} := \sum_{Per} \hat{a}(x_{i1}, \ldots, x_{in})
\]

(35)

where the sum extends over all possible clusters of \( n \) micro objects out of the \( N \) constituents of the many-body system. Furthermore, a pre-factor of the order \( N^{-1} \) frequently occurs in front of the sum.

If we try to observe now possible off-diagonal elements of \( \hat{A} \), that is, expectation values between different macro states, we get approximately, making certain simplifying assumptions

**Observation 6.2** The degree of overlap between different macro states with respect to the macro observable \( \hat{A} \) is approximately

\[
| \langle \Phi_i | \hat{A} | \Phi_j \rangle | \approx N!/n!(N - n)! \cdot \tau^{(N-n)}
\]

(36)

with \( \tau \) a small number \( (\ll 1) \) which denotes the individual overlap of the wave function relative to the same microscopic constituents in the different macro states, which do not belong to the cluster, coupled in a contribution coming from e.g. \( \hat{a}(x_{i1}, \ldots, x_{in}) \).
Conclusion 6.3 Interference between macroscopically different macro states could only be observed, if we were able to construct observables which do correlate $n \approx N \gg 1$ microscopic constituents at a time. The observables we are usually using in physics have however $n \ll N$. A situation where $n \approx N$ holds, is called by Ludwig in [33] a super-macro-cosmos.

We now come to an interesting point which was not treated in the preceding analysis, i.e., the possibility that the Hamiltonian time evolution generates interference effects, that cannot be observed at a fixed time $t$. This possibility was for example mentioned by Legett in [35] and [22]. This possibility does not contradict our previous analysis which dealt with superpositions of different macro states at an arbitrary but fixed time. But, to say it in plain words, a superposition of e.g. two distinct macro states, $\Phi_1 + \Phi_2$, which behaves at time $t = 0$, according to our analysis, macroscopically as a mixture of $\Phi_1$ and $\Phi_2$ can, due to the Hamiltonian time evolution, evolve into another macro state, $\Phi(t)$, at some $t \neq 0$ which is not the mixture of the separate evolution of $\Phi_1$ and $\Phi_2$.

To give a concrete example, we assume that $\Phi_1, \Phi_2$ are spatially separate at $t = 0$ ($(\Phi_1, \Phi_2)(t) = 0$) so that no interference effects can be observed at time $t = 0$. But at a later time they may display a marked overlap so that $(\Phi_1(t), \Phi_2(t)) \neq 0$. This can easily be achieved for micro states (using e.g. a beam splitter, mirrors and/or a magnetic field) and there is in our view no a priori reason why the same cannot be accomplished for macroscopic (many-body) wave functions.

Conclusion 6.4 It may happen that we have at time $t = 0$ a superposition $\Phi_1 + \Phi_2$ of e.g. two macroscopically distinct states which hence behaves like a mixture of $\Phi_1$ and $\Phi_2$ with respect to the algebra of macro observables. But at a later time $\Phi(t) = \Phi_1(t) + \Phi_2(t)$ is different from the mixture of $\Phi_1(t)$ and $\Phi_2(t)$.

With the notations of [10] we can represent this more quantitatively. Let the state at $t = 0$ be

$$\Psi(0) = \sum_{J_i} b_{J_i} \Phi_{J_i}$$

(37)

The time evolution $U(t)$ leads to

$$\Psi(t) = U(t) \circ \Psi(0) = \sum_{J_i} b_{J_i} U(t) \circ \Phi_{J_i}$$

(38)
This equals
\[
\sum_{Ji} \sum_{J^\prime i^\prime} b_{Ji}(0) < \Phi_{J^\prime i^\prime}, U(t) \Phi_{Ji} > \Phi_{J^\prime i^\prime} = \sum_{Ji} (\sum_{J^\prime i^\prime} b_{J^\prime i^\prime}(0) < \Phi_{Ji}, U(t) \Phi_{J^\prime i^\prime} >) \Phi_{Ji}
\]
\[
= \sum_{Ji} b_{Ji}(t) \Phi_{Ji}
\]
with
\[
< \Phi_{Ji}, U(t) \Phi_{J^\prime i^\prime} > = \sum_n < \Phi_{Ji}, \psi_n > \cdot e^{-iE_n t/\hbar} \cdot < \psi_n, \Phi_{J^\prime i^\prime} >
\]
and \( \psi_n \) the eigenstates of the (many-body) Hamiltonian. We hence have
\[
\sum_i |b_{Ji}(t)|^2 = w_J(t) = \sum_{J^\prime i^\prime} \sum_i \left( \sum_{J^\prime i^\prime} < \Phi_{Ji}, U(t) \Phi_{J^\prime i^\prime} > \cdot b_{J^\prime i^\prime}(0) \cdot b_{J^\prime i^\prime}(0) \right)
\]
\[
|b_{Ji}(0)|^2 \approx \sum_i |b_{Ji}(0)|^2 / D_J = w_J(0) / D_J
\]
Observation 6.5 The \( w_J(t) \) are in general not completely defined by the \( w_J(0) \).

In order to get more manageable formulas we will make (cf. [10]) two disorder assumptions.

Assumption 6.6 (Disorder)

\[
w_J(t) \approx \sum_{J^\prime i^\prime} \sum_i < \Phi_{Ji}, U(t) \Phi_{J^\prime i^\prime} > |^2 \cdot |b_{J^\prime i^\prime}(0)|^2
\]

and
\[
|b_{Ji}(0)|^2 \approx \sum_i |b_{Ji}(0)|^2 / D_J = w_J(0) / D_J
\]
with \( D_J \) the dimension of the subspace (phase cell) belonging to \( J \).

With these (statistical) assumptions we get

Conclusion 6.7 Macroscopically we get
\[
w_J(t) = \sum_{J^\prime} T_{J,J^\prime}(t) w_{J^\prime}(0)
\]
with

\[ T_{J,J'}(t) = D_J^{-1} \sum_{i,i'} | < \Phi_{Ji}, U(t) \Phi_{J'i'} |^2 \]  

(45)

That is, if the microscopic time evolution, induced by \( H \), couples micro states lying in different phase cells, \( w_J(t) \) does not depend only on \( w_J(0) \). However, if it couples only micro states coming from the same phase cell, \( T_{J,J'}(t) \) is diagonal and we have

\[ w_J(t) = T_{J,J}(t) w_J(0) \]  

(46)

**Corollary 6.8** We see that in order that a measuring apparatus functions as expected, we have to assume or, rather, to guarantee that within the observation time the macroscopic time evolution is diagonal in the above sense. One should note that this is the usual behavior of such mechanical devices anyhow.

7 Conclusion

We have shown that one can rigorously construct a subalgebra of commuting macro observables within the set of quantum observables of a generic many-body system. The common (almost) eigen values of this set of macro observables are then the macroscopic properties of the many-body system. Furthermore, for the subalgebra of macro observables the basis ambiguity is lost (no complementarity!) and there is hence no need for a (measurement-like) decoherence-by-environment mechanism to fix the so-called pointer basis. The pointer basis is in our approach already apriori fixed by the design of the measurement instrument and by the spectral properties of the corresponding microscopic many-body Hamiltonian together with the structure of the set of macro observables.
