ABSTRACT

This review aims at summarising and discussing the current status concerning the clinical presentation, pathogenesis, diagnosis, and treatment of spinal cord affection in mitochondrial disorders (MIDs). A literature search using the database Pubmed was carried out by application of appropriate search terms and their combinations. Involvement of the spinal cord in MIDs is more frequent than anticipated. It occurs in specific and non-specific MIDs. Among the specific MIDs it has been most frequently described in LBSL, LS, MERRF, KSS, IOSCA, MIRAS, and PCH and only rarely in MELAS, CPEO, and LHON. Clinically, spinal cord involvement manifests as monoparesis, paraparesis, quadraparesis, sensory disturbances, hypotonia, spasticity, urinary or defecation dysfunction, spinal column deformities, or as transverse syndrome. Diagnosing spinal cord involvement in MIDs requires a thoroughly taken history, clinical exam, and imaging studies. Additionally, transcranial magnetic stimulation, somato-sensory-evoked potentials, and cerebro-spinal fluid can be supportive. Treatment is generally not at variance compared to the underlying MID but occasionally surgical stabilisation of the spinal column may be necessary. It is concluded that spinal cord involvement in MIDs is more frequent than anticipated but may be missed if cerebral manifestations prevail. Spinal cord involvement in MIDs may strongly determine the mobility of these patients.

KEYWORDS: Mitochondrial, mtDNA, myelon, myelopathy, respiratory chain, spinal cord, transverse syndrome

INTRODUCTION

Mitochondrial disorders (MIDs) are usually multisystem disorders, either at onset or evolve from a mono-organ disease to a mitochondrial multi-organ disorder syndrome (MIMODS) as the disease progresses.[1] The organs most frequently affected in MIMODS are the skeletal muscle, the central nervous system (CNS), the peripheral nerves, the eyes, ears, endocrine organs, the heart, lungs, intestines, kidneys, blood, bone, and the skin.[2] Concerning the CNS involvement, affection of the brain dominates research interests. However, CNS involvement is not restricted to the brain but can be found also in the spinal cord. Spinal cord involvement in MIDs most frequently occurs together with affection of the brain but may occur without cerebral abnormalities as well. Considering and recognizing spinal cord involvement in MIDs is essential since it may influence the management of these patients.

This review aims at summarizing and discussing the current status concerning the clinical presentation, pathogenesis, diagnosis, and treatment of spinal cord affection in MIDs.

MATERIALS AND METHODS

Data for this systematic review were identified by searches of MEDLINE for references of relevant articles. Search terms used were all acronyms known for specific MIDs (n = 50) and the terms “MID,” “mtDNA,” “encephalomyopathy,” and “mitochondrion” in individual combination with the terms “spinal cord,” “myelon,” “spine,” “myelopathy,” “scoliosis,” “transverse syndrome,” or “spinal column,” results of the
These capillaries were lined by swollen endothelial cells and separated by damaged neutrophils. There was some infiltration of macrophages and reactive astrocytosis, resembling pathological features as described in LS. Postmortem, neuropathological studies in a 22-year-old male with KSS revealed mild spongiosis and astrocytosis of the long descending tracts. Dorsal columns of the cervical cord showed loss of myelin and axonal loss. In another KSS case, autopsy disclosed severe demyelination of the white matter in the cervical cord and severe neuronal loss in Clarke’s horn cells of the cervical spinal segments. In two patients with KSS, autopsy showed severe neuronal loss in Clarke’s horn cells and severe demyelination of the spinal cord.
initial few millimeters of the spinal anterior roots distal to the glial-Schwann cell junction.\textsuperscript{[16]} Mild demyelination was observed in the dorsal spinal roots.\textsuperscript{[16]}

**Leigh syndrome**

LS is an early-onset progressive MID, characterized by elevated lactate and pyruvate and bilateral symmetric hyperintense lesions in the basal ganglia, thalamus, brainstem, cerebral white matter, or spinal cord on T2-weighted MRI.\textsuperscript{[17]} LS is the most frequent disorder of energy production in children.\textsuperscript{[18]} Typical abnormalities on spinal MRI include bilaterally symmetric, high-signal alterations in the spinal cord.\textsuperscript{[19,20]} Rarely, the typical symmetric cerebral symmetric lesions in LS are confined to the spinal cord and are absent in the brain.\textsuperscript{[3]} In a 6-month-old Hispanic male with early-onset LS, involvement of the cervical spinal cord and brainstem were responsible for the initial clinical presentation.\textsuperscript{[21]} At age 2 months, the cerebral MRI was normal. Repeat MRI of the cerebrum and the cervical spine at age 3.5 months showed abnormal signal intensity and restricted diffusion involving the brainstem (pons and medulla) and upper cervical spinal cord.\textsuperscript{[21]} In a 3-year-old female with the clinical diagnosis of LS who died suddenly and unexplained, autopsy showed symmetrical, necrotizing lesions scattered within the spinal cord’s gray matter.\textsuperscript{[22]} In a series of 5 children with LS, isolated affection of the spinal cord without brain abnormalities was described in a 17-month-old female at autopsy.\textsuperscript{[3]} Altogether, 4 of the 5 patients had spinal cord involvement [Figure 1].\textsuperscript{[3]} T2-hyperintensities extending from the medulla to the cervical spinal cord were also found in a 15-month-old female with LS.\textsuperscript{[23]} A 10-year-old patient with LS and intractable Lennox–Gastaut syndrome had mild demyelination, proliferation of capillaries, and gliosis of the entire spinal cord at autopsy.\textsuperscript{[24]} Postmortem histopathological investigations in an 8-year-old male with LS revealed symmetrical microcyst formation, vascular proliferation, proliferation of astrocytes, fibrillary gliosis, and partial destruction of the myelin sheaths with relative preservation of the neuronal cell bodies in the spinal cord.\textsuperscript{[25]}

**Leukoencephalopathy, brain stem and spinal cord involvement and lactic acidosis**

Leukoencephalopathy, brain stem and spinal cord involvement and lactic acidosis (LBSL) is a rare specific MID due to mutations in the DARS2 gene encoding mitochondrial aspartyl-tRNA synthetase.\textsuperscript{[26]} Clinically, patients present with childhood or juvenile-onset intellectual decline (learning dysfunction), slowly progressive ataxia, pyramidal signs (spasticity), and dorsal column dysfunction.\textsuperscript{[27]} MRI of the spine shows inhomogeneous T2-hyperintensities in the spinal tract.\textsuperscript{[28]} Proton-magnetic resonance spectroscopy (MRS) of the frontal and cerebellar white matter shows elevated lactate, reduced N-acetyl-aspartate, increased myoinositol, and mildly elevated choline.\textsuperscript{[29]} Neuropathological investigations typically show vacuolar changes in the white matter of the cerebrum and spinal cord.\textsuperscript{[30]} MRI does not necessarily reflect clinical presentation and the histological findings why it should not be used to assess disease severity or prognosis.\textsuperscript{[31]} In a 1-year-old male with psychomotor delay, quadraplegia, deafness, and anemia due to a mutation in the DARS2 gene, spinal MRI revealed calcifications of the spinal cord.\textsuperscript{[22]} A 35-year-old female with mild balance impairment since her early teenage years, developed slowly progressive unsteady gait with lower limb weakness and stiffness since age 20 years.\textsuperscript{[33]} Neurological examination revealed spastic paraparesis with marked impairment of vibration and position perceptions and waddling gait.\textsuperscript{[33]} Spinal MRI in this patient showed T2-hyperintensities in the posterior columns, anterior and posterior spinocerebellar tracts, and lateral corticospinal tracts [Figure 2], indicating continuous involvement of the corresponding pathways in the brainstem.\textsuperscript{[33]}

**Pontocerebellar hypoplasia**

Histological examination of the spinal cord of an infant with pontocerebellar hypoplasia (PCH) due to a mutation in the SLC25A46 gene who had died 1 day after birth revealed loss of motor neurons in the anterior horns.\textsuperscript{[34]} The remaining motor neurons had a “ballooning” appearance.\textsuperscript{[34]} The sister of this patient also had PCH, died at age 18 days, and had mild reduction of motor neurons in the anterior horns and “ballooning” in some of the remaining motor neurons.\textsuperscript{[34]} Knock-down of the SLC25A46 gene in zebrafish also caused spinal motor neuron loss.\textsuperscript{[35]}

\textbf{Figure 1:} T2-weighted sagittal magnetic resonance imaging (repetition time 3000 ms/echo time 120 ms) depicting increased signal change in cervical and thoracic cord in a patient with Leigh syndrome\textsuperscript{[3]}

\textbf{Figure 2:} Pontocerebellar hypoplasia (PCH) due to a mutation in the SLC25A46 gene who died 1 day after birth. Histological examination of the spinal cord showed loss of motor neurons in the anterior horns.
In a patient with LHON spinal cord lesions due to age 53 years, she experienced particularly, in Journal of Neurosciences in Rural Practice ¦ Volume 9 ¦ Issue 2 ¦ April-June 2018

7 of them. Among these, the variant m.14484T>C in the ND6 gene, spinal MRI showed diffuse demyelinating lesions extending from T6 to T11.[43] In a patient with LHON spinal cord lesions due to concomitant neuromyelitis optica (NMO) have been reported.[42] In patients with LHON and features of multiple sclerosis (MS), respectively NMO, it is conceivable that “demyelinating” lesions are in fact stroke-like lesions attributable to the MID with some clinical and instrumental features suggesting MS, respectively, NMO. In a patient with LHON and MS, new “inflammatory lesions” were seen on MRI of the brain and spinal cord 14 months after discontinuation of natalizumab.[43] Particularly, in seronegative “NMO” patients, spinal cord involvement in LHON should be suspected.

**Infantile-onset spinocerebellar ataxia**

Infantile-onset spinocerebellar ataxia (IOSCA) is a severe autosomal recessively inherited neurodegenerative disorder characterized by progressive atrophy of the cerebellum, brainstem and spinal cord, and sensory axonal neuropathy.[36] IOSCA is due to mutations in the nuclear gene C10orf2 encoding the twinkle protein.[36] In two autopsy cases, CNS atrophy was the dominant morphological feature, which was most severe in the spinal cord.[37] Atrophy there was most prominent near the dorsal roots, the dorsal columns, and the posterior spinocerebellar tracts.[37] There was also severe loss of neurons in the dorsal nucleus (Clarke’s column).[37] In a study of 17 IOSCA patients, 9 underwent MRI of the spinal cord of which 4 showed moderate atrophy of the upper cervical cord.[38]

**Mitochondrial recessive ataxia syndrome**

Mitochondrial recessive ataxia syndrome (MIRAS) is a specific MID, clinically characterized by adult-onset ataxia, neuropathy, psychiatric abnormalities, and cognitive impairment. MIRAS is most frequently due to mutations in POLG1. In a 56-year-old female with MIRAS, who deceased from pulmonary embolism, neuropathological workup revealed atrophy of the posterior columns of spinal cord, particularly of the gracile tract and the posterior spinocerebellar tracts [Figure 3].[39] Clarke’s dorsal nuclei showed some neuronal loss, while anterior horns or intermediolateral columns were spared.[39]

**Leber’s hereditary optic neuropathy**

In a study of 46 patients with leber’s hereditary optic neuropathy (LHON), thoracic kyphosis was found in 7 of them.[40] In a single patient with LHON, due to the variant m.14484T>C in the ND6 gene, spinal MRI showed diffuse demyelinating lesions extending from T6 to T11.[43] In a patient with LHON spinal cord lesions due to concomitant neuromyelitis optica (NMO) have been reported.[42] In patients with LHON and features of multiple sclerosis (MS), respectively NMO, it is conceivable that “demyelinating” lesions are in fact stroke-like lesions attributable to the MID with some clinical and instrumental features suggesting MS, respectively, NMO. In a patient with LHON and MS, new “inflammatory lesions” were seen on MRI of the brain and spinal cord 14 months after discontinuation of natalizumab.[43] Particularly, in seronegative “NMO” patients, spinal cord involvement in LHON should be suspected.

**Chronic progressive external ophthalmoplegia**

In a 55-year-old female with a paternal history of ptosis, chronic progressive external ophthalmoplegia (CPEO), and ptosis developed since age 40 years.[44] These clinical manifestations were due to a mutation in the C10orf2 gene.[44] By age 53 years, she experienced sudden-onset ascending paresthesias from lower limbs to mid trunk without involvement of the sphincters.[44] On neurologic examination, she exhibited a Lhermitte’s sign, 3/5 MRC shoulder abduction and elbow flexion weakness, suspended loss of touch and temperature at C7–C8 levels, impaired proprioception in toes, and lower limb brisk reflexes. Spinal MRI, performed 4 weeks after clinical onset, showed a gadolinium-unenhanced T2-hyperintensity along the posterior columns extending bilaterally for 13 mm at C7–T1 levels.[44]

**Nonspecific mitochondrial multi-organ disorder syndrome**

In a study of 33 patients with a genetically confirmed MID (mtDNA point mutations or deletions [n = 21],
SURF1 mutations \( [n = 7] \), POLG1 mutations \( [n = 5] \), 4 of 6 patients undergoing MRI of the spinal cord had nonspecific signal changes\(^{[14,45]} \). In a study of six patients carrying ISCA2 mutations, one had signal abnormalities in the cervical spinal cord.\(^{[46]} \) In a single patient with MIMODS due to a tRNA (Glu) mutation causing Complex-I deficiency, neuropathological investigations at autopsy revealed descending anterograde degeneration in the medullary pyramids and corticospinal tracts.\(^{[47]} \) In a 66-year-old female carrying a POLG1 mutation, neuropathological studies at autopsy revealed profound dorsal column and dorsal spinocerebellar tract degeneration.\(^{[48]} \) Autopsy after death at age 59 years from pneumonia in a patient carrying a POLG1 mutation revealed myelin loss of the gracile fascicle in the cervical spinal cord.\(^{[49]} \) Pure motor dysfunction manifesting with quadriplegia and involvement of the cranial nerves has been repeatedly reported in MIDs, which may mimic motor neuron disease.\(^{[4,5]} \) This mimicry may be due to involvement of the anterior horn cells in the mitochondrial defect.

**Diagnosis**

Diagnosis of spinal cord involvement in MIDs requires an extensive individual history, a thorough clinical examination, imaging investigations, cerebrospinal fluid (CSF) investigations, transcranial magnetic stimulation (TMS), somatosensory-evoked potentials (SSEPs), and neuropathological work-up in case of decease. MRI may show atrophy, T2-hypo- or hyperintensities, enhancing (inflammatory) lesions, restricted diffusion, demyelination, or calcifications. MRS may show a lactate peak. CSF investigations may be normal, may show lactic acidosis, or may reveal mild or marked pleocytosis, IgG production, and positive oligoclonal bands.\(^{[50]} \) TMS may show prolongation of the central conduction time and of MEP latencies. Affection of the spinal cord may be documented by delayed SSEPs.\(^{[51]} \) Neuropathological investigations may show atrophy, neuronal loss, gliosis, inflammation, edema, cyst formation, or vacuolisation. Blood tests may show lactic acidosis, creatine-kinase elevation, or elevation of pyruvate.

**Treatment**

Treatment of spinal cord involvement in MIDs is usually supportive, including physical therapy and rehabilitation to improve motor function, and occasionally there might be a need for special education or speech therapy.\(^{[52]} \) Rehabilitation and physical therapy are helpful in the prevention of secondary complications such as contractures and scoliosis.\(^{[32]} \) In case of spinal deformities surgical corrections may be an option but this procedure has been carried out only in single cases. In a patient with LS posterior spinal fusion as a palliative procedure resulted in activation of the underlying MID and finally deterioration of the phenotype.\(^{[53]} \) In case of urinary retention, placement of a transurethral catheter or implantation of a suprapubic catheter may be necessary.

**DISCUSSION AND CONCLUSIONS**

This review shows that the spinal cord is involved in various MIDs. Spinal cord involvement is most frequently reported in LBSL, LS, MERRF, KSS, IOSCA, MIRAS, PCH, and MIMODS, and more rarely in MELAS, CPEO, and LHON. Clinical manifestations of spinal cord involvement include weakness, sensory and autonomic disturbances, sphincter dysfunction, or transverse syndrome. These abnormalities may overlap with cerebral manifestations in case of cerebral involvement. In some cases, spinal cord affection may be the initial manifestation of a MID, as in LS.\(^{[21]} \) Some cases may present with features of a motor neuron disease, thus mimicking spinal muscular atrophy or amyotrophic lateral sclerosis.\(^{[4,5]} \) Rarely, spinal cord involvement may manifest as sensory or motor transverse syndrome. With progression of the MID, spinal cord involvement may advance as well.

There is no uniform pattern of spinal cord involvement in MIDs, but most frequently the dorsal columns, the corticospinal tracts, or the spinocerebellar tracts are involved. Spinal cord involvement in MELAS is characterized by degeneration and neuronal loss of anterior and posterior corticospinal tracts. Spinal cord involvement in MERRF is characterized by neuronal loss in Clarke’s column and the anterior and posterior horn and by gliosis of the corticospinal tracts, the spinocerebellar tracts, and the dorsal columns. Spinal cord involvement in KSS is characterized by vacuolation and gliosis of the dorsal columns and the corticospinal tracts.\(^{[14]} \) Affection of the spinal cord in LS may manifest on imaging as bilaterally symmetric T2-hyperintensities of the cord and histologically as symmetrical microcyst formation, vascular proliferation, proliferation of astrocytes, fibrillar gliosis, and destruction of the myelin sheaths.\(^{[23]} \) There may be necrosis of the gray matter, demyelination, capillary proliferation, and gliosis of the cervical cord.\(^{[24]} \) Spinal cord lesions in LBSL on imaging include T2-hyperintensities in the posterior columns, in the anterior and posterior spinocerebellar tracts, and the lateral corticospinal tract. In single cases, calcifications may be seen. Histologically, vacuolation can be found. Spinal cord involvement in PCH includes loss of anterior horn cells and ballooning of neurons.\(^{[34]} \) The spinal cord in IOSCA is atrophic, particularly near the dorsal roots, the dorsal columns, and the posterior spinocerebellar tracts.\(^{[37]} \) Spinal cord abnormalities in MIRAS include atrophy of posterior columns and the
spino cerebellar tracts and neuronal loss in Clarke’s dorsal nuclei.\(^{(39)}\)

Diagnosing spinal cord involvement in MIDs requires the application of spinal MRI, spinal computed tomography, spinal MRS, SSEPs, TMS, CSF investigations, and autopsy. Treatment of spinal cord involvement relies on the same measures as applied for MIDs in general.\(^{(54)}\) Transverse syndromes may be managed as transverse syndromes due to other causes. In case of secondary spinal column abnormalities, orthopedic measures may be helpful. For the clinician, it is important to consider spinal cord involvement in MIDs and to initiate appropriate diagnostic steps if the clinical presentation suggests spinal cord involvement and if cerebral lesions are absent or do not explain the clinical presentation. Spinal cord involvement in MIDs must be considered as a differential diagnosis of motor neuron disease, transverse syndrome, MS, neomyelitis optica, myelitis, ADEM, or myelopathy. Imaging modalities should not be applied to assess severity or prognosis of spinal cord lesions in MIDs.
