Abstract Aedes aegypti is the principal mosquito vector for many arboviruses that increasingly infect millions of people every year. With an escalating burden of infections and the relative failure of traditional control methods, the development of innovative control measures has become of paramount importance. The use of gene drives has sparked significant enthusiasm for genetic control of mosquitoes; however, no such system has been developed in Ae. aegypti. To fill this void, here we develop several CRISPR-based split gene drives for use in this vector. With cleavage rates up to 100% and transmission rates as high as 94%, mathematical models predict that these systems could spread anti-pathogen effector genes into wild populations in a safe, confinable and reversible manner appropriate for field trials and effective for controlling disease. These findings could expedite the development of effector-linked gene drives that could safely control wild populations of Ae. aegypti to combat local pathogen transmission.

Introduction

Due to the high annual incidence of vector-borne disease, the associated economic burdens, and the lack of effective vaccines, interest in the innovation of novel population-control methods to prevent pathogen transmission is increasing. Aedes aegypti is the principal mosquito vector of several arboviruses, including yellow fever, chikungunya, dengue, and Zika (Scott and Takken, 2012). This mosquito alone places roughly half of the world’s population at risk of acquiring vector-borne diseases while causing an estimated 390 million dengue infections annually (Bhatt et al., 2013). Traditional mosquito control strategies, including long-lasting insecticide-treated bed nets (LLINs), chemical insecticides, and environmental management (Schreck, 1991), have significantly reduced mosquito-borne disease burdens; however these interventions are largely unsustainable due to the development of both genetic and behavioral vector resistance that decrease their efficacy (Vontas et al., 2012), high costs, and the need for repeated applications with limited spatial impact. Furthermore, chemical interventions, a fundamental tool for vector control, negatively affect non-target beneficial organisms, such as pollinators. Therefore, there is a pressing global need for alternative safe and effective approaches to control mosquito disease vectors.
Species-specific mosquito population suppression technologies, such as the Wolbachia incompatible insect technique (IIT) and the release of dominant lethal gene (RIDL), are currently being implemented on a small-scale in the field to control populations of Ae. aegypti (Harris et al., 2012; McMeniman et al., 2009; Phuc et al., 2007). While these technologies improve Ae. aegypti control capabilities, they require continuous inundation, which is laborious and cost prohibitive to many areas with the largest vector-borne disease burdens. In addition to IIT, Wolbachia has also been used for population replacement in various locations (Hoffmann et al., 2011; Jiggins, 2017; Schmidt et al., 2017), as certain strains can spread to fixation while reducing the vector’s susceptibility to dengue virus (Walker et al., 2011). However, the literature suggests the effectiveness of different Wolbachia strains varies so far as to even enhance vector competence in some contexts, which may lead to a reevaluation of this technique (Amuzu et al., 2018; Dodson et al., 2014; Hughes et al., 2014; Hughes et al., 2012; King et al., 2018; Murdock et al., 2015; Zéle et al., 2014). Therefore, there has been renewed interest in developing novel species-specific and cost-effective genetic technologies that provide long-lasting disease reduction with limited effort.

One innovative technology, first articulated by Burt (2003), utilizes homing-based gene-drive technologies to expedite the elimination and eradication of vector-borne diseases (Burt, 2014; Champer et al., 2016; Esvelt et al., 2014; Marshall and Akbari, 2017; Marshall and Akbari, 2016). Conceptually, these drives function by exploiting the organism’s innate DNA repair machinery to copy or ‘home’ themselves into a target genomic location prior to meiosis in the germline. This process converts wild type alleles into drive alleles in heterozygotes, thereby forcing super-Mendelian inheritance of the drive into subsequent generations, irrespective of the fitness cost to the organism. Theoretically, this inheritance scheme can spread the drive and any linked anti-pathogen ‘cargo genes,’ to fixation in a population in a short time frame (Buchman et al., 2019; Dong et al., 2018; Yen et al., 2018), even with modest introduction frequencies (Burt, 2003). Importantly, if these drives are linked with effective anti-pathogen cargo genes, they could deliver efficient and cost-effective vector control (Burt, 2003). The drawback to this scheme came from the difficulty in engineering homing drives with various endonucleases, however the recent CRISPR revolution has streamlined their development (Champer et al., 2016; Esvelt et al., 2014). In fact, proof-of-concept CRISPR-based homing gene drives have recently been developed in several organisms including yeast (Basgall et al., 2018; DiCarlo et al., 2015; Roggenkamp et al., 2018; Shapiro et al., 2018), flies (Champer et al., 2019; Champer et al., 2018; Champer et al., 2017; Kandul et al., 2019a; KaramiNejadRanjbar et al., 2018; Oberhofer et al., 2018), mice (Grunwald et al., 2019), and two malaria vector species, Anopheles gambiae (Hammond et al., 2016; Hammond et al., 2017; Kyrou et al., 2018) and Anopheles stephensi (Gantz et al., 2015). All of these CRISPR-based homing gene drives minimally consist of a Cas9 endonuclease, which facilitates the genome integration of the gene drive and a guide RNA (gRNA) cassette, which encodes the sequence-specific integration site targeted by Cas9. When these two components are expressed together in the germline at the correct time and quantity, they can cause drive conversion at some frequency, a process in which one copy of the drive becomes two copies, thereby biasing the inheritance of the drive.

Unfortunately, a gene-drive system has yet to be developed in Ae. aegypti, the lack of which is principally due to the absence of tools necessary to engineer drives. In response to these deficiencies, here we molecularly characterized drive components and then evaluated and optimized these components in several drive systems in Ae aegypti. As a safety precaution, we engineered ‘split drives’ (referred to as split drives from hereon) with a molecularly unlinked endonuclease, thereby allowing the user to spatially and temporally confine the drive (Akbari et al., 2015a; Champer et al., 2016; Committee on Gene Drive Research in Non-Human Organisms: Recommendations for Responsible Conduct, Board on Life Sciences, Division on Earth and Life Studies, National Academies of Sciences, Engineering, and Medicine, 2016; Esvelt et al., 2014). To improve drive efficiency, we targeted a highly conserved region in a phenotypic gene with cleavage rates, indicating biallelic cutting, of 100% and homing rates, indicating the super-Mendelian transmission rate of the drive, as high as 94%. In addition to demonstrating drive efficiency, we performed mathematical modeling that suggested split drives are particularly valuable in gene drive development since: i) several consecutive releases of male mosquitoes harboring the split drive and anti-pathogen cargo, at an achievable 1:1 ratio with the wild population, could spread disease refractoriness in wild populations, ii) the split drive should not significantly spread into neighboring populations, and iii) dissociation of the unlinked endonuclease and guide RNA components, in
addition to the fitness costs associated with the split drive and cargo, may cause the drive to be eliminated from the population on a timescale that could accommodate local arbovirus elimination. These highly desirable features could enable safe testing of a split drive system in the field prior to the release of a more invasive, self-propagating, linked-drive system, and could lead to the development of new technologies to prevent vector-borne disease transmission.

Results

Rational target site selection for the drive
To develop a binary Cas9 gRNA approach that could be leveraged for the development of gene drives, we built on our previous work that generated Ae. aegypti strains expressing the Cas9 endonuclease in both germline and somatic cells and demonstrated their robust cleavage and improved homology directed repair (HDR) efficiencies (Li et al., 2017). We targeted an easily screenable gene with consistent and viable disrupted phenotype, the white gene (AAEL016999), which is an ATP-binding cassette (ABC) transporter (Bhalla, 1968; Coates et al., 1997; Li et al., 2017). To locate a highly conserved target sequence in white, we bioinformatically compared the whole-genome sequences of 143 Ae. aegypti mosquitoes sampled throughout California (n = 127), Florida (n = 4), Mexico (n = 3), Puerto Rico (n = 6), and South Africa (n = 3) (Figure 1—source data 1) (Lee et al., 2019). From this analysis, we discovered a putative gRNA target sequence in exon 3 of white (gRNA0) that was 100% conserved in these wild populations (Figure 1—source supplement 2A–B). To target this highly conserved sequence and determine cleavage efficiency at this site, we synthesized and injected gRNAs into embryos derived from exu-Cas9 (Exuperantia, AAEL010097) females that maternally deposit Cas9. We achieved a 92.7 ± 5.8% mutation efficiency in the injected G0s, which is consistent with our previous work in this line (Li et al., 2017), demonstrating that this target site is accessible to Cas9 cleavage and that this gRNA is highly active.

Characterization of functional polymerase-III promoters
Next, we needed a promoter to ensure proper strength and timing of gRNA expression for cleavage and homing to occur in the germline. U6 non-coding small nuclear RNA (snRNA) polymerase III promoters are ideal for gRNA expression due to their nucleus-associated transcription and unmodified 5’ and 3’ regions (i.e., no 5’ cap or 3’ polyA tail); consequently, they have been used to drive gRNA expression in various species (Gantz et al., 2015; Hammond et al., 2016; Kondo and Ueda, 2013). Unfortunately, U6 promoters have not been functionally characterized in Ae. aegypti. There are six known U6 genes in Ae. aegypti (Matthews et al., 2018), however their promoters remain to be characterized. Therefore, to characterize these promoters for gRNA expression, we engineered six constructs each with a predicted U6 promoter (termed U6a–U6f from hereon) derived from Ae. aegypti to drive expression of gRNA0 (Figure 1—figure supplement 2C). To transiently assess promoter activity, we microinjected each construct separately into exu-Cas9 derived embryos (Li et al., 2017) (Figure 1A). Of the six injected constructs, only four (U6a–d) induced somatic loss-of-function variegated biallelic white-eye loss-of-function phenotypes in G0 embryos with moderate mutation frequencies ranging from 32.5–71.3% (Figure 1B), indicating that these four promoters can transiently express gRNA0. We then evaluated germline mutation rates by outcrossing mosaic G0 mosquitoes to recessive white mutants (wD19/wD19) harboring a 19 bp deletion at the white gRNA cut site which would lead to heritable the recessive loss-of-function phenotypes in successfully edited mosquitoes. These phenotypes were then scored in the G1 progeny with rates ranging 27.6–67.5%, indicating efficient germline editing (Figure 1A–B).

Development of a binary CRISPR approach
To measure cleavage and mutagenesis efficiencies of genome-integrated drive components, we developed a simple fluorescence-based system that would be compatible and orthogonal to the white mosaic readout. We developed this system by genetically encoding the four functional U6a–U6d-gRNA0 transgenes by injecting these constructs into Ae. aegypti embryos (designated as wild type [wt]) and establishing a transgenic line for each construct. Transgenesis was confirmed by the enhanced green fluorescent protein (eGFP) transgenesis marker (Figure 1—figure supplement 2C), and positives were outcrossed to wt strains to establish stocks. Somatic cleavage efficiencies were
estimated by crossing males from each line (U6a-U6d-gRNA) to females of Cas9 expression lines, exu-Cas9 and ubiq-Cas9 (ubiquitin L40, AAEL006511) which rely on different promoters to express Cas9 (Li et al., 2017). The frequency of somatic white mutagenesis was scored in the trans-heterozygous progeny (Figure 1C). Interestingly, the rates of mosaicism, an intermediate phenotype with both wt and knockout characteristics (i.e. black and white patchy eyes see Figure 2), varied depending on the Cas9 and the gRNA promoters. As the timing and level of both Cas9 and gRNA expression is important for inducing mosaicism (Kandul et al., 2019b; Yen et al., 2014), this could contribute to this variation, or it could also be position dependent as the integration of the transgene cassettes was not site specific. Interestingly, the combination of the ubiq-Cas9 strain and the
U6b-gRNA<sup>wt</sup> and U6c-gRNA<sup>wt</sup> strains induced up to 100% white somatic knockout frequencies, with varied rates of eye pigment mosaicism, indicating that these U6 promoters are highly active and timing appropriate when encoded in the genome to induce knock-out phenotypes (Figure 1C).

**Engineering split drives**

Given the above promising results, we next wanted to use these components to develop split drives. To engineer split drives, we separated the drive components into two elements: a gene-drive element (GDe) and the Cas9 endonuclease ((Figure 1—figure supplement 3). Because we did not know which U6 promoter would be optimal for homing in the germline, we engineered four GDe’s (U6a-GDe–U6d-GDe), each consisting of gRNA<sup>wt</sup> under the control of a different functional U6 promoter (U6a–U6d) that also contained a dominant tdTomato marker (red fluorescent protein) for tracking and two outer homology arms immediately flanking the gRNA<sup>wt</sup> target site to mediate HDR at the white locus (Figure 1—figure supplements 2D and 3A). While no previous efforts have been
undertaken to improve sgRNA function in Ae. aegypti, to attempt to further increase gRNA expression, the gRNA scaffold was modified slightly as previously described (Dang et al., 2015) to eliminate cryptic termination sequences. We established transgenic lines by injecting wt embryos with Cas9 recombinant protein pre-mixed with gRNAw (Cas9/gRNAw) in combination with a GDe construct to serve as the template for site-specific integration via Cas9-mediated HDR (Figure 2—figure supplement 1A). Transgenic mosquitoes, wGDe/w+, were readily identified as G1 larvae by their dominant tdTomato expression and black (w+) eyes, and they were then intercrossed to establish lines. Integration of the GDe’s into the white locus was genetically confirmed by the presence of homozygous (wGDe/wGDe) individuals expressing tdTomato with recessive white (w−) eyes, which was additionally confirmed by genomic sequencing of the left and right insertion boundaries all of which inserted perfectly except U6d-GDe which unexpectedly had an 276 bp insertion in the right homology arm (Figure 2—figure supplement 2).

Sex-biased inheritance of GDe

Next, we confirmed the Mendelian inheritance of each GDe by reciprocal outcrossing of 20 individual heterozygous (wGDe/w+) individuals to wt (w+/w+). The expected result was that both male and female heterozygous individuals would transmit the wGDe gene to their progeny at the Mendelian rate of 50%. Indeed, the heterozygous wGDe/w+ females did meet this expectation, conferring wGDe inheritance to their progeny at normal Mendelian rates. The wGDe/w+ males, however, displayed sex-segregated transmission of wGDe to either mostly females at 99.8 ± 0.3% (type I △ in Figure 2—figure supplement 1, Supplementary file 2) or to mostly males at 99.8 ± 0.2% (type II △ in Figure 2—figure supplement 1, Supplementary file 2). This result is not unexpected as white has been previously been described as a sex-linked gene in Ae. aegypti (Bhalla, 1968), and recent genome sequencing has confirmed this linkage (Dudchenko et al., 2017; Matthews et al., 2018) as white is located in close proximity to Nix (AAEL022912), a dominant male-determining factor (M-factor) located on chromosome I (Aryan et al., 2019; Hall et al., 2015). There is also little to no recombination in this region, especially in males (Fontaine et al., 2017; Severson et al., 2002; Toups and Hahn, 2010; Hall et al., 2014), which would further support sex-linkage at this loci. Therefore, depending on which chromosome the GDe initially integrated, the GDe and Nix were either linked, producing nearly all male progeny, which inherited both wGDe and Nix to exhibit male-biased inheritance, or the GDe was inherited separately from Nix (wGDe/w+) to exhibit female-biased inheritance (Figure 2—figure supplement 1). Nevertheless, when both sexes were considered, heterozygous wGDe/w+ parents transmitted wGDe to their progeny at the 50% normal Mendelian inheritance rate.

Split drives induce super-Mendelian inheritance

To determine whether split drives could selfishly bias transmission, which could be exploited to rapidly and efficiently drive an anti-pathogen effector into a population, we performed a number of genetic crosses to determine transmission efficiencies. First, we estimated somatic cleavage efficiencies by outcrossing each wGDe strain to the exu-Cas9 strain to generate trans-heterozygous wGDe/w+; exu-Cas9/+ individuals. We found that rates of maternal carryover-dependent cleavage, which occurs when mothers maternally deposit high levels of Cas9 into their embryos and is indicated by the presence of mosaic phenotypes, varied depending on U6 promoter (26–100%), while the paternal carryover of Cas9 was not sufficient to induce these phenotypes (Figures 2A and 3A; Supplementary file 3a, Supplementary file 3b). Next, to measure homing efficiencies, we bidirectionally outcrossed G1 trans-heterozygotes wGDe/w+; exu-Cas9/+ to wt and quantified somatic cleavage and inheritance frequencies in G2 progeny (Figure 2). From these crosses, cleavage and homing efficiencies varied, most notably trans-heterozygous wGDe/w+; exu-Cas9/+ females induced somatic mosaicism in 96.3 ± 4.0% of their progeny (Figure 3B, Supplementary file 3c). Furthermore, modest super-Mendelian inheritance was observed (70.9 ± 7.8% in G2 progeny) which is significantly greater than the expected 50% for normal Mendelian transmission, while no cleavage or homing was observed from trans-heterozygous G1 male outcrosses to wt (Figure 3C; Supplementary file 3d). To distinguish the contribution of maternal effects to differential drive transmission, we repeated these crosses with paternal Cas9 inheritance; however, there were no significant differences in transmission rates in the G1 progeny based on the parentage of the Cas9 donor (Figures 2A and 3B–C; Supplementary files 3e–3f).
Cas9-associated variability in homing efficiency

Given the modest homing efficiencies in females, and the lack of homing and cleavage in males developed above, we wanted to further optimize the system to ensure better drive performance. To do this, we varied Cas9 expression and timing to test for improved homing efficiencies. The best performing U6b-GDe/+ line was outcrossed to additional previously developed Cas9 strains (Li et al., 2017), each with a unique promoter expressing Cas9: 4nitro-Cas9 (4-nitrophenyl phosphatase, AAEL007097), trunk-Cas9 (trunk, AAEL007584), nup50-Cas9 (nucleoporin 50 kDa, AAEL005635), or ubiq-Cas9, which enabled us to test the effect of differential Cas9 expression on homing efficiency. Homing and cleavage efficiencies were evaluated in the G1 trans-heterozygotes.
w^{U6b-GDe}/w++; Cas9/+ with maternally or paternally inherited Cas9 (Figure 2). The G1 trans-heterozygotes resulting from outcrossoes of these maternal Cas9 lines to U6b-GDe had a somatic mosaic white phenotype and cleavage rates of 25.3 ± 6.3% (4nitro-Cas9), 85.8 ± 4.6% (trunk-Cas9), and 100% (nup50-Cas9 and ubiq-Cas9) (Figure 3D, Supplementary file 4a). Moreover, zygotic Cas9 activity induced the somatic mosaic white phenotypes 49.0 ± 7.1% of the time in G1 trans-heterozygotes from paternally inherited nup50-Cas9 crosses (Figure 3D, Supplementary file 4b). Interestingly, homing efficiencies varied by Cas9 strain; for example, trans-heterozygous w^{U6b-GDe}/w++; nup50-Cas9/+ females induced this somatic mosaicism in 100 ± 0% of their G2 progeny with an average 80.5 ± 5.0% inheritance rate in G2 progeny, while 51.0 ± 3.9% of G2 progeny from w^{U6b-GDe}/w++; nup50-Cas9/+ male crosses had this somatic mosaicism and 66.9 ± 5.4% of the G2 progeny inherited the drive (Figure 3E–F; Supplementary files 4c–4d). The role of maternal effects in differential drive transmission was assessed by repeating these drive experiments with paternal Cas9 lines in G2, however we did not detect significant differences in drive inheritance between maternal and paternal Cas9 lines (t-test with equal variance, p>0.05; Figure 3E–F; Supplementary files 4e–4f).

Multi-generation split drive stability

Gene drives need to have a predictable behavior and stability across many generations, so these properties of the split-drive were determined over multiple consecutive generations by bidirectional outcrossoes of w^{U6b-GDe}/w++; exu-Cas9/+ and w^{U6b-GDe}/w++; nup50-Cas9/+ females and males to wt lines, which should identify generational variations in cleavage or homing efficiencies indicating instability. In general, the cleavage and transmission rates were relatively stable over multiple generations (Figure 3—figure supplement 1). However, super-Mendelian transmission of w^{U6b-GDe} varied between individual mosquito crosses in both split drive systems. For example, the average transmission rate for w^{U6b-GDe}/w++; exu-Cas9/+ females was 68.9 ± 8.9% (range 50–88%) and for w^{U6b-GDe}/w++; nup50-Cas9/+ females was 80.8 ± 8.9% (range 59–94%); (Figure 3—figure supplement 1; Supplementary files 5a–5b). Moreover, w^{U6b-GDe}/w++; exu-Cas9/+ males did not induce somatic white cleavage nor bias w^{U6b-GDe} transmission (50.0 ± 4.2%; Figure 3—figure supplement 1A, Supplementary file 5c), while w^{U6b-GDe}/w++; nup50-Cas9/+ males did induce white cleavage in 48.5 ± 4.0% of progeny and biased transmission of the w^{U6b-GDe} allele to 67.3 ± 5.2% of progeny over multiple generations (Figure 3—figure supplement 1B; Supplementary file 5d).

Discovery of drive-resistant alleles

While tracking drive stability over successive generations, we consistently discovered drive-resistant alleles, which could limit the duration of spread of these drives in real-world settings. For example, w^{U6b-GDe}/w++; nup50-Cas9/+ females transmitted white mutant phenotypes to 0.31 ± 0.07% of progeny that did not inherit both split drive transgenes, indicating that drive-resistant mutations were indeed generated at low frequency (Supplementary file 5b). To determine whether these mutations occurred in the germline, we outcrossed these individuals to white recessive mutants, expecting to see white phenotypes if even one copy of white was disrupted in the germline. These experiments yielded 100% white-eye progeny, indicating that trans-heterozygous w^{U6b-GDe}/w++; nup50-Cas9/+ females deposited the Cas9 protein loaded with gRNAw (Cas9/gRNAw) and this complex induced white germline mutations in progeny that did not inherit the w^{U6b-GDe} transgene (Supplementary file 6). To confirm this on a molecular level, we performed genomic PCR/sequencing of the white locus from individual mutant mosquitoes and found variation in cleavage repair events (Figure 3—figure supplement 2). For example, we identified loss-of-function resistance alleles (w0) that frequently contained indels at the gRNAw target site, making them unrecognizable to subsequent cleavage. This maternal carryover effect of the Cas9/gRNAw complex was previously described in other drive systems and will likely be an issue when maternal promoters are utilized for drives (Gantz et al., 2015; Kandul et al., 2019b; Lin and Potter, 2016; Oberhofer et al., 2018).

Fitness of gene drive lines

The fitness cost of gene drives and their associated cargo directly impact the behavior and stability of gene drives in wild populations (Burt, 2003). Gene drives with high fitness costs are more likely to go to extinction in a population despite strongly biased gene drive inheritance. To evaluate the potential fitness costs associated with the gene drive components, fecundity, egg hatch rate, larval...
development time, male competitiveness and adult survival were used as overall indicators of the fitness of the w^{U6b-GDe}, nup50-Cas9 and w^{U6b-GDe}/+ lines. There were no significant differences in any of these fitness parameters between the transgenic and wt lines, with the exception of female fecundity (Supplementary file 7a). Female fecundity was significantly lower in the nup50-Cas9 and the w^{U6b-GDe}/+ lines compared to the wt lines. Cas9 expression was toxic to many organisms (Cobb et al., 2015; Jiang et al., 2014; Wendt et al., 2016), particularly when it is expressed at high levels (Cho et al., 2018), so it is not unexpected that germline expression of Cas9 in the nup50-Cas9 and w^{U6b-GDe}/+ lines may result in the reduced fecundity of these lines. This result is further supported by the fact that there was no significant difference between the w^{U6b-GDe} gRNA only and the wt lines. Reduced fecundity was also only demonstrated in females expressing Cas9, while males were unaffected. Maternal deposition of Cas9 has been shown to be high enough in Drosophila melanogaster to facilitate gRNA directed mutagenesis in offspring in the absence of Cas9 inheritance (Kandul et al., 2019b; Lin and Potter, 2016), so presumably Cas9 can be highly abundant early in embryogenesis and perhaps abundant enough to cause toxicity and reduced fecundity.

Multi-release of split drives results in high-frequency spread

Our next goal was to evaluate weekly releases of males homozygous for the split drive to determine whether this system could effectively drive an anti-pathogen gene (linked to the gRNA allele) into a population at a high frequency (>80%) for an extended duration sufficient for disease control. To do this, we used our molecular work to inform the parameters (Supplementary file 7b) of simulated split drive releases of the best-performing system described above (w^{U6b-GDe}/w+; nup50-Cas9/+). Modeling results suggested that 10 consecutive weekly releases of 10,000 homozygous split drive males into a population with an equilibrium size of 10,000 adults would be sufficient to drive the split drive to a high frequency in the population (~97% having at least one copy of the gRNA/anti-pathogen allele) (Figure 4A). Mosquitoes with the gRNA/anti-pathogen alleles would then be slowly eliminated, falling to a frequency of ~87% within three years of the final release. The inheritance bias induced when the Cas9 and gRNA co-occur would give the split drive system an advantage over a comparable inundative release of mosquitoes with the anti-pathogen allele (Figure 4B). A hypothetical construct with linked Cas9 and gRNA components and identical homing and fitness cost parameters demonstrated substantial spread after a single release of 10,000 adult males homozygous for the construct but was outnumbered by in-frame resistant alleles four years following the release (Figure 4C). The number of in-frame resistant alleles generated could be reduced by carrying out linked system releases of a similar magnitude to those for the split drive system, or by using a linked system with a higher accurate homing rate, perhaps achievable by restricting Cas9 expression to the germline (Hammond et al., 2018; Kandul et al., 2019a).

Split drives are persistent and confinable

A key strength of a split drive system is that it is expected to be reversible and largely confinable to a partially isolated population, making it of particular interest for field trials. As a comparison, the hypothetical linked homing drive discussed above, assuming a standard migrant exchange rate of 1% per mosquito per year, spreads to an over 67% allele frequency in the neighboring population following a single release (Figure 4C, Figure 4—figure supplement 1C). In contrast, the split drive cargo (gRNA/anti-pathogen allele) reaches a peak frequency of ~30% in the neighboring population four years after 10 releases (Figure 4—figure supplement 1A) before being gradually eliminated by virtue of the fitness cost. In fact, this fitness cost causes the Cas9 allele to be eliminated in both populations, falling to a frequency of ~10% in the release population within four years post release, and barely reaches a frequency of 2.4% in the neighboring population, followed by a progressive decline of the gRNA/anti-pathogen allele in both populations. The reversal of the split drive system can be accelerated by the release of wild-type males. After just 10 releases, the frequency of the split drive system in the population is expected to be sufficient for interrupting local disease transmission over a three year period. Figure 4D depicts the duration for which the anti-pathogen allele is predicted to remain in over 80% of female mosquitoes when the number of releases and fitness cost of the gRNA/anti-pathogen allele are varied. This duration exceeds three years for the release scheme described above, and for fitness costs less than 10% in gRNA/disease-refractory allele homozygotes.
Aedes aegypti is a globally distributed vector that spreads deadly pathogens to millions of people annually. Current control methods are inadequate for this vector and therefore new innovative technologies need to be developed and implemented. With the aim of providing new tools for Aedes aegypti control, here we engineer and test the first gene drives developed in this species. Importantly, to make these drives safe and confinable, we engineered these systems as split drives. These drives functioned at very high efficiency and may provide a tool to control this vector. To develop these drives, initially we functionally characterized several drive components that performed with high efficiency in both somatic cells and the germline. Additionally, we discovered a drive target sequence, within the white gene, that is highly conserved across many geographically distinct populations, providing a useful phenotypic readout of drive functionality, and demonstrating that highly conserved drive target sites can be found through extensive genomic sequencing of wild populations. Multiple bidirectional genetic crosses of transgenic lines with optimized drive components revealed that homing and cleavage efficiencies are largely dependent on the timing and expression of drive components and maternal deposition can result in embryonic activity and the generation of drive resistant alleles. Despite the creation of resistant alleles, however, mathematical modeling predicts that these split drives can spread locally and are also confinable and reversible, making them suitable for field trials and capable of local disease control once effectors are linked.
Notably, components characterized in this study including the polymerase III U6 promoters crossed with robustly Cas9 expression strains, can also be used to accelerate basic functional gene analysis in Ae aegypti. For example, tissue specific Cas9 strains could be crossed to U6-driven gRNA strains disrupting essential genes, to enable biallelic mutations in specific tissues (e.g. neurons) which otherwise would not be possible due to lethality if disrupted in all cells. Additionally, if linked, these components could generate a potent drive that could self-disseminate for wider regional mosquito control. Our models predict that if these components were directly linked, assuming homing and cleavage rates similar to when unlinked, the drive would provide a window of >80% disease resistance among the female Ae. aegypti population for several years following a release (Figure 4F) and spread from one population to another (Figure 4C). These components could also be used in the future to develop self-limiting population suppression technologies, such as a precision-guided sterile insect technique (Kandul et al., 2019b), or to target conserved sex-determination genes such as doublesex (dsx) to generate a potent homing-based population suppression drive similar to the drive recently developed for Anopheles gambiae (Kyrou et al., 2018). Alternatively, these components could be used to generate a novel population suppression design by encoding a functional copy of Nix (Aryan et al., 2019; Hall et al., 2015), as the cargo, thereby converting females into fertile males while the drive spreads through and suppresses the population. Finally, these components support the development of other drives, including trans-acting toxin- and cis-acting antidote- (TA) based drives (Kandul et al., 2019b; Oberhofer et al., 2019), evolutionarily stable homing-based replacement drives that target haplosufficient essential genes and encode a recoded (i.e., cleavage resistant) rescue of the target gene (Champer et al., 2016; Kandul et al., 2019b) or even TA under-dominance-based drives (Champer et al., 2016), all of which could be instrumental for spreading anti-pathogen effectors (e.g., Buchman et al., 2019) into wild disease-transmitting populations.

While this is a major step towards developing field-worthy gene-drive systems in Ae. aegypti, there are still limited effectors available to link with population modifying drives that will limit the immediate use of these technologies. Most antiviral effectors developed in Ae. aegypti to date rely upon small RNA pathway-directed targeting of viral genomes (Buchman et al., 2019; Franz et al., 2014; Franz et al., 2006; Mathur et al., 2010; Yen et al., 2018); however, these antiviral transgenes are not easily multiplexed and the diversity of arboviruses transmitted by this vector as well as the high mutation rate of these viruses (Steinhauer et al., 1992) makes their practicality in the field tenuous. New, innovative effectors are in development, for example, the recent broad neutralizing antibody-based anti-dengue effector (Buchman et al., 2019), but long-term studies of viral resistance to all current antiviral effectors are limited, so their long-term effectiveness is unknown (Marshall et al., 2019). Furthermore, effector-associated fitness costs could impact the success of these technologies. While drive technologies should overcome some of these fitness costs, as we balance the optimization of drive efficacy with the minimization of drive risks, we will likely still need to develop effectors with reduced fitness costs. Current effectors have achieved efficacy against only a limited number of viral families and strains, usually those which are most highly lab adapted, and may have concerning fitness costs (Marshall et al. 2019). Therefore, additional resources are needed to develop antiviral effectors that have reduced fitness costs, achieve broad antiviral activity against the diversity of viruses vectored by Ae. aegypti, and limit viral resistance despite high viral mutation rates.

It should be pointed out that gene-drive technologies are imperfect. Drive efficiencies are impacted by target-site availability, timing, the expression of drive components, host-specific factors such as the timing of meiosis and recombination, as well as the generation of resistant alleles that form as a result of non-homologous end-joining (NHEJ) repair of CRISPR-mediated DNA cleavage as opposed to homology directed repair (HDR). Notwithstanding, significant efforts are underway to optimize next generation drives that incorporate molecular design architectures predicted to mitigate the generation and selection of resistant alleles and improve conversion efficiencies. These efforts include rational target-site design, regulation of the expression and timing of the nuclease, multiplexing drive targets, improved regulatory elements, and targeting ultra-conserved regions in essential genes that are recorded in the drive, enabling the selective elimination of non-functional NHEJ-repaired alleles (Hammond and Galizi, 2017; Raban and Akbari, 2017; Champer et al., 2016; Marshall et al., 2017; Kandul et al., 2019a; Kandul et al., 2019b; Oberhofer et al., 2019). While these future drive designs are expected to be more efficient than current systems, it should be noted that even imperfect drives with modest homing efficiencies are still predicted to be quite
invasive (Noble et al., 2017), and will likely be useful for field implementation which could confer long-lasting entomological and epidemiological impacts.

Given the remarkable progress in the gene drive field and potential of gene drives to spread globally, understandably the discussion of the ethics, risks, governance, and the guidance of gene drives in the field have come to the forefront (Adelman et al., 2017; Akbari et al., 2015a; James et al., 2018; Kaebnick et al., 2016). As gene-drive technologies advance and field trials become a necessary step toward understanding the efficacy and behavior of drives in wild populations, it is important that facilities planning and management, infrastructure upgrades, talent development for deployment and monitoring, and public engagement are advanced to support the sustainability of gene drive technologies. Safe, non-invasive, self-limiting split drive technologies, such as the systems developed here, are a responsible choice for studying gene drives in the wild, as they safeguard against spreading to non-target populations and will allow the assessment of potential risks and unintended consequences. This may help establish the necessary infrastructure, while simultaneously controlling disease burdens, in preparation for a potential subsequent release of an efficient linked-drive system that can self-disseminate catalytically into broader landscapes. Taken together, our results provide compelling evidence for the feasibility of future effector-linked split drive technologies that can contribute to the safe, sustained control and potentially the elimination of pathogens transmitted by this species.

Materials and methods

Insect rearing

Mosquitoes used in all experiments were derived from the Ae. aegypti Liverpool strain (designated as wild-type [wt], Supplementary file 8a). Of note, the Ae. aegypti reference genome sequences were generated using this strain (Matthews et al., 2018; Nene et al., 2007). Mosquitoes were raised in incubators at 28.0°C with 70–80% humidity and a 12 hr light/dark cycle. Larvae were fed ground fish food (TetraMin Tropical Flakes, Tetra Werke, Melle, Germany) and adults were provided 0.3 M aqueous sucrose ad libitum. Adult females were blood fed three to five days after eclosion using anesthetized mice. Mosquitoes were examined, scored, and imaged using the Leica M165FC fluorescent stereo microscope equipped with the Leica DMC2900 camera. All animals were handled in accordance with the Guide for the Care and Use of Laboratory Animals as recommended by the National Institutes of Health and supervised by the local Institutional Animal Care and Use Committee (S17187).

Profile of natural variation at white target site

To assess the natural variation within the white target site, we used data from individual whole genome sequencing of 143 Ae. aegypti specimens sampled in California (N = 127), Florida (N = 4), Puerto Rico (N = 6), Mexico (N = 3), and South Africa (N = 3) (Figure 1—figure supplement 1, Figure 1—source data 1) and sequenced to an approximate depth of 10x on an Illumina HiSeq 4000 producing 17.1 giga base pairs (Gbp). Then 17.1 Gbp of sequence reads were mapped with BWA-MEM v0.7.15 (Li, 2013) to the latest version of the reference genome of Ae. aegypti (AaegL5 [Matthews et al., 2018]). Polymorphisms were called with Freebayes v1.0.1 (Garrison and Marth, 2012), applying all the default parameters except for ‘theta = 0.01’ and ‘max-complex-gap=3’. We employed the most conservative approach by applying no filtering to the called polymorphisms to maintain the broadest possible set of potential variation. Additionally, we checked the polymorphism data for Ae. aegypti available on https://www.vectorbase.org (accessed 1/2/19) and found no published SNP’s in the region of the white target site. We therefore consider the target site likely conserved in natural populations.

Construct design and assembly

The Gibson enzymatic assembly method was used to build all constructs. To generate the gRNA constructs, the piggyBac plasmid (Akbari et al., 2015b) was digested with FseI and Ascl, and the linearized fragment was used as a backbone for construct assembly. Constructs for the U6 promoter screen contained the following fragments: the 5’-end flanking sequence of the U6 snRNA, which was selected as the promoter region; a 20-base sequence of the gRNA" (Figure 1—figure supplement...
2A); a 76-base fragment with a gRNA scaffold; and a 3xP3-eGFP-SV40 fragment. The first three fragments were generated using commercial gene synthesis (gBLOCK by IDT and GenScript). The 3xP3-eGFP fragment was amplified from a previously described plasmid harboring the 3xP3 promoter and coding sequence of eGFP (Addgene #104968 and 100705) using primers AE01, AE02, AE03, and AE04 (Supplementary file 8a, Supplementary file 8b). A total of six plasmids were generated and are referred to as follows: U6a-T, U6b-T, U6c-T, U6d-T, U6e-T and U6f-T (Figure 1—figure supplement 2C, Supplementary file 8a).

We engineered four gene-drive element (GDe) constructs carrying different U6 promoters for site-specific integration at the white locus: U6a-GDe, U6b-GDe, U6c-GDe, and U6d-GDe. Each plasmid contained the following fragments (Figure 1—figure supplement 2D): (1) left and right homology arms of ~1 kb in length, which are complementary to the Ae. aegypti white locus immediately adjacent to the 5' and 3' ends of the gRNA cut site, respectively, were gene synthesized by GenScript; (2) a U6 promoter with a 20-base gRNA sequence and a 76-base gRNA scaffold, which was PCR amplified from U6a-T, U6b-T, U6c-T, and U6d-T constructs with the following primers: AE05 and AE06, AE07 and AE08, AE09 and AE10, AE11 and AE12, respectively; (3) the 3'UTR region of the corresponding U6 snRNA was gene synthesized by GenScript; (4) a 3xP3-ttdTomato-SV40 fragment, which was amplified from the previously described plasmid (Addgene #104968) using the following primers: AE13 and AE14, AE15 and AE14, AE16 and AE14, AE17 and AE14; (5) an Opie2-dsRed-SV40 fragment, which was amplified from the previously described plasmid (Addgene #100705) using primers AE18 and AE19 (Supplementary file 8a, Supplementary file 8b). All plasmids were grown in JM109 chemically competent cells (Zymo Research #T3005) and isolated using Zippy Plasmid Miniprep (Zymo Research #D4037) and Maxiprep (Zymo Research #D4028) kits (Supplementary file 8a). Each construct sequence was verified using Source Bioscience Sanger sequencing services. A list of primer sequences used in the above construct assembly can be found in Supplementary file 8b. We have also made all plasmids and sequence maps available for download and/or order at Addgene (www.addgene.com) with identification numbers listed in Figure 1—figure supplement 2.

Embryonic collection and CRISPR microinjections were performed following previously established procedures (Aryan et al., 2014; Kistler et al., 2015). The concentration of plasmids used for the U6 promoter screen was 300 ng/µL. Injected G0 and G1 progeny were visualized at the larval, pupal, and adult life stages under a dissecting microscope (Olympus SZ51 and Leica M165FC). The heritable mutation rates were calculated as the number of G1 progeny with the loss-of-function mutation out of the number of all G1 progeny crossed with the white (w–) strain mosquitoes. To integrate each GDe construct at the white locus, a mixture containing 100 ng/µL of synthetic gRNA*, 100 ng/µL of each U6-GDe plasmid (U6a-GDe, U6b-GDe, U6c-GDe, and U6d-GDe), and 100 ng/µL of Cas9 protein was injected into 500 embryos for each plasmid. Synthetic gRNAs (Synthego) and recombinant Streptococcus pyogenes Cas9 protein (PNA Bio Inc, Supplementary file 8a) were obtained commercially and diluted to 1,000 ng/µL in nuclease-free water and stored in aliquots at –80°C. A total of 233, 271, 191, 215 G0 adults were recovered for U6a-, U6b-, U6c-, and U6d-GDe injections, respectively. Successful integration into the white locus was determined by visually identifying the eye-specific 3xP3-ttdTomato fluorescence in G1 heterozygous mosquito larvae with black eyes (w16-GDe/w+) and in G2 homozygous mosquito larvae with white eyes (w16-GDe/w16-GDe). In addition, site-specific integration of U6-GDe constructs was confirmed by amplifying and Sanger sequencing both the left and right integration points (Figure 2—figure supplement 2) from a genomic DNA prep of each w16-GDe line with the following primers: AE20, AE21, AE22, and AE23 (Supplementary file 8b).

Assessment of split gene-drive efficacy

Both gene-drive (GD) and Cas9 elements are required for a functional split drive. To generate G1 trans-heterozygous w16-GDe/w+; Cas9/+ male and female mosquitoes with an active split drive, we reciprocally crossed w16-GDe/w+ and Cas9/Cas9 strains. While selecting trans-heterozygous mosquitoes, we scored the loss-of-function mutation of white in all G1 progeny. Then, G1 trans-heterozygous mosquitoes were mated to wt for 4 days, and the white mutation and w16-GDe transmission frequencies were calculated in G2 progeny. Females were blood fed on anesthetized mice on the
fifth day. Three days later, more than twenty females were allowed to lay eggs individually into a 50 mL vial filled with water and lined with wet filter paper. The larval progeny from each female were counted and scored for w\textsuperscript{U6-GDe} and Cas9 by 3xP3-tdTomato and Opie2-dsRed expression, respectively. Females that failed to take blood and produce progeny were excluded from the analysis. According to Mendelian inheritance, the expected G\textsubscript{2} transmission rate of w\textsuperscript{U6-GDe} is 50% under this crossing scheme; the higher rate indicates super-Mendelian inheritance (Figure 2A). White mutagenesis and w\textsuperscript{U6-GDe} transmission rates by trans-heterozygous w\textsuperscript{U6-GDe}/w+; Cas9/+ mosquitoes each carrying GDe with four different U6 promoters were compared to those of the corresponding w\textsuperscript{U6-GDe}/w+ line without Cas9 in the genetic background. The homing and cleavage efficiencies of the two split-drive systems, w\textsuperscript{U6b-GDe}/w+; exu-Cas9/+ and w\textsuperscript{U6b-GDe}/w+; nup50-Cas9/+; nup50-Cas9/, were observed for the following four generations by scoring the markers in the progeny from reciprocal crosses of trans-heterozygous and wt mosquitoes.

**Molecular characterization of w\textsuperscript{R} alleles**

To test whether w\textsuperscript{R}-resistant alleles were present in germ cells, mosquitoes harboring w\textsuperscript{R} alleles were genetically crossed into the w\textsuperscript{19A} (recessive mutant background, and their progeny was scored for white loss-of-function mutations. Genomic DNA was extracted from an individual mosquito of each progeny group using the DNeasy Blood and Tissue Kit (QIAGEN) following the manufacturer’s protocol, and a white region carrying the gRNA\textsuperscript{w} target site was PCR amplified with primers AE24 and AE25. Because the tested mosquitoes were heterozygous w\textsuperscript{R}/w\textsuperscript{19A} for white alleles, a PCR amplicon from each mosquito was first cloned into an open plasmid using Gibson enzymatic assembly, and seven clones were PCR amplified and Sanger sequenced to identify novel w\textsuperscript{R} alleles. De novo-mutated w\textsuperscript{R} alleles were identified by comparing them with both w+ and w\textsuperscript{19A} alleles using Sequencher and 5.0 SnapGene 4.2. The same method was used to confirm the presence of w+ non-cleaved alleles in a few mosquitoes with black eyes, which were later inferred to be w+/w\textsuperscript{19A} and w+/w\textsuperscript{U6b-GDe}.

**Fitness of transgenic strains**

To determine if the presence of a transgene(s) conferred a fitness cost, multiple fitness parameters were evaluated between w\textsuperscript{U6b-GDe}/nup50-Cas9, w\textsuperscript{U6b-GDe}, nup50-Cas9 and wt mosquitoes. Insectary conditions were as described in the insect rearing section. Fecundity and fertility were assessed from reciprocal male and female crosses to the wt strain. For the female fecundity and fertility assessments, 20 females were mated to 20 wt males and for the male fecundity and fertility assessments, single males were mated to 20 wt females. After four days, female mosquitoes were blood fed until fully engorged and individually transferred into plastic vials with tap water and lined with an egg paper. Mosquitoes were allowed to oviposit for three days and after fecundity was assessed as the number of eggs laid per female. Eggs were stored in the insectary for four days to allow full embryonic development then hatched in a vacuum chamber. Larvae were counted on the third day post hatch. Fertility was calculated as the percentage of eggs hatched per female. An analysis of variance (ANOVA) and Tukey post-hoc test were performed to compare differences in fecundity and fertility between all groups. To assess larval to pupal development time, transgenic and wt were distributed into pans, at a density of 10 larvae per pan, containing 2.5 L of ddH2O and 0.6 mL of 1:1 Tetramin fish food:water. Larvae were counted twice daily until pupation and then date of pupation and emergence were recorded. Larval development time was calculated for each sex as there are sex-specific differences in larval development time in this species. An ANOVA and Tukey post-hoc test were performed to compare differences in larval development between all groups. Male mating competitiveness was assessed by 1:1 transgenic male:wt male competition studies in 30 small cages. Transgenic and wt males 2 days post emergence and raised under the same standardized larval conditions were placed into a small cage containing a female wt mosquito. Females were allowed to acclimate to the cage for 72 hours prior to male release. Mating, blood feeding and oviposition, as well as egg collection and hatching conditions, were as described for the fertility and fecundity studies. Larvae at three days post hatch were screened for transgene markers under a Leica M165FC fluorescent microscope. Females with transgenic offspring were scored as mated to transgenic males and females with no transgenic offspring were scored as mated to wt males. All females produced eggs. A chi-squared test was used to determine whether there were differences in the number of observed
and expected matings to a transgenic male. To assess adult mosquito survival, one cage of each transgenic or wt strain containing equal numbers of male and females were monitored daily for survival until all mosquitoes had died. Median time to death and differences between transgenic and wt survival curves were calculated by a Mantel-Cox log rank test. Due to sex specific differences in survival, analyses also were separated by sex. All statistical analyses were performed using GraphPad Prism software (GraphPad Software, La Jolla, California, USA). P values > 0.05 were considered not significant.

**Mathematical modeling**

To model the expected performance of a split drive functioning as a confinable and reversible gene-drive system and as a test system prior to the release of a linked homing drive for Ae. aegypti, we simulated release schemes for split drive, linked homing drive, and inundative releases of males carrying a refractory allele using the MGDrivE simulation framework (Sánchez et al., 2018) (https://marshallab.github.io/MGDrivE/). This framework models the egg, larval, pupal, and adult mosquito life stages (both male and female adults are modeled) implementing a daily time step, overlapping generations, and a mating structure in which adult males mate throughout their lifetime while adult females mate once upon emergence, retaining the genetic material of the adult male with whom they mate for the duration of their adult lifespan. Density-independent mortality rates for the juvenile life stages are assumed to be identical and are chosen for consistency with the population growth rate in the absence of density-dependent mortality. Additional density-dependent mortality occurs at the larval stage, the form of which is taken from previous studies (Deredec et al., 2011). The inheritance patterns for the split drive, linked homing drive, and refractory gene systems are modeled within the inheritance module of the MGDrivE framework (Sánchez et al., 2018) along with their impacts on female fecundity and adult mortality rate. We parameterized our split drive model according to the best-performing system in this study (wU6b-GDe/w+/ nup50-Cas9/+): i) a cleavage frequency of 100.0% in females and 51.0% in males, ii) HDR frequency 80.5% in females and 66.9% in males, and iii) each Cas9 allele was associated with a 7.8% reduction in female fecundity (Figure 4—figure supplement 2). Ballpark parameter estimates were used in cases where direct measurements were not available: i) a sixth of non-HDR events were assumed to lead to in-frame/cost-free resistant alleles (i.e. half of the mutations that preserve the reading frame), with the remaining leading to out-of-frame/costly resistant alleles, and ii) by default, we assumed a 10% reduction in mean lifespan associated with gRNA/disease-refractory allele homozygotes, and no fitness cost in heterozygotes, although a range of values were explored for this parameter. We implemented the stochastic version of the MGDrivE framework to capture the randomness associated with rare events such as resistant allele generation. We simulated two partially isolated populations each consisting of 10,000 adults at equilibrium, exchanging migrants at a rate of 1% per mosquito per generation, with weekly releases of 10,000 adult males over a defined period. Ae. aegypti life history and intervention parameter values are listed in Supplementary file 7b.

**Statistical analysis**

Unless described previously, statistical analysis was performed in JMP 8.0.2 by SAS Institute Inc. Twenty replicates were used to generate statistical means for comparisons. P values were calculated for a two-sample Student’s t-test with equal variance. Point plots were built in Prism 7 by GraphPad.

**Acknowledgements**

This work was supported by funding from a Defense Advanced Research Project Agency (DARPA) Safe Genes Program Grant (HR0011-17-2- 0047) awarded to OSA and subcontracted to GCL and JMM. We acknowledge funding support from the UC Davis Bridge Funding Program, UC Davis School of Veterinary Medicine Vector-Borne Disease Pilot Grant Program, and the Pacific Southwest Regional Center of Excellence for Vector-Borne Diseases funded by the U.S. Centers for Disease Control and Prevention (Cooperative Agreement 1U01CK000516). We thank Judy Ishikawa for help rearing and maintaining all mosquito strains produced in this study. We also thank Allison Weakley, Kendra Person, and Hans Gripkey for field mosquito collection data processing including DNA extraction, DNA quantification, and library preparations. We thank personnel from Consolidated Mosquito Abatement District (Ms. Jodi Holeman and Ms. Katherine Ramirez), Coachella Valley,
Delta, Greater LA County (Dr. Susan Kluh), and San Mateo County Vector Control Districts and Fresno, Kern, Madera County, Northwest (Dr. Major Dhillon, District Manager), Orange County (Mr. Michael Hearst, District Manager), and San Gabriel Valley Mosquito and Vector Control Districts, Kings Mosquito Abatement District, Community Health Division of the Department of Environmental Health (Ms. Rebecca Lafreniere, Chief and Ms. Elizabeth Pozzebon, Director), Imperial County Public Health Department, San Bernardino County Mosquito and Vector Control Program, San Diego County Dept. of Environmental Health, Vector Control, Dr. Chelsea Smartt (Florida Medical Entomology Laboratory), and Dr. Christopher Barker (UC Davis) for providing specimens used in this study. We also thank Dr. Anthony J Cornel (UC Davis) and Dr. Leo Braack (University of Pretoria, South Africa) for the collection of South African samples and Dr. Danny Governer and SANParks for permitting collection from Shingwedzi in the Kruger National Park. We also thank Dr. Lutz Froenicke and his team at the UC Davis DNA Technologies Core for genome sequencing.

(c) Eye phenotypes in G3, G4, G5 progeny from \( \delta w^{U6b-GDe}/w+; \) exu-Cas9/+ X \( \delta w+/w+ \) (wt). (d) Eye phenotypes in G3, G4, G5 progeny from \( \delta w^{U6b-GDe}/w+; \) nup50-Cas9/+ X \( \delta w+/w+ \) (wt).

- Supplementary file 6. Eye phenotypes in progeny from the w- mosquitoes sampled at G2, G3, G4, and G5 (\( w^{U6b-GDe}/w+; \) nup50-Cas9/+ X \( w+/w+ \)) and \( w^{19}/w^{19} \) reference mosquitoes.

- Supplementary file 7. Transgene and model fitness parameters. (a) Effect of transgenes on fitness. Comparisons of several fitness parameters between wildtype (WT) and transgenic lines expressing gRNAs targeting the w gene (\( w^{U6b-GDe} \) only, Cas9 only (nup50-Cas9) or both gRNAs targeting the w gene and Cas9 (\( w^{U6b-GDe}/nup50-Cas9 \)). The transgenic and WT mosquitoes only differed significantly in one fitness parameter, female fecundity, which suggests that the transgenic strains do not have a major impact on mosquito fitness. The survivorship of transgenic versus WT mosquitoes is also shown. (b) Parameter values used in Ae. aegypti population model. (Carvalho et al., 2015; Christophers, 1960; Fockes et al., 1993; Horsfall, 1972; Otero et al., 2006; Simoy et al., 2015; Taylor et al., 2001).
