(Dated: August 27, 2020)

Trapped-ion quantum computers have demonstrated high-performance gate operations in registers of about ten qubits. However, scaling up and parallelizing quantum computations with long one-dimensional (1D) ion strings is an outstanding challenge due to the global nature of the motional modes of the ions which mediate qubit-qubit couplings. Here, we devise methods to implement scalable and parallel entangling gates by using engineered localized phonon modes. We propose to tailor such localized modes by tuning the local potential of individual ions with programmable optical tweezers. Localized modes of small subsets of qubits form the basis to perform entangling gates on these subsets in parallel. We demonstrate the inherent scalability of this approach by presenting analytical and numerical results for long 1D ion chains and even for infinite chains of uniformly spaced ions. Furthermore, we show that combining our methods with optimal coherent control techniques allows to realize maximally dense universal parallelized quantum circuits.

I. INTRODUCTION

Trapped atomic ions are a leading platform for quantum information processing [1–7]. High-fidelity gate operations, qubit initialization and readout, as well as long coherence times have been demonstrated in trapped-ion quantum computers which consist of tens of individually addressable qubits [8–12]. However, while state-of-the-art ion traps can sustain 1D chains of more than a hundred ions, scaling up and, in particular, parallelizing gate operations is challenging due to the increasing complexity of the spectrum of phonon modes, which serve as data buses for the transmission of quantum information [1, 13].

Traditionally, this problem has been addressed by using segmented traps in which small ion crystals are shuttled between different zones that are dedicated to qubit storage and manipulation, respectively [14–17].

In this paper, we address the challenge of scaling up and parallelizing quantum computations with long 1D ion strings by combining well-developed conventional linear Paul traps [18] with programmable optical tweezer arrays, which are commonly utilized as a powerful tool in quantum simulation with neutral Rydberg atoms [19, 20].

Here, instead, we consider using programmable optical tweezer arrays to pin specific ions in a linear trap [21], and thereby engineer localized phonon modes [22–24]. These designer phonon modes form the basis to implement scalable and parallel entangling gates. The required capabilities to optically address individual ions are available in current experiments [25, 26].

By dynamically reconfiguring the tweezer array, the designer phonon modes can be adjusted during running quantum computations, and thus offer great flexibility to achieve an effective “optical segmentation” of the ion chain.

Possible quantum circuits provided by optical segmentation are illustrated schematically in Figs. 1(a) and (b): In the first example, a subregister formed by three consecutive qubits which are marked by cyan shading is decoupled from the other qubits by “optical tweezer walls” [21] that consist of pairs of optically pinned ions. By using the phonon modes which are localized in between the tweezer walls, a multi-qubit gate can be performed on the subregister. The second example relies on the long-range connectivity in chains of trapped ions to implement an entangling gate between the two qubits marked by pink shading and which are both pinned by optical tweezers.

In this work, we focus on the implementation of quantum circuits which are composed of parallel gates between pairs of nearest-neighbor qubits. Pinning pairs of neighboring ions with optical tweezers as illustrated in Fig. 1(c) gives rise to localized phonon modes which correspond to center-of-mass (COM) and stretch oscillations of the pinned pairs. In micro traps with segmented electrodes, an analogous local mode structure arises for two ions which are shutted to an interaction zone of the trap. The optical segmentation enables performing entangling gates on all pairs of pinned ions in parallel, which corresponds to the first layer of the quantum circuit shown in Fig. 1(d).

Due to the emergence of a local phonon mode structure with only two relevant localized phonon modes per pinned pair, high-fidelity scalable and parallel gates can be performed in long ion chains without resorting to optimal coherent control techniques. Further, the gate time is determined by the splitting of the localized phonon modes, and is thus independent of the total number of ions in the chain. Indeed, as we show analytically and numerically, tweezer gates can be performed even in infinitely long chains [27]. Further, the gate time is determined by the splitting of the localized phonon modes, and is thus independent of the total number of ions in the chain.

Finally, we discuss different ways to minimize crosstalk between parallel two-qubit entangling gates based on optimal control of time-modulated laser-pulse amplitudes as developed by Duan et al. [28]. This enables the implementation of dense “brick wall circuits.” Such dense circuits have a wide range of applications, for exam-
Figure 1. Schematic setup and circuits. (a) Specific ions in a long 1D chain are pinned by optical tweezers. This leads to the formation of localized phonon modes, e.g., for the subregister formed by the three ions which are marked by cyan shading, and for the pair of distant qubits which are marked by pink shading and which are pinned by equally strong optical potentials. (b) The localized phonon modes can be utilized to implement multi-qubit entangling gates. Buffer ions at the ends of the chain are not used as qubits. (c) In this work, we focus on implementing parallel two-qubit entangling gates which use the localized phonon modes of pairs of neighboring pinned ions. (d) After a first layer of the circuit which corresponds to the product of gates $U_1 U_2 U_3$ that act on distinct qubits, the tweezers are focused on different ions to perform the second layer corresponding to the gate operation $U_4 U_5$.

The paper is structured as follows: We start in Sec. II with a short review of some aspects of quantum gates with trapped ions. In Sec. III we discuss how to design localized phonon modes for quantum computing. Subsequently in Secs. IV and V we show how these localized modes can be used to implement scalable and parallel tweezer gates with and without optimal control respectively. Finally we give an outlook in Sec. VI.

II. ENTANGLING QUANTUM GATES WITH TRAPPED IONS

For reference, we find it convenient to summarize some fundamentals of quantum computing with trapped ions. Based on this, we state the decomposition of quantum circuits into single-qubit and nearest-neighbor entangling gates and discuss how one can quantify the performance of a two-qubit quantum gate.

A. Quantum computing with trapped ions

The implementation of quantum logic gates in 1D chains of laser-cooled trapped ions relies on the laser-induced coupling between long-lived internal states of the ions, which encode the qubits, and the phonon modes of the ion chain, which serve as quantum data buses. Entanglement between qubits is established through the exchange of real [1] or virtual [38–41] phonons. We focus on the latter approach, known as Mølmer-Sørensen gate [40], which is insensitive to finite temperatures of the phonon modes. In a suitable rotating frame, the corresponding qubit-phonon coupling Hamiltonian for $N$ ions with $3N$ motional modes reads

$$H = \sum_{\alpha \in \{x,y,z\}} \sum_{i,n=1}^{N} \eta_{\alpha,i}^n \hbar \Omega_\alpha(t) \sin(\mu_i t) \times (a_{\alpha,n}^\dagger e^{i\omega_{\alpha,n} t} + \text{H.c.}) \sigma_i^z,$$

where the first sum is over the spatial directions $\alpha$ of the 3D motion of the ions. As illustrated in Fig. 1(a), we choose the coordinate system such that $x$ and $y$ directions are transverse to the weak trap axis, which is along the $z$ direction. In the form given above, the Hamiltonian is valid in the Lamb-Dicke limit, in which the amplitudes of oscillations of the ions around their equilibrium positions are small in comparison to optical wavelengths. This justifies an expansion to first order in the Lamb-Dicke parameter matrix, which we define as

$$\eta_{\alpha,i}^n = k_{L,\alpha} \sqrt{\frac{\hbar}{2m\omega_{\alpha,n}}} M_{\alpha,i}^n,$$

with the effective laser wave vectors with components $k_{L,\alpha}$ that are assumed to be equal for all ions [42]. Here $m$ is the mass of the ions, $\omega_{\alpha,n}$ is the frequency of the phonon mode $n \in \{1, \ldots, N\}$ in spatial direction $\alpha$, and the element $M_{\alpha,i}^n$ of the phonon mode matrix is given by the amplitude of the phonon mode vector $n$ on ion $i \in \{1, \ldots, N\}$. The phonon mode matrix is derived in Appendix A.

The Hamiltonian (1) results from addressing the ions with pairs of laser beams which are detuned by $\pm \mu_i$ from the qubit transition [38–41]. We assume that the detuning $\mu_i$ and the laser pulse shape as described by a time-modulated Rabi frequency $\Omega_i(t)$ can be chosen for each ion $i$ individually. The annihilation and creation operators of phonons with frequency $\omega_{\alpha,n}$ are denoted by...
where \( I \) is the set of all pairs of neighboring qubits on which gates are to be performed in the layer under consideration. Since any entangling two-qubit gate can be decomposed into single-qubit rotations and entangling operations which are generated by \( \sigma_x^i \sigma_x^{i'} \) [47], we can assume without loss of generality that \( U_{i,i'} \) is an \( xx \) gate,

\[
U_{i,i'} = e^{i \chi_{i,i'}^{0} \sigma_x^{i} \sigma_x^{i'}}
\]

with couplings \( \chi_{i,i'}^{0} \) for different pairs \((i, i')\) all having the same positive or negative sign and \( |\chi_{i,i'}^{0}| \in [0, \pi/4] \) [47]. Throughout this work we consider maximally entangling gates with \( \chi_{i,i'}^{0} = \pm \pi/4 \) as a benchmark case. This benchmark is particularly relevant since the unitary (8) with \( \chi_{i,i'}^{0} = \pm \pi/4 \) is up to single-qubit rotations equivalent to the CNOT gate [48] which forms a universal gate set together with single-qubit rotations [49].

### B. Gate imperfections

Any experimental implementation of quantum logic gates with trapped ions is affected by various sources of imperfections which are not captured by the model Hamiltonian (1) [42]. However, even within this model, the unitary \( U \) (3) deviates in general from the target gate unitary \( U_0 \) (7). We distinguish three types of such intrinsic gate imperfections: Residual qubit-phonon entanglement, over- and underrotation errors, and crosstalk. To formalize this distinction, we factorize the gate unitary as \( U = U_{\alpha}U_{\chi} \), where

\[
U_{\alpha} = e^{i \sum_{i=1}^{N} \phi_i \sigma_x^i}, \quad U_{\chi} = e^{i \sum_{i<n'=1}^{N} \chi_{i,i'} \sigma_x^i \sigma_x^{i'}}.
\]

Deviations of \( U_{\alpha} \) from the identity, \( U_{\alpha} \neq 1 \), imply that qubits and phonons are entangled at the end of the gate operation. Over- and underrotation errors as well as crosstalk occur for \( U_{\chi} \neq U_0 \).

The adverse effect of residual qubit-phonon entanglement can be quantified in terms of the average fidelity [50] per gate, which we define as

\[
F = \left( \int d\Psi \langle \Psi | U_{\chi}^{\dagger} \text{tr}_{\text{ph}}(U | \Psi \rangle \langle \Psi | \otimes \rho_{\text{ph}} U^{\dagger}) U_{\chi} | \Psi \rangle \right)^{1/2},
\]

where the trace is over the motional degrees of freedom, \( \rho_{\text{ph}} \) denotes a thermal state of phonons, and the integration is over the Fubini-Study measure [51]. We note that usually the fidelity is defined with respect to the ideal target gate, i.e., with \( U_{\chi} \) replaced by \( U_0 \), to explicitly include over- and underrotation errors as well as crosstalk. In contrast, we quantify these types of errors separately as detailed below. To account for the exponential dependence of the total fidelity \( F_{\text{tot}} \) on the number \( G \) of gates which are being performed in parallel—which in the cases of interest to us scales with the number of gates \( G \sim N \)—we include an exponent \( 1/G \) in the definition of the fidelity per gate. In the limit of high fidelity, the infidelity per gate \( \delta F = 1 - F \) can be approximated by [42]

\[
\delta F = 4 \frac{1}{G} \sum_{i,n=1}^{N} |\alpha_i|^2 (2\bar{n}_n + 1),
\]

where \( \bar{n}_n \) is the average thermal occupation of phonons in the mode with frequency \( \omega_n \). For simplicity, we assume in the following that \( \bar{n}_n = 0.5 \) for all phonon modes.

We note that for the tweezer gates we describe below, an additional contribution to the infidelity is due to spontaneous scattering of photons of the tweezer beams. As
discussed in Appendix B, promising candidates to implement tweezer gates are $^{24}\text{Mg}^+$ ions, for which the infidelity due to scattering of photons is on the order of $10^{-3}$ for the tweezer parameters we assume below, and can be reduced further for weaker optical trapping.

Over- and underrotation errors of the gate $U$ corresponds to deviations of the qubit-qubit coupling $\chi_{i,i'}$ from the desired value $\chi_{i,i'}^0$ for pairs of qubits $(i, i')$ which are contained in $I$ in Eq. (7), i.e., which are affected by the ideal gate $U_0$. In contrast, crosstalk is due to unwanted nonzero qubit-qubit couplings for pairs of qubits which are not contained in $I$. To separate these types of errors, we factorize the qubit-qubit coupling in Eq. (3) as $U_\chi = U_1 U_C$, where

$$U_1 = \prod_{(i,i') \in I} e^{i \chi_{i,i'} \sigma_i^x \sigma_{i'}^x}, \quad U_C = \prod_{(i,i') \in I'} e^{i \chi_{i,i'} \sigma_i^x \sigma_{i'}^x},$$

and where $I'$ contains all ordered pairs of qubits which are not included in $I$. We quantify these gate errors in terms of the diamond norm of the error superoperators $E_1 = U_1 - U_0$ and $E_C = U_C - I$, where $U_0(\rho) = U_0^2 \rho U_0$ for $a = 0, 1, C$, and $\mathbb{I}(\rho) = \rho$ for $a = 27, 52, 53$. Bounds on the errors per gate are given by [54]

$$\frac{1}{G} \|E_1\|_\diamond \leq \delta_\chi = \frac{2}{G} \sum_{(i,i') \in I} \left| \chi_{i,i'} - \chi_{i,i'}^0 \right|,$$

$$\frac{1}{G} \|E_C\|_\diamond \leq \delta_C = \frac{2}{G} \sum_{(i,i') \in I'} \left| \chi_{i,i'} \right|,$$

where we defined the over-/underrotation error $\delta_\chi$ and the crosstalk $\delta_C$.

III. OPTICAL DESIGN OF LOCALIZED PHONON MODES

Our goal is to design localized phonon modes in long laser-cooled ion strings, which, as we go on to show in Secs. IV and V, enable the implementation of scalable and parallel entangling quantum gates. In particular, we engineer specific types of mode matrices $M^a_{i,i'}$ by using optical tweezers that are focused on the equilibrium positions of specific ions and thus pin these ions as we describe in Appendix A. The tweezers are realized by Gaussian laser beams along the $y$ direction as illustrated in Fig. 1(a). In the vicinity of the focuses of the tweezers, the optical potential can be approximated as harmonic. The optical trapping frequency along the beam axis is negligible. In contrast, the optical trapping frequency $\omega_{0,i}$ along the transverse $x$ and the longitudinal $z$ directions is determined by the beam intensity and waist at the position of ion $i$, and we assume that $\omega_{0,i}$ does not depend on the internal state of the ions and can take on values up to $\omega_{0,i} \lesssim 0.4 \omega_x$ for typical transverse trapping frequencies $\omega_x = 2 \pi \times 3$ MHz. In Appendix B, we discuss experimental requirements to realize such strong qubit-state-independent optical potentials for different ionic species.

In the following, we first consider localized phonon modes of a single pair of pinned, neighboring ions in a long chain. This allows us to delimit the regime of strong pinning in which the phonon modes of the pinned ions decouple from the modes of the spectator ions. We then illustrate these ideas with concrete examples of finite and infinite chains.

A. Pinning a single ion pair in a long chain

To engineer transverse $x$ phonon modes which are localized on a pair of neighboring ions $i$ and $i + 1$ and which can thus be used to perform an entangling gate on this pair, we consider a situation in which the pinning on the ions forming the pair is the same $\omega_{0,i} = \omega_{0,i+1}$ whereas the remaining spectator ions are not pinned. The residual Coulomb interaction (see Appendix A for details) has two effects: First, the interaction between the pinned ions leads to the formation of localized COM and stretch modes given by

$$M^\text{COM}_{x,i,i'} = (\delta_{\ell^2} + \delta_{\ell^2,i+1}) / \sqrt{2},$$

$$M^{\text{stretch}}_{x,i,i'} = (\delta_{\ell^2} - \delta_{\ell^2,i+1}) / \sqrt{2}.$$  \hspace{1cm} (15)

These are the desired modes to implement two-qubit entangling gates. The frequency splitting of these modes is determined by the Coulomb interaction, $\omega_{\text{COM}} - \omega_{\text{stretch}} \approx 3 \pi \epsilon_0 d_i^3 / (4 \pi \epsilon_0 d_i^3 m \omega_x)$, where $d_i = |z_i,0 - z_{i,0}|$ is the distance between the equilibrium positions $z_i,0$ of the ions along the trap $z$ axis, $\epsilon$ is the elementary charge and $\epsilon_0$ is the vacuum permittivity. Second, the interaction between pinned and spectator ions slightly admixes oscillations of the spectator ions to the localized modes, i.e., the mode vectors Eq. (15) acquire nonzero amplitudes on ions $i' \notin \{i, i + 1\}$. This unwanted effect is strongly suppressed if the difference between the squares of the local oscillation frequencies of the pinned and spectator ions, as given in Eq. (A3), is large in comparison to their residual Coulomb interaction.

More generally, for transverse $x$ phonon modes of a chain of ions with mean spacing $d$, the regime of strong pinning in which localized phonon modes emerge can be conveniently characterized in terms of two dimensionless parameters:

$$\epsilon = \sqrt{\frac{\epsilon_0^2}{4 \pi \epsilon_0 d^3 m \omega_x^2}}, \quad \nu_0 = \frac{\omega_0}{\omega_x},$$

where for simplicity we assume that all ions are pinned with the same optical trapping frequency $\omega_0$. As detailed in Appendix A, localized COM and stretch modes of a pair of pinned ions decouple from the motion of spectator ions if $\nu_0^2 / \epsilon^2 \gg 1$.

In experiments, $\epsilon$ is typically a small parameter. For example, we obtain $\epsilon \approx 0.07$ for a spacing of $d = 10 \mu m$.
in a chain of $^{24}\text{Mg}^+$ ions with a transverse trapping frequency of $\omega_x = 2\pi \times 5.5 \text{ MHz}$, or $^{40}\text{Ca}^+$ ions with $\omega_x = 2\pi \times 4.2 \text{ MHz}$. The ratio $\nu_0^2/\epsilon^2$ can be increased by either increasing the tweezer trapping frequency $\omega_0$ or by increasing the spacing of the ions $d$.

**B. Localized phonon modes in a finite chain**

As an example, we consider a chain of $N = 60$ ions as depicted in Fig. 2(a). We assume harmonic confinement along the trap $z$ axis with trapping frequency $\omega_z$. Starting from the sixth ion, optical tweezers are arranged to divide the chain into groups of $p = 6$ ions. The resulting mode matrix $M_{x,i}^n$ for $i, n \in \{1, \ldots, N\}$ for oscillations in the transverse $x$ direction is shown in Fig. 2(b). Orange boxes mark pinned ions, and gray boxes indicate buffer ions at the ends of the chain. The spacing of these ions deviates strongly from the approximately uniform spacing in the center of the chain, and we exclude them from gate operations. As explained above, the residual Coulomb coupling leads to the formation of localized COM and stretch modes of the pinned pairs. In the figure, COM and stretch modes are distinguished by the same color of $M_{x,i}^n$ and $M_{x,i+1}^n$ for two neighboring ions which oscillate in phase and different colors for oscillations with opposite phase. As an additional effect which is due to the long-range character of the residual Coulomb interaction, the localized modes of distinct pinned pairs hybridize, where the number of ions in pinned pairs, which is 18 for this example, determines the number of hybridized modes. These modes are highlighted by blue shading in the figure.

To perform entangling gates on pairs of pinned ions, the hybridization of localized phonon modes is in principle not desirable. However, as long as the frequency splitting of the localized modes due to the hybridization is so small that it cannot be resolved on the time scale of the gate operation, the hybridization has only a small effect on the gate performance. This picture generalizes the concept of local oscillation modes from single ions [55] to pairs of ions.

The order of mode indices $n$ in Fig. 2(b) reflects the mode frequency, with $n = 1$ corresponding to the mode with the highest frequency. For transverse oscillations, this is a COM-like mode, which is given here by the in-phase oscillation of local COM modes of the outermost pairs. The second-highest-frequency mode with $n = 2$, in turn, corresponds to a superposition of the local COM modes of the outermost pairs with opposite phase. For this example, due to the reflection symmetry with regard to the center of the trap, these hybridized modes are equal superpositions of oscillations of pairs to the left and right of the trap center. Superpositions of local COM modes are followed at lower frequencies by superpositions of local stretch modes.

The phonon mode spectrum of the chain, both with and without tweezers, is shown in Fig. 2(c). The spectra of oscillations in the longitudinal $z$ and transverse $x$ direction, which are shown in orange and blue, respectively, are strongly modified in the presence of tweezers with strength $\nu_0 = \omega_0/\omega_x = 0.4$: The spectrum of oscillations along the trap $z$ axis is gapped [21], and the almost dense set of frequencies splits up into several subsets. Most prominently, both for the $z$ and $x$ modes, a subset of modes, which correspond to hybridized COM and stretch modes of the pinned pairs, appear shifted above the remaining mode frequencies. For the transverse $x$ direction, the assignment between mode frequencies and mode vectors is indicated with blue and green shading. The spectrum of transverse $y$ modes, which is shown in green in Fig. 2(c), is not affected by the tweezers because we neglect the trapping along the direction of the tweezer beam.

**C. Phonon band structure for infinite chains**

To demonstrate the inherent scalability of our approach, we also present theoretical results for tweezer gates in infinite ion chains as illustrated in Fig. 3(a). In the simultaneous limit $N \rightarrow \infty$ and $\omega_z \rightarrow 0$, the system acquires discrete translational invariance under the
between modes \(\lambda = 1\). Within a unit cell, there is a clear separation of COM and stretch modes of pinned pairs in Fig. 3(b) for \(\alpha = \frac{x}{p}\) bands, where the highest two bands correspond to COM and stretch oscillations of the pinned ions, and the modes with \(n \in \{3, \ldots, p\}\) which involve the ions which are not pinned.

As shown in Fig. 3(c), modifications of the mode frequencies due to tweezers are particularly clear in infinite systems. The bands which are formed by \(z\) and \(x\) modes split up into \(p = 6\) bands in the presence of tweezers. In particular, COM and stretch modes of the pinned pairs hybridize between unit cells to form bands. The widths of these bands are vanishingly small on the scale of the figure. Moreover, close inspection reveals that the width of the stretch band is smaller than the width of the COM band by one order of magnitude. These features of the COM and stretch bands can be understood in terms of perturbation theory in the small parameter \(\epsilon^2/\nu_0^2\) as we show in Appendix A 2. The perturbative treatment shows that the widths of the COM and stretch bands are \(\sim \epsilon^2 \omega_x/p^3\) and \(\sim \epsilon^2 \omega_z/p^5\), respectively. That is, the widths are suppressed with the size of the unit cell \(p\), with an even stronger suppression for the stretch band.

IV. ENTANGLING TWEEZER GATES

The optical design of phonon modes as described above forms the basis to implement parallel two-qubit entangling gates. In the following, we discuss the requirements for and performance of tweezer gates in infinite as well as finite ion chains.

A. Infinite chains

We consider a periodic array of pinned pairs of ions which are separated by \(p - 2\) spectator ions, and we aim at performing two-qubit entangling gates on all pairs of pinned ions in parallel. As illustrated in Fig. 3(b) the spectrum of transverse \(x\) phonon modes comprises \(p\) bands with mean frequencies \(\omega_n\) and bandwidths \(\Delta_n\).

We aim at implementing gates using dominantly the COM or stretch bands with mean frequencies \(\omega_1 = \omega_{\text{COM}}\) and \(\omega_2 = \omega_{\text{stretch}}\) respectively. This can be achieved if the resolved-sideband condition

\[
|\mu - \omega_n| \ll \mu, \omega_n,
\]

is met where \(\mu > \omega_1\) for the COM band with \(n = 1\), and \(\mu < \omega_2\) for the stretch band with \(n = 2\). The choice of tuning above the COM or below the stretch band ensures that the detuning \(\mu\) is as far away as possible from the respective other band which should not be excited.

Note that contributions from higher bands with \(n \in \{3, \ldots, p\}\) to the displacement (5) and qubit-qubit coupling (6) are strongly suppressed: First, these bands are far detuned with \(\mu - \omega_n \gtrsim \omega_l\) with the frequency of the optical potential \(\omega_l\). Second, the contribution of these bands to the displacement (5) and the qubit-qubit coupling (6) is proportional to \(|\eta_{l,i}^{n,\lambda}/\omega_0|\), which is
We note that due to the proportionality to \( \Omega \) typically \( \Omega = 0 \) for the ions which are not pinned, these do not close perfectly. The physical picture described below is not visible on the scale of the figure. (b) Closer inspection reveals that the phase space curves for different values of \( k \) are not perfectly closed. The area under the squared modulus of the displacement at the end of the gate operation, shown here for \( n = \lambda = 2 \), determines the infidelity \((11)\). Parameters of the ion chain are \( p = 6 \), \( \nu_0 = 0.4 \), and \( \epsilon = 0.07 \).

Figure 4. Phase space trajectories for parallel entangling gates in an infinite chain. (a) Displacement of the phonon mode \( k, n, \lambda \) due to its coupling to the ion at position \( l = i = 1 \) as described by Eq. (5). For the chosen detuning close to \( \mu_{\text{stretch}} \) in Eq. (19), the stretch mode with \( n = \lambda = 2 \) and \( k \approx 1.55 \) such that \( \omega_{k,2} = \omega_2 \) equals the mean frequency of the stretch band experiences the strongest displacement. The phase space trajectory of the COM mode with the same values of \( k \) and \( \lambda \) forms a smaller circle which is traversed twice. Trajectories of modes with \( n \geq 3 \) are not visible on the scale of the figure. (b) Closer inspection reveals that the phase space curves for different values of \( k \) are not perfectly closed. The area under the squared modulus of the displacement at the end of the gate operation, shown here for \( n = \lambda = 2 \), determines the infidelity \((11)\). Parameters of the ion chain are \( p = 6 \), \( \nu_0 = 0.4 \), and \( \epsilon = 0.07 \).

The precise values of \( \mu \) and, in particular, \( \tau \), follow from the condition of minimal infidelity. For an isolated pair of ions with COM and stretch mode frequencies \( \omega_1 \) and \( \omega_2 \), respectively, this can be achieved for \((41, 44)\)

\[
(\mu - \omega_\lambda) \tau = 2\pi l_n,
\]

where \( l_n \) is an integer. Particular choices for gates which use dominantly the COM and stretch modes are given by, respectively, \( l_1 = 1 \) and \( l_2 = 2 \), and \( l_1 = -2 \) and \( l_2 = -1 \). The resulting detunings are

\[
\mu_{\text{COM}} = 2\omega_1 - \omega_2, \quad \mu_{\text{stretch}} = 2\omega_2 - \omega_1, \tag{19}
\]

and in both cases the gate duration \( \tau = 2\pi/(\omega_1 - \omega_2) \) is set by the mode splitting. These choices of detunings and gate duration ensure that the displacement \((5)\), when considered as a function of the upper limit of integration \( \tau' \in [0, \tau] \), performs a closed loop in phase space \([38–41]\).

In the present case of an infinite chain, condition Eq. (18) remains valid in the case of two narrow bands, if the bandwidths \( \Delta_n \) are sufficiently small in the sense that \( \Delta_n \tau \ll 1 \). However, clearly this condition cannot be met for all frequencies \( \omega_{k,n} \) which form a band and correspond to different quasimomenta \( k \). For the results we show below, we first fix \( \tau \) according to Eq. (18) for either the COM or the stretch band by setting either \( l_1 = 1 \) or \( l_2 = -1 \) and by choosing \( \omega_n \) as the mean frequency of the respective band, and we then determine numerically the value of \( \mu \) which yields the lowest infidelity, which typically deviates only slightly from the values given in Eq. (19). As above, the Rabi frequency \( \Omega_{l,i} = \Omega_0 \) on the pinned ions is chosen according to the condition \( \chi^{l,l'}_{i,i} = \pm \pi/4 \) if \((l,i)\) and \((l',i')\) are neighboring pinned ions, i.e., \( l' = l \) and \( i' = i + 1 \). For the remaining ions which are not pinned, we set \( \Omega_{l,i} = 0 \).

We first consider the implementation of parallel gates which use the stretch band in an ion chain with \( p = 6 \), \( \nu_0 = 0.4 \) and \( \epsilon = 0.07 \). To minimize the infidelity we choose \( \mu/\omega_x \approx 1.065 \) and \( \omega_x \tau \approx 1.37 \times 10^3 \) as described above. The required Rabi frequency to perform a maximally entangling gate is given by \( \eta_0 \Omega_0/\omega_x \approx 4.75 \times 10^{-3} \), where the dimensionless factor

\[
\eta_0 = k_{L,x} \sqrt{\hbar/(2m\omega_x)} \tag{20}
\]

contains all parameters in the definition of the Lamb-Dicke parameter matrix \((2)\) which are specific to different ionic species.

In panel Fig. 4(a), we show the displacement \((5)\) as a function of the upper limit of integration \( \tau' \in [0, \tau] \) and for \( n = 1, 2 \) and \( k \approx 1.55 \) which corresponds to the mean frequency \( \omega_2 \) of the stretch band. These values of \( n \) and \( k \) yield the largest values of the displacement, i.e., the corresponding modes contribute most to the gate. On the scale of the figure, the displacement for bands with \( n \geq 3 \) is not visible. The physical picture described below Eq. (19) is clearly reflected in the figure: The phase space trajectories for both the stretch and the COM modes shown in the figure are closed, where the trajectory of the COM mode is traversed twice. However, closer inspection of the vicinity of the origin reveals that the trajectories of modes which belong to the COM band and have different values of the quasimomentum \( k \) do not close perfectly. In panel Fig. 4(b) we show the displacement at the end of the gate operation as a function of \( k \) for both the
stretch and the COM bands. According to Eq. (11), the area under these curves determines the infidelity, and the figure shows that the dominant contribution to the infidelity is indeed due to the COM modes. We find $\delta F = 5.7 \times 10^{-4}$.

The infidelity is higher for gates which use predominantly the COM band. This is because the width of the COM band is much larger than the width of the stretch band and, therefore, the phase space trajectories for different $k$ deviate more strongly from perfect closure. In particular, for $\mu/\omega_S \approx 1.079$ slightly below the COM band, $\omega_\tau \approx 1.37 \times 10^3$, and $\eta_0 \Omega_0/\omega_S \approx 4.77 \times 10^{-3}$, we obtain $\delta F = 2.1 \times 10^{-3}$ which is higher than the value we obtain for the stretch band by an order of magnitude.

We next analyze over-/underrotation errors and crosstalk as defined in Eqs. (13) and (14), respectively. For the implementation of gates we discuss in this section, the Rabi frequency is chosen such that $\chi_{i,i'} = \chi_{i,i'}^0$ for $(i, i') \in I$, i.e., the over-/underrotation error vanishes exactly, $\delta \chi = 0$.

However there is unwanted crosstalk corresponding to nonzero qubit-qubit couplings between ions which belong to distinct pairs. The dominant contributions to crosstalk are due to (i) unwanted excitation of the stretch or COM band, and (ii) the finite width of these bands. Concerning (i), we note that for a given detuning, say $\mu > \omega_1$, the COM and stretch bands induce ferromagnetic and antiferromagnetic couplings. In other words, they yield contributions to $\chi_{i,i'}^{l,l'}$ with opposite sign, which thus partially cancel each other. This partial cancellation has to be compensated by increasing the Rabi frequency $\Omega_0$ to achieve $\chi_{i,i'}^{l,l'} = \pm \pi/4$ on the target ions, which then, however, also increases unwanted couplings which contribute to the crosstalk (14). This effect is suppressed by tuning close to a sideband Eq. (17), i.e., by dominantly exciting either the COM or the stretch band.

With regard to (ii), the fact that a finite bandwidth leads to crosstalk can be understood intuitively from the fact that the effective coupling between local (within single unit cells) COM or stretch modes determines the bandwidth. Crosstalk is negligible if the effective coupling and thus the bandwidth is much smaller than all other relevant scales. In particular, the finite bandwidth can be neglected and $\omega_{k,n}$ for the COM and stretch bands can be replaced by the respective central frequencies $\omega_n$ in Eq. (6) if

$$|\mu - \omega_n| \gg \Delta_n.$$  

We note that by Eq. (17) this also implies that $\mu, \omega_n \gg \Delta_n$. If we combine this condition with Eq. (18) for the gate duration, we find the intuitive criterion that to minimize crosstalk the gate should be performed fast on the timescale which is set by the effective coupling between pinned pairs. This picture generalizes the concept of local oscillation modes from single ions [55] to pairs of ions. We note that the mentioned condition can always be met efficiently by increasing the size of the unit cell $p$.

For the gate shown in Fig. 4, we find $C = 4.1 \times 10^{-2}$. The crosstalk for a gate using the COM band and with $p = 6$ is $C = 1.7 \times 10^{-1}$, i.e., again one order of magnitude higher than for the stretch band. The crosstalk can be reduced by increasing the unit cell size $p$. In particular, for gates which use the stretch band and for $p \geq 9$, we obtain $C < 10^{-2}$ such that $C/\chi_{i,i'} < 1\%$ for $(i, i') \in I$.

Finally, we note that while the long-range character of the residual Coulomb interaction has the adverse effect of leading to crosstalk between distant qubits, it can also be utilized to implement gates between qubits which are not nearest neighbors. This can be achieved, for example, by pinning the ions at positions 1 and $q$ where $2 < q \ll p$ within each unit cell. This leads to a reduction of the splitting between the COM and stretch bands by a factor of $\sim 1/(q - 1)^3$, and the gate time increases correspondingly according to Eq. (18).

### B. Gate performance

We study how infidelity, crosstalk and gate duration depend on the tweezer pinning strength as measured by the dimensionless optical trapping frequency $v_0$, and the strength of the residual Coulomb coupling $\epsilon$ in Fig. 5. The main panel of this figure shows the infidelity $\delta F$ for $p = 6$ and for optimized choices of gate duration and detuning as discussed above. For large values of $\epsilon$ in the white region, the gap which separates the COM and stretch bands is more than half of the gap which separates the stretch band from the bands of the ions which are not pinned and, therefore, the pinned ions are not suf-
sufficiently decoupled from the ions which are not pinned. In this region, gates cannot be performed with reasonable infidelity. High-fidelity gates can be performed for values of $\epsilon$ below the black diagonal line, which corresponds to a threshold value of $\delta F = 10^{-3}$.

We next analyze how the gate speed and crosstalk are affected by the optical trapping frequency $\nu_0$ for a fixed value of the infidelity $\delta F = 10^{-3}$, i.e., for $\epsilon$ on the black diagonal line in Fig. 5. The inset in the upper left corner of the figure shows the gate duration for various values of the unit cell size $p$. The gate duration is set by the splitting between COM and stretch bands, which according to Eq. (A16) is proportional to $\epsilon^2$ for $\epsilon \ll 1$. The resulting analytical prediction of the scaling $\tau \sim 1/\epsilon^2 \sim 1/\nu_0^2$ on the line $\delta F = 10^{-3}$ is shown as dashed gray line in the inset and agrees well with the numerical data. (The vertical offset between the gray line and the numerical data is introduced to improve the visibility.) For $\nu_0$ in the range from 0.1 to 0.4, we obtain gate durations between $\omega_s^2 \tau = 0.05 \times 10^4$ and $10^4$. For a typical value of $\omega_s^2 = 2\pi \times 3$ MHz, this corresponds to gate times ranging from 27 $\mu$s to 531 $\mu$s.

The crosstalk for fixed infidelity $\delta F = 10^{-3}$ is shown in the inset in the lower right corner in Fig. 5. While the crosstalk remains approximately constant as a function of $\nu_0$, it can be suppressed by increasing the unit cell size $p$. As already stated above, we find $C < 10^{-2}$ for $p \geq 9$.

### C. Finite chains

Here we show how the methods for implementing parallel tweezer gates can be applied in finite 1D ion strings. For concreteness, we assume harmonic trapping along the trap $z$ axis. In contrast to before the Hamiltonian in question is no longer invariant under discrete translations, which leads to stark changes in the mode spectrum as well as the mode functions themselves (see the discussion around Fig. 2). As we point out further below this is not necessarily a negative aspect and indeed further improves the gate performance. For this, the detunings $\mu_i$, the Rabi frequencies $\Omega_i(t)$ in Eq. (1), and the gate time have to be controlled for each ion pair. This is due to the fact that for each pair of target ions and in order to fulfill Eq. (18) one has to identify the corresponding COM and stretch mode and choose the detuning and the gate time accordingly. These deviations are strongest for ions at the ends of the chain where the inter-ion distances are considerably larger than for the rest of the chain. Therefore, we introduce several buffer ions on each end which are not used for quantum computation. We choose the number of buffer ions such that the relative standard deviation for the inter-ion distances of the other ions lies below 10%. Furthermore, we choose the axial trapping frequency $\omega_z$ such that the mean inter-ion distance of the non-buffer ions corresponds to $\epsilon = 0.07$, i.e., the value that we chose for the infinite system.

In Fig. 6 we show numerical results for a system of 130 ions, 15 of which on each side are used as buffer ions. As before we choose $p = 6$ to implement a total number of 17 maximally entangling gates in parallel. The two panels in Fig. 6 correspond to different schemes of optical pinning by the tweezer: In panel (a), each pair of target ions is pinned with the same tweezer strength $\nu_0 = 0.4$ and alternating between $\nu_{01} = 0.4$ and $\nu_{02} = 0.36$ for panels (a) and (b), respectively. For comparison, we also show the detuning $\mu_\infty$ and Rabi frequency $\Omega_\infty$ for an infinite chain with $\epsilon = 0.07$ and $\nu_0 = 0.4$.

Figure 6. Tweezer gates in finite chains. We show individual detunings and Rabi frequencies for 17 maximally entangling tweezer gates targeting the stretch mode along a chain of 130 ions with 15 buffer ions on each side ($p = 6$, $\epsilon = 0.07$). Optical tweezers generate a trapping frequency that is uniform $\nu_0 = 0.4$ and alternating between $\nu_{01} = 0.4$ and $\nu_{02} = 0.36$ for panels (a) and (b), respectively. For comparison, we also show the detuning $\mu_\infty$ and Rabi frequency $\Omega_\infty$ for an infinite chain with $\epsilon = 0.07$ and $\nu_0 = 0.4$. 
types of misadjustments: Deviations of the focuses of the tweezers from the equilibrium positions of the ions, variations in the optical trapping frequencies due to intensity fluctuations of the tweezers, and misalignment of the tweezers with the y direction. As figures of merit, we study how these imperfections affect the infidelity as well as the over-/underrotation error.

Including tweezer misadjustments in the optical potential (A4) for ion $i \in \{1, \ldots, N\}$ yields

$$V_{i}^{\text{twz}}(r_i) = \frac{m}{2} (\omega_{0,i} + \delta \omega_i)^2 [\Pi(\theta_i, \phi_i) (\delta r_i - \delta \chi_i)]^2 .$$

Here, $\delta \omega_i$ is a shift of the optical trapping frequency, $\delta \chi_i$ is the deviation of the focus of the tweezer from the equilibrium position of the ion $r_{i,0}$ in the absence of an optical potential, and $\delta r_i = r_i - r_{i,0}$ is the displacement of the ion from $r_{i,0}$. In Appendix C, we explain how the shift of the equilibrium position of the ion due to deviations of the focus of the tweezer from $r_{i,0}$ can be calculated perturbatively. Finally, the angles $\theta_i$ and $\phi_i$ describe the misalignment of the tweezer beam with the $y$ axis, and $\Pi(\theta_i, \phi_i)$ is the projector onto the plane orthogonal to the tweezer beam axis. We assume that fluctuations of the parameters $\delta \omega_i$, $\delta \chi_i$, $\theta_i$, and $\phi_i$ are normally distributed around zero, independent for each ion, and constant on the timescale of gate operations.

Figure 7 shows the infidelity and over-/underrotation error as a function of the strength of misadjustments. In particular, to generate the data shown in the figure, 40 samples of each of the dimensionless parameters $50 \delta \omega_i/\omega_{0,i}$, $\delta \chi_i/\omega_{0,i}$ where $t_0 = (e^2/4\pi \epsilon_0 m \omega_{0,i}^2)^{1/3}$, $\theta_i$, and $\phi_i$ are drawn from a Gaussian distribution with width $\sigma$. The factor of 50 for shifts of the optical trapping frequency is introduced so that the infidelities and over-/underrotation errors are comparable for all types of misadjustments on the range of values of $\sigma$ shown in Fig. 7. If we require $\delta F \lesssim 10^{-2}$ and $\delta \chi \lesssim 4 \times 10^{-2}$, this allows for standard deviations $\sigma$ of approximately 0.04 to 0.05 (the combination of all three types of misadjustments leads to the slightly more stringent requirement $\sigma \lesssim 0.02$ to 0.03), which can be related to misadjustments of 70 nm for the tweezer focuses, $2^\circ$ for the incidence angles, and 10 kHz for the pinning frequencies, corresponding to relative intensity errors of $3 \times 10^{-3}$ in a typical experiment with $d = 10 \mu m$ and $\omega_x = 2\pi \times 3$ MHz. All three conditions can be satisfied in state-of-the-art experiments.

**E. Dynamical reconfiguration of tweezer arrays**

To perform consecutive layers of the quantum circuit shown in Fig. 1(d) the tweezer array has to be reconfigured dynamically. In particular, the second layer in the circuit in Fig. 1(d) can be implemented by switching off the tweezers which are focused on the ions which are affected by the gates $U_1$, $U_2$, and $U_3$, and by subsequently switching on optical tweezers focused on the equilibrium positions of the ions which are affected by the gates $U_4$ and $U_5$.

---

**Figure 7. Tweezer misadjustments.** We show the infidelity (11) (blue) and the over-/underrotation error (13) (orange) as a function of the strength of fluctuations $\sigma$ for three types of misadjustments and for their combination. For each type of misadjustment, the infidelity and the over-/underrotation error are averaged over 40 realizations. We consider here a chain of 130 ions with 15 buffer ions on each side, and parameters $p = 6$, $\epsilon \approx 0.07$, and $\nu_0 = 0.4$.

---

**D. Infidelity and over-/underrotation errors from tweezer misadjustments**

An important question for the experimental implementation of tweezer gates concerns the sensitivity of the gate performance to misadjustments of the optical tweezer array. To address this question, we consider three distinct types of misadjustments: Deviations of the focuses of the tweezers from the equilibrium positions of the ions, variations in the optical trapping frequencies due to intensity fluctuations of the tweezers, and misalignment of the tweezers with the y direction. As figures of merit, we study how these imperfections affect the infidelity as well as the over-/underrotation error.

Including tweezer misadjustments in the optical potential (A4) for ion $i \in \{1, \ldots, N\}$ yields

$$V_{i}^{\text{twz}}(r_i) = \frac{m}{2} (\omega_{0,i} + \delta \omega_i)^2 [\Pi(\theta_i, \phi_i) (\delta r_i - \delta \chi_i)]^2 .$$

Here, $\delta \omega_i$ is a shift of the optical trapping frequency, $\delta \chi_i$ is the deviation of the focus of the tweezer from the equilibrium position of the ion $r_{i,0}$ in the absence of an optical potential, and $\delta r_i = r_i - r_{i,0}$ is the displacement of the ion from $r_{i,0}$. In Appendix C, we explain how the shift of the equilibrium position of the ion due to deviations of the focus of the tweezer from $r_{i,0}$ can be calculated perturbatively. Finally, the angles $\theta_i$ and $\phi_i$ describe the misalignment of the tweezer beam with the $y$ axis, and $\Pi(\theta_i, \phi_i)$ is the projector onto the plane orthogonal to the tweezer beam axis. We assume that fluctuations of the parameters $\delta \omega_i$, $\delta \chi_i$, $\theta_i$, and $\phi_i$ are normally distributed around zero, independent for each ion, and constant on the timescale of gate operations.

Figure 7 shows the infidelity and over-/underrotation error as a function of the strength of misadjustments. In particular, to generate the data shown in the figure, 40 samples of each of the dimensionless parameters $50 \delta \omega_i/\omega_{0,i}$, $\delta \chi_i/\omega_{0,i}$ where $t_0 = (e^2/4\pi \epsilon_0 m \omega_{0,i}^2)^{1/3}$, $\theta_i$, and $\phi_i$ are drawn from a Gaussian distribution with width $\sigma$. The factor of 50 for shifts of the optical trapping frequency is introduced so that the infidelities and over-/underrotation errors are comparable for all types of misadjustments on the range of values of $\sigma$ shown in Fig. 7. If we require $\delta F \lesssim 10^{-2}$ and $\delta \chi \lesssim 4 \times 10^{-2}$, this allows for standard deviations $\sigma$ of approximately 0.04 to 0.05 (the combination of all three types of misadjustments leads to the slightly more stringent requirement $\sigma \lesssim 0.02$ to 0.03), which can be related to misadjustments of 70 nm for the tweezer focuses, $2^\circ$ for the incidence angles, and 10 kHz for the pinning frequencies, corresponding to relative intensity errors of $3 \times 10^{-3}$ in a typical experiment with $d = 10 \mu m$ and $\omega_x = 2\pi \times 3$ MHz. All three conditions can be satisfied in state-of-the-art experiments.

---

**To perform consecutive layers of the quantum circuit shown in Fig. 1(d) the tweezer array has to be reconfigured dynamically. In particular, the second layer in the circuit in Fig. 1(d) can be implemented by switching off the tweezers which are focused on the ions which are affected by the gates $U_1$, $U_2$, and $U_3$, and by subsequently switching on optical tweezers focused on the equilibrium positions of the ions which are affected by the gates $U_4$ and $U_5$.**
The dynamical reconfiguration of the optical tweezer array can cause heating by exciting phonon modes. Crucially, throughout the switching process, the phonon spectrum remains gapped, i.e., the smallest phonon frequency is larger than zero as in the right panel in Fig. 3(c), and heating is suppressed if the switching is performed adiabatically with respect to the phonon gap. Based on adiabatic perturbation theory, we derive conditions for adiabaticity for the worst-case scenario of an infinite ion chain in Appendix D. In this derivation, we assume for simplicity that all phonon modes are cooled to their ground state. We consider a switching protocol in which initially the first two ions within each unit cell of size $p$ are pinned, and at the end of the protocol the second and third ion are pinned. That is, during a time $\tau_s$, optical tweezers on the first and third ion are simultaneously switched off and on, respectively.

This process is adiabatic, i.e., the excitation of phonon modes is suppressed, if $\omega_2\tau_s \gg 8$ for $p = 4$ and $\omega_2\tau_s \gg 11$ for $p = 6$, for $\epsilon = 0.07$ and $\nu_0 = 0.4$. Consequently, the switching time can be much shorter than the gate duration, which is $\omega_2\tau \approx 1400$ for gates with minimal control for the same values of $\epsilon$ and $\nu_0$. Therefore, the total time it takes to execute a quantum circuit is dominated by the time for gate operations. Even shorter switching times are permissible for smaller values of $\nu_0$ and larger values of $\epsilon$.

V. OPTIMIZED TWEEZER GATES

The optimal choice of detunings and gate durations described above enables the implementation of parallel entangling tweezer gates in finite and infinite ion chains with a simple laser pulse. However, the density of the resulting quantum circuits is restricted by crosstalk. This limitation can be overcome and dense circuits as shown in Fig. 8 can be realized with techniques of optimal coherent control where all phonon modes are cooled to their ground state.

To optimize the operation of parallel entangling gates, we consider here the temporal modulation of the amplitudes of the laser pulses which drive the gates [27, 42, 44, 57–59]. Originally, optimization of the amplitude shape was devised to implement fast gates with high fidelity. Our focus here is on suppressing crosstalk in order to implement circuits with high density and fidelity. The control problem to be solved can be stated in terms of two conditions: The first condition reads $\chi_{i,i'} = \chi_{i,i'}^0$, where we set $\chi_{i,i'}^0 = -\pi/4$ for $(i,i') \in I$ and $\chi_{i,i'}^0 = 0$ for $(i,i') \in I'$, and where the sets of pairs of ions $I$ and $I'$ are defined as in Eqs. (7) and (12). The second condition, $\alpha_i^n = 0$, ensures that there is no infidelity due to residual entanglement between qubits and phonon modes. To meet these conditions, we introduce as independent control parameters a variable number $S$ of pulse amplitudes $\Omega_i^n$ and detunings $\mu_i$ for ions $i \in \{1, \ldots, N\}$. Specifically, the laser pulse which affects ion $i$ with detuning $\mu_i$ is divided into $S$ segments of equal duration with constant pulse amplitude $\Omega_i^n$ within a segment such that $\Omega_i(t) = \Omega_i^n$ for $(s-1)\tau/S \leq t < s\tau/S$. If both of the above conditions are satisfied exactly, the implemented gate $U$ in Eq. (3) is identical to the ideal gate $U_0$ in Eq. (7). In practice, however, it is not possible to find exact solutions of this control problem. Instead, we search for approximate solutions by formulating the above conditions as an unconstrained optimization problem, i.e., we formulate a cost function $L$ which has to be minimized with respect to $\Omega_i = (\Omega_i^1, \ldots, \Omega_i^S)$ and $\mu_i$ for given $\tau$. A minimum with $L = 0$ would correspond to an exact solution of the control problem.

The definition of a cost function $L$ is not unique and we work with the choice $L = L_X + L_\alpha$, where

$$L_\alpha = \sum_{i=1}^{N} \left( \sum_{n=1}^{N} \alpha_i^n \right)^2, \quad L_X = \sum_{(i,i') \in J} \left( \chi_{i,i'} - \chi_{i,i'}^0 \right)^2,$$

(23)

and $J$ is a set of ion pairs which is specified below. $L_X$ corresponds to the simplest polynomial in Rabi frequencies which has a minimum with $L_X = 0$ at $\chi_{i,i'} = \chi_{i,i'}^0$. The square in the definition of $L_\alpha$ ensures that $L_\alpha$ is a polynomial of Rabi frequencies of the same order as $L_X$. More details can be found in Appendix E.

We consider now an infinite chain which is subdivided by optical tweezers into unit cells of size $p = 4$. Our goal is to perform entangling gates on both the set of pinned ions as well as the set of ions which are not pinned to realize a maximally dense quantum circuit as illustrated in Fig. 9. Crosstalk between these two sets of ions is suppressed through the small spatial overlap of the respective phonon modes. Therefore, we minimize the cost function for both sets independently, and we calculate
the infidelity and crosstalk which result from performing the independently optimized gates simultaneously a posteriori.

To suppress crosstalk within each set of ions, it is sufficient to allow for only a small number $G$ of independent sequences of Rabi frequencies $\Omega_i$: First, we choose the sequences of Rabi frequencies to be the same for two neighboring pinned or not pinned ions, i.e., we set $\Omega_{2i-1} = \Omega_{2i}$. Second, since crosstalk is negligible for sufficiently distant pairs of ions, we limit the “active” suppression of crosstalk through the minimization of $L$ to a group of $G$ neighboring pairs of ions within each subset. The resulting $G$ independent sequences $\Omega_i$ are applied periodically in space, that is, we set $\Omega_i = \Omega_i + G$. Thus, for gates on pinned ions, the set $J$ in Eq. (23) contains pairs $(i, i')$ for which the first is any one of the pinned ions up to unit cell $G$, $i \in \{1, 2, 5, 6, \ldots, 4G - 3, 4G - 2\}$ and $i'$ runs over all ions to the right of $i$. For gates on ions which are not pinned, the first ion $i$ in $(i, i')$ is in the set $i \in \{3, 4, 7, 8, \ldots, 4G - 1, 4G\}$ and again $i'$ runs over all ions to the right of $i$.

The gate optimization for infinite systems is illustrated in Fig. 9 for $\omega_{x, \tau} = 1500$, $S = 8$, and $G = 4$. Panel 9(a) shows the mode spectrum for $p = 4$ with COM and stretch bands both for the set of pinned and not pinned ions. We minimize $L$ independently for both sets of ions for detunings $\mu$ in ranges indicated by blue shaded areas. Panel 9(b) shows the corresponding values of the cost function as the detuning is varied. The optimal detuning for each set is determined by the global minimum of $L$. Panel 9(c) shows the optimal sequences of Rabi frequencies both in the time domain and in discrete Fourier space. The Fourier representation is defined as

$$\tilde{\Omega} = F\Omega, \quad F_{s,s'} = \frac{1}{\sqrt{S}} \sin(\pi s (s' - 1/2)/S),$$

which corresponds to a discrete sine transform. Interestingly, the Fourier representations of the optimal pulse sequences are first of all dominated by few Fourier modes. Moreover, the dominant Fourier modes alternate along the ion chain, with a pulse sequence which contains only odd Fourier components being followed by a sequence that is composed of even Fourier components and vice versa. This observation hints at a mechanism to suppress crosstalk which is akin to refocusing circuits [60, 61]. We stress that this mechanism is “discovered” here by an unbiased optimization algorithm.

If the independently optimized sets of gates are performed simultaneously, we find an average over/underrotation error and crosstalk per gate of $\sigma \approx 2.3 \times 10^{-7}$ and $C \approx 2.2 \times 10^{-3}$, respectively, and an average infidelity of $\delta F \approx 3.3 \times 10^{-4}$. While the infidelity is comparable to the results presented in Sec. IV A, crosstalk is significantly lower even though we consider here entangling gates acting on all ions in parallel. The values of the infidelity and crosstalk as well as the gate speed can be improved further by increasing the number of segments $S$ and the number of independent gates $G$. As noted above, this will lead to a concomitant increase of the required maximum Rabi frequency, which sets a limit on the achievable gate performance. At the same time, the complexity of the optimization problem as determined by the number of independent parameters grows linearly both with $S$ and $G$.

### B. Finite chains

The results of the previous section show that optimal control can successfully be employed in order to implement dense and parallel tweezer gates in a periodic chain of equidistant ions. For this the periodicity of the system is a crucial requirement since then a small number of optimized pulse sequences can be repeated along the chain. We now introduce a method for finite chains that does not require periodicity. The central idea is to employ optimal control techniques given in Ref. [42] in order to independently optimize the infidelities for each tweezer gate and subsequently suppress crosstalk through the choice of laser detunings.

As in the previous section we divide the gate duration into $S$ segments with different but constant Rabi frequencies $\Omega_i^s$ for $s \in \{1, \ldots, S\}$ and ions $i \in \{1, \ldots, N\}$. The authors of Ref. [42] describe how to choose such a sequence of Rabi frequencies in order to implement a single two-qubit gate for given gate duration and laser detuning and with minimal infidelity. Below we extend their ideas to dense quantum circuits of parallel tweezer gates as shown in Fig. 8(b). Our method works as follows: In a first step for each target ion pair $(i, i') \in I$ we determine a set of detunings $\mu$ in the vicinity of the corresponding localized modes for which an optimized pulse sequence yields an infidelity below a certain threshold value $\delta F_{\text{thresh}}$. Secondly we apply an iterative optimization algorithm to choose a detuning $\mu(x, i')$ from each of these sets such that the total crosstalk becomes small for $\mu = (\mu(x, i')|_{i \neq i'}) \in I$. This is done by looping through the target pairs $I$ from the left end of the chain to the right end while applying the following routine: For the first pair, as well as in the case that for a given pair there is no detuning for which $\delta F < \delta F_{\text{thresh}}$, select the detuning that yields the lowest infidelity. Else select the detuning that minimizes crosstalk with all other pairs for which the detuning has already been fixed. Below we choose to iterate the optimization $5$ times which is sufficient to achieve convergence.

In Fig. 10 we show numerical results for a system of $130$ ions with $15$ buffer ions on each side. As in the infinite case we choose $p = 4$ in order to implement a dense circuit consisting of $50$ maximally entangling tweezer gates in parallel, using individual optimal control and the iterative optimization as described above, where we set $\delta F_{\text{thresh}} = 10^{-3}$. As in the previous section we allow $S = 8$ segments for each pulse sequence and we choose a gate duration of $\omega_{x, \tau} = 1500$. This yields an infidelity $\delta F = 10^{-3}$ and a crosstalk $C = 2.77 \times 10^{-4}$ for a max-
Figure 9. Pulse optimization in an infinite chain. (a) Phonon mode spectrum for $p = 4$, $\nu_0 = 0.4$, and $\epsilon = 0.07$. (b) The minimization of the cost function $L$ is performed independently for pinned and not pinned ions. The upper and lower panels show the cost function for optimal sequences of Rabi frequencies for a range of detunings around the COM and stretch bands of pinned and not pinned ions, respectively. (c) For the optimal detunings we show the corresponding $G = 4$ independent sequences of Rabi frequencies both in the time domain and in discrete Fourier space. Purple and green correspond to positive and negative Rabi frequencies respectively. The Fourier representations are dominated by few modes which belong to subspaces of Fourier space which alternate along the chain: A pulse sequence which contains only odd Fourier components is followed by a sequence that is composed of even Fourier components and vice versa.

Figure 10. Pulse optimization in a finite chain. We show the chosen detunings (see main text) to implement a dense circuit of 50 parallel, maximally entangling tweezer gates in a chain of 130 ions with 15 buffer ions on each side ($p = 4$, $\nu_0 = 0.4$, $\epsilon \approx 0.07$). The horizontal lines mark the mode frequencies. We allow $S = 8$ segments and set the gate duration to $\omega_x \tau = 1500$, which requires a maximal Rabi frequency of $\eta_0 \Omega / \omega_x = 0.007$. If higher Rabi frequencies are available one could increase the number of segments for the pulse sequences in order to further improve infidelity or to speed up the gate [42].

### VI. OUTLOOK

In this work, we developed the implementation of scalable parallel gate operations using localized transverse phonon modes generated by optical tweezers. To be concrete, we considered quantum circuits with spatially recurring structures of nearest-neighbor two-qubit gates as illustrated in Figs. 1(d) and 8(b). The dynamical reconfigurability of programmable tweezer arrays enables reshaping phonon modes on the fly. This is a key feature of optical segmentation of ion chains and facilitates the efficient implementation of universal parallelized quantum circuits.

Immediate extensions of the methods developed in this paper are illustrated schematically in Fig. 1(a). First, multi-qubit gates can be performed on subregisters which are separated by “optical tweezer walls” [21]; second, the COM and stretch modes of pairs of distant ions can be used to implement entangling gates for qubits which are not nearest neighbors. Combining these capabilities leads to the realization of 1D quantum networks which connect nodes that correspond to subregisters of long 1D chains. Beyond these opportunities for quantum algorithms
and gate-based digital quantum simulation, designer phonon modes which are shaped through optical potentials open up new possibilities for analog quantum simulation, which can be realized through virtual far off-resonant excitation of phonon modes.

In addition to the applications of optical tweezers in the implementation of quantum gates and the design of Hamiltonians for analog quantum simulation, they also provide new possibilities to tackle challenges on a more fundamental level of quantum hardware design. For example, while we focused here on programming the phonon mode structure for a given configuration of the ion chain, where the equilibrium positions of the ions are fixed by the trapping potential and Coulomb interactions, and tweezers are focused on the equilibrium positions, also the equilibrium positions themselves can be shifted by using optical forces. This enables, e.g., to achieve uniform ion spacings along the chain to facilitate individual control by addressed laser beams for gate operations, and thus provides an alternative to anharmonic potentials [42, 62]. Further, laser cooling of phonon modes can be carried out more efficiently in an ion chain which is divided into subregisters [21].

An interesting question concerns the extension of the methods developed in this paper to 2D and 3D structures [63–65]. Further studies are required to elucidate the interplay between micromotion [66, 67], which is not negligible in specific spatial directions, and the localization properties of phonon modes in higher dimensions.

1D chains of trapped ions which are subject to programmable arrays of optical tweezers.

1. Phonon modes of finite chains

The Hamiltonian for the classical 3D motion of $N$ ions in a harmonic trap reads

$$H_0 = \sum_{i=1}^{N} \left( \frac{p_{i}^2}{2m} + V(r_i) \right) + \frac{e^2}{4\pi\epsilon_0} \sum_{i<i'=1}^{N} \frac{1}{|r_i - r_{i'}|},$$

(A1)

where $r_i = (r_{x,i}, r_{y,i}, r_{z,i})^\text{T} = (x_i, y_i, z_i)^\text{T}$ and $p_i = (p_{x,i}, p_{y,i}, p_{z,i})^\text{T}$ are, respectively, the position and momentum of ion $i$, and the electronic trapping potential is given by $V(r) = \sum_{a \in \{x,y,z\}} \frac{1}{2} m \omega_a^2 r_a^2$. We assume tight confinement in the transverse $x$ and $y$ directions, such that the equilibrium positions $r_{i,0}$ of the ions are along the $z$ axis, $r_{i,0} = (0,0,z_i,0)^\text{T}$, and form a linear 1D chain. If the number of ions $N$ is increased, the axial trapping frequency $\omega_z$ has to be reduced for the linear configuration of the ion chain to remain stable [68–70].

Phonon modes of the ion chain correspond to quantized small-amplitude oscillations of the ions around their equilibrium positions. An expansion of the Hamiltonian Eq. (A1) to second order in $\delta r_i = r_i - r_{i,0}$ leads to

$$H_{0,\alpha} = \sum_{i=1}^{N} \left( \frac{p_{i,\alpha}^2}{2m} + \frac{1}{2} m \omega_{\alpha,i}^2 \delta r_{\alpha,i}^2 \right) + \frac{e^2 s_{\alpha}}{4\pi\epsilon_0} \sum_{1<i'<1}^{N} \frac{\delta r_{\alpha,i} \delta r_{\alpha,i'}}{|z_i,0 - z_{i',0}|^3},$$

(A2)

with $s_x = s_y = 1$ and $s_z = -2$. To this order of the expansion, oscillations of the ions in the transverse $x$ and $y$ directions and the longitudinal $z$ direction decouple. The ions perform harmonic oscillations around their equilibrium positions with local trapping frequencies

$$\omega_{\alpha,i}^2 = \omega_{\alpha}^2 - \frac{e^2 s_{\alpha}}{4\pi\epsilon_0 m} \sum_{i' \neq i}^{N} \frac{1}{|z_i,0 - z_{i',0}|^3}. $$

(A3)

These oscillations are coupled by the residual Coulomb interaction described by the last term in Eq. (A2). To design phonon modes, we consider adjusting the local

### Appendix A: Phonon modes in 1D ion chains with optical tweezers

In the following, we derive phonon mode matrices $M_{\alpha,i}$ and mode frequencies $\omega_{\alpha,i}$ for finite and infinite 1D chains of trapped ions which are subject to programmable arrays of optical tweezers.

1. Phonon modes of finite chains

Phonon modes of the ion chain correspond to quantized small-amplitude oscillations of the ions around their equilibrium positions. An expansion of the Hamiltonian Eq. (A1) to second order in $\delta r_i = r_i - r_{i,0}$ leads to

$$H_{0,\alpha} = \sum_{i=1}^{N} \left( \frac{p_{i,\alpha}^2}{2m} + \frac{1}{2} m \omega_{\alpha,i}^2 \delta r_{\alpha,i}^2 \right) + \frac{e^2 s_{\alpha}}{4\pi\epsilon_0} \sum_{1<i'<1}^{N} \frac{\delta r_{\alpha,i} \delta r_{\alpha,i'}}{|z_i,0 - z_{i',0}|^3},$$

(A2)

with $s_x = s_y = 1$ and $s_z = -2$. To this order of the expansion, oscillations of the ions in the transverse $x$ and $y$ directions and the longitudinal $z$ direction decouple. The ions perform harmonic oscillations around their equilibrium positions with local trapping frequencies

$$\omega_{\alpha,i}^2 = \omega_{\alpha}^2 - \frac{e^2 s_{\alpha}}{4\pi\epsilon_0 m} \sum_{i' \neq i}^{N} \frac{1}{|z_i,0 - z_{i',0}|^3}. $$

(A3)

These oscillations are coupled by the residual Coulomb interaction described by the last term in Eq. (A2). To design phonon modes, we consider adjusting the local

### AUTHOR CONTRIBUTIONS

LS and PZ guided the research based on original ideas proposed by PZ. LS and TO performed the analytical and numerical studies underlying the manuscript. LP, PS and TM contributed the experimental feasibility study, and experimental perspective. The manuscript was written...
trapping frequencies by focusing optical tweezers on the equilibrium positions of the ions as detailed in Sec. III. The optical potential which is generated by the tweezers is described by an additional contribution to the Hamiltonian which reads \( H_1 = \sum_{i=1}^{N} V_{i}^{\text{twz}}(r_i) \), where

\[
V_{i}^{\text{twz}}(r_i) = \frac{1}{2} m \omega_{0,i}^2 \left( \delta r_{x,i}^2 + \delta r_{y,i}^2 \right).
\]  

(A4)

Normal mode coordinates \( \xi_{\alpha,n} \) are introduced via the linear transformation \( \delta \xi_{\alpha,i} = \sum_{n=1}^{N} M_{\alpha,n}^i \xi_n \), where \( M_{\alpha,n}^i \) is the mode matrix which diagonalizes the phonon Hamiltonian \( H_{\text{ph}} = H_0 + H_1 \), i.e., which brings the Hamiltonian to a form that corresponds to decoupled harmonic oscillators with frequencies \( \omega_{\alpha,n} \). The normal-mode oscillations of the ion chain can be quantized by introducing annihilation and creation operators for phonons, \( a_{\alpha,n} \) and \( a_{\alpha,n}^\dagger \), respectively. In terms of these operators, the deviation of ion \( i \) from its equilibrium position can be expressed as

\[
\delta r_{\alpha,i} = \sqrt{\frac{\hbar}{2m}} \sum_{n=1}^{N} \frac{M_{\alpha,n}^i}{\omega_{\alpha,n}} \left( a_{\alpha,n} + a_{\alpha,n}^\dagger \right).
\]  

(A5)

The qubit-phonon Hamiltonian Eq. (1) couples the qubits which are encoded in individual ions to the quantized normal-mode oscillations of the ion chain.

2. Phononic band structure of infinite chains

We proceed to derive the phononic band structure for an infinitely long 1D ion chain with uniform spacing \( d \). The ions are subject to a spatially periodic array of optical tweezers which subdivides the ion chain into unit cells of size \( p \). Within each unit cell, the first two ions are pinned by optical tweezers with trapping frequency \( \omega_0 \), and the remaining \( p-2 \) ions are not pinned as illustrated in Fig. 3(a).

We label the ions by their unit cell \( l \in \mathbb{Z} \) and their position \( i = 1, \ldots, p \) within the unit cell, where the pinned ions correspond to the positions \( i = 1, 2 \). The classical Hamiltonian for small-amplitude oscillations of the ions around their respective equilibrium positions can be written as \( H_{\text{ph}} = \sum_{l \in \mathbb{Z}} H_{\alpha,l} \), where \( H_{\alpha,l} \) is given by the sum of Eq. (A2) and the optical potential in Eq. (A4) in the simultaneous limit \( N \rightarrow \infty \) and \( \omega_z \rightarrow 0 \):

\[
H_{\alpha,l} = \sum_{l \in \mathbb{Z}} \sum_{i=1}^{p} \left( \frac{p_{\alpha,i}^2}{2m} + \frac{1}{2} m \omega_{\alpha,i}^2 \delta r_{\alpha,i}^2 \right)
+ \frac{1}{2} s_{\alpha} \sum_{l,l', i \in \mathbb{Z}, i \neq i'} \delta \alpha, l, i \delta C_{i-l', \alpha, i}^{l', \alpha, i'} \delta r_{\alpha, l', i}.
\]  

(A6)

The local trapping frequency which the ions at position \( i \) within each unit cell experience is given by

\[
\omega_{\alpha,i}^2 = \omega_0^2 - \frac{s_\alpha e^2 \zeta(3)}{2 \pi \epsilon_0 d^3 m} + \omega_{\alpha,0}^2 (\delta_{i,1} + \delta_{i,2}),
\]  

(A7)

where, according to Eq. (A4), \( \omega_{\alpha,0} = \omega_{z,0} = \omega_0 \) and \( \omega_{\alpha,0} = 0 \), and \( \zeta(s) \) is Riemann zeta function. The translationally invariant coupling coefficient \( C_{i}^{l} \) reads

\[
C_{i}^{l} = \begin{cases} 0 & \text{for } l = 0 \text{ and } i = 0, \\ \frac{e^2}{4 \pi \epsilon_0 d^3} \frac{1}{|pl+l'|} & \text{else}. \\
\end{cases}
\]  

(A8)

a. Phononic band structure for periodic tweezer arrays

We seek the normal mode matrix which diagonalizes the potential energy contribution to Eq. (A6). It is convenient to write the latter as \( H_{\text{pot.},\alpha} = \frac{1}{2} m \omega_0^2 V_{\alpha} \), where \( V_{\alpha} \) is dimensionless. For concreteness and to simplify the notation, we focus in the following on oscillations in the \( x \) direction, and we omit the subscript \( \alpha = x \). The normal modes of oscillations in the \( y \) and \( z \) directions can be found analogously.

To account for the translational invariance of the phonon Hamiltonian (A6) in the unit-cell index \( l \), we interpret the coordinates \( \delta x_{l,i} \) as coefficients of a Fourier series, \( c_{k,i} = \sum_{l \in \mathbb{Z}} e^{-i k l} \delta x_{l,i}, \) where \( k \) is analogous to the quasimomentum of an electron in a solid. In terms of the new complex coordinates \( c_{k,i} \), the potential energy reads

\[
V = \int_{-\pi}^{\pi} \frac{dk}{2\pi} \sum_{i,l,i'} \sqrt{\nu_{k,i}} v_{i,i'}^k e^{ikl} c_{k,i'}^*,
\]  

(A9)

where

\[
v_{i,i'}^k = V_l \delta_{i,i'} + J_{i,i'}^k, \quad J_{i,i'}^k = \sum_{l \in \mathbb{Z}} J_l^e e^{-ikl},
\]  

(A10)

with \( V_l = 1 - 2e^2 \zeta(3) + \nu_0^2 (\delta_{i,1} + \delta_{i,2}) \) and \( J_l^e = C_l^e / (m \omega_0^2) \). We next introduce new coordinates \( b_{k,n} = \sum_{l=1}^{p} B_{k,n}^l c_{k,l,i} \), where \( B_{k,n}^l \) is the unitary matrix which diagonalizes \( v_{i,i'}^k \) with eigenvalues \( \nu_{k,n} = \omega_{k,n}/\omega_0 \). While \( V \) is diagonal in terms of the coordinates \( b_{k,n} \), they cannot be interpreted as proper normal mode coordinates because they are complex and not independent: Since \( \delta x_{l,i} \) are real, it follows that \( b_{k,n}^* = b_{-k,n} \). Therefore, we restrict the range of values of the quasimomentum to \( k \in [0, \pi] \), and we decompose \( b_{k,n} \) and \( B_{k,n}^l \) into real and imaginary parts, \( b_{k,n} = 1/\sqrt{2} (\xi_{k,n,1} + i \xi_{k,n,2}) \) and \( B_{k,n}^l = \Xi_{k,n,1}^l + i \Xi_{k,n,2}^l \), to obtain

\[
\delta x_{l,i} = \int_{0}^{\pi} \frac{dk}{2\pi} \sum_{n=1}^{p} \sum_{\lambda=1}^{2} M_{l,i}^{k,n,\lambda} \xi_{k,n,\lambda}.
\]  

(A11)

\( \xi_{k,n,\lambda} \) are the desired real and independent normal mode coordinates, and the normal mode transformation matrices are given by

\[
M_{l,i}^{k,n,1} = \sqrt{2} \left( \cos(kl) \Xi_{k,n,1}^l - \sin(kl) \Xi_{k,n,2}^l \right),
\]

\[
M_{l,i}^{k,n,2} = -\sqrt{2} \left( \cos(kl) \Xi_{k,n,2}^l + \sin(kl) \Xi_{k,n,1}^l \right).
\]  

(A12)
b. Perturbative expansion for strong pinning

For strong pinning $\nu_0 \gg \epsilon$, the matrix $v^k$ can be diagonalized perturbatively in $J^k_i \propto \epsilon^2$. To zeroth order, we obtain two degenerate subspaces which correspond to the ions which are pinned and not pinned. The respective eigenvalues are $1 - 2\epsilon^2\zeta(3) + \nu_0^2$ and $1 - 2\epsilon^2\zeta(3)$, and have degeneracy $2$ and $p - 2$. To obtain the leading corrections to the eigenvalues in degenerate perturbation theory, we omit the elements $v^k$ which couple the degenerate subspaces, whereupon $v^k$ becomes block-diagonal. The matrix $B^k$ that diagonalizes the $2 \times 2$ block of $v^k$ which describes the pinned ions reads

$$B^k \approx \Xi^1 = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}, \quad (A13)$$

where we omit corrections $\sim 1/p^3$ which are small for $p \gtrsim 4$. Evidently, for $p \to \infty$, the modes which form the highest two bands are indeed COM and stretch modes of pairs of pinned ions within each unit cell. The corresponding two $2 \times 2$ blocks of mode matrices in Eq. (A12) are given by $M^{k,1}_i = \sqrt{2}\cos(kl)\Xi^1$ and $M^{k,2}_i = -\sqrt{2}\sin(kl)\Xi^1$. Perturbative corrections to the mode matrices are of order $O(\epsilon^2/\nu_0^2)$. The mode frequencies of the COM and stretch bands are

$$\nu_{k,n} = \sqrt{1 - 2\epsilon^2\zeta(3) + \nu_0^2 + J^k_0 \pm |J^k_i|}, \quad (A14)$$

where $n = 1$ for the COM band and $n = 2$ for the stretch band. The width of these bands is determined by terms in Eq. (A14) which depend on the quasimomentum $k$, i.e., by $J^k_0 \pm |J^k_i|$. For $p \gtrsim 4$, we find

$$J^k_0 + |J^k_i| \sim \epsilon^2 \left( 1 + \frac{4}{p^3} \text{Re}(\text{Li}_3(\epsilon^k)) \right),$$

$$J^k_0 - |J^k_i| \sim -\epsilon^2 \left( 1 + \frac{12}{p^3} \text{Re}(\text{Li}_3(\epsilon^k)) \right), \quad (A15)$$

where $\text{Li}_n(z) = \sum_{n=1}^{\infty} \frac{z^n}{n^n}$ denotes the polylogarithm. That is, the widths of the COM and the stretch bands are suppressed as $1/p^3$ and $1/p^5$, respectively. For $p \to \infty$, these bands become flat with frequencies

$$\nu_n = \sqrt{1 - 2\epsilon^2\zeta(3) + \nu_0^2 \pm \epsilon^2}. \quad (A16)$$

In this limit, pairs of pinned ions are completely decoupled, and the corresponding modes are strictly local within unit cells.

Appendix B: Experimental feasibility study

Here we study the experimental feasibility of the proposed scheme to perform tweezer-assisted parallel gates in a trapped-ion quantum device. We consider both optical and ground-state qubit encodings for different ionic species. A significant contribution to the infidelity of tweezer gates is due to scattering of photons of the optical tweezers. In the following, we discuss how the choice of qubit encoding and wavelength of the optical tweezer lasers affects the spontaneous scattering rate and therefore the infidelity of the gate.

Our discussion is based on the following model for the interaction of an optical tweezer beam with a trapped ion: The dipole potential induced by the optical tweezer is given by [71]

$$U_{\text{dip}}(r) = -\frac{1}{2\epsilon_0 c} \text{Re}(\alpha) I(r), \quad (B1)$$

where $\epsilon_0$ is the vacuum permittivity, $c$ is the speed of light, $I(r)$ is the intensity of the tweezer beam at position $r$, and $\alpha$ is the polarizability of the internal state of the ion. In general, the polarizability is different for the two states which encode the qubit. Therefore, a question we have to address below is how to ensure that both qubit states experience the same optical potential.

The scattering rate in the center of the Gaussian tweezer beam with frequency $\omega$, for a transition with resonance frequency $\omega_0$ and linewidth $\Gamma$, is [71]

$$\Gamma_{\text{sc}}(\omega) = \frac{3c^2}{\hbar \omega_0^3} \left( \frac{\omega_0^2}{\omega_0^2 + \Gamma} \right)^2 \frac{P}{W_0^2}, \quad (B2)$$

with the total light power $P$ and the beam waist $W_0$. For a tightly focused beam with wavelength $\lambda$, the beam waist is approximately given by [72]

$$W_0 \approx 0.41 \times \frac{\lambda}{NA}, \quad (B3)$$

where $NA$ is the numerical aperture of the focusing optics. All following estimations are carried out assuming $NA = 0.7$, as shown in Ref. [73] in an ion-trapping experiment. Scattering rates from different transitions are summed up, whereas their trap potential partially cancels if the sign of the detuning $\omega_0 - \omega$ is opposite.

For a given spontaneous scattering rate $\Gamma_{\text{sc}}$ and gate duration $\tau$, the infidelity of the gate due to scattering of light can be estimated as [74]

$$\delta F_{\text{sc}} = \frac{3}{2} \Gamma_{\text{sc}} \tau. \quad (B4)$$

1. Ground state qubit encoding

A first approach to ensure that both qubit states experience the same optical potential is to encode both of them in the ground state of the ion [4]. In this case, the AC-Stark shift for $\pi$-polarized light is not state dependent, and the tweezer wavelength can be varied over a broad range. We consider the species $^{24}\text{Mg}^+$, $^{40}\text{Ca}^+$, $^{88}\text{Sr}^+$, $^{138}\text{Ba}^+$ and $^{171}\text{Yb}^+$, which are used in experiments targeting quantum information processing [4].
For all investigated ionic species, we only consider contributions to the optical trapping and to spontaneous scattering from the $S$ to $P$ transitions with linewidths of several MHz [75]. In Fig. 11, we show the infidelity $\delta F_{\text{sc}}$ as a function of the tweezer wavelength. The infidelity exhibits a single minimum, which lies in between a regime at short wavelengths near the resonance and a regime at long wavelengths, for which the beam waist (B3) and, therefore, the required power to reach the strong pinning regime increases. Here we set $\epsilon = 0.07$ and $\nu_0 = 0.4$ as in the examples considered in the main text. This results in $\nu_0^2/\epsilon^2 \approx 32$, deeply in the regime of strong pinning. The gate time is estimated according to Eqs. (A16) and (18).

The lowest infidelities can be achieved for $^{24}\text{Mg}^+$ followed by $^{40}\text{Ca}^+$. For $^{24}\text{Mg}^+$ ions in a trap with transverse trapping frequency $\omega_x = 2\pi \times 3 \text{ MHz}$ and a tweezer wavelength of 400 nm, the contribution of spontaneous scattering to the infidelity is $\delta F_{\text{sc}} \approx 4.9 \times 10^{-3}$. The corresponding inter-ion distance is $d = 15 \mu\text{m}$. The infidelity caused by spontaneous scattering can be reduced by either increasing $d$ and increasing $\omega_x$ (see Fig. 12), with the downside of increased heating rates [76], or by relaxing the condition on being in the strong trapping regime, which leads to higher infidelities from other sources (see Fig. 5). For $\epsilon = 0.07$ and $\nu_0 = 0.2$, a scattering-induced infidelity of $\delta F_{\text{sc}} \approx 1.2 \times 10^{-3}$ can be achieved. For the same values of $\omega_x$, $\epsilon$ and $\nu_0$, the infidelity for $^{40}\text{Ca}^+$ ions is $2.8 \times 10^{-3}$ with $d = 12.6 \mu\text{m}$ and a tweezer wavelength of 532 nm. The required power of the optical tweezers is on the order of a couple of mW for both species.

Figure 11. Infidelity due to spontaneous scattering for $\epsilon = 0.07$, $\nu_0 = 0.4$ and $\omega_x = 2\pi \times 3 \text{ MHz}$ for different atomic species. The steep slope at short wavelengths is caused by the excessive scattering close to the resonance of the $S \leftrightarrow P$ transition. At long wavelengths, the infidelity increases due to an enlarged spot-size for a diffraction limited spot for the assumed numerical aperture.

Figure 12. Spontaneous scattering infidelity for parallel gates performed on $^{24}\text{Mg}^+$ ground-state qubits with 400 nm tweezer wavelength for varying ion distance $d$ and radial trap frequency $\omega_x$. By choosing $d$ and $\omega_x$, $\epsilon$ is fixed, and $\nu_0$ is determined in order to reach the strong pinning regime. The gray region marks parameter combinations that lead to a zigzag configuration of the ion string.

2. Optical qubit encoding

For an optical qubit, the qubit levels are encoded in two different electronic states. An apparent approach to ensure equal optical trapping potentials for both qubit states is to choose the tweezer wavelength as a magic wavelength with respect to the transition between the two qubit states. However, the polarizabilities of $^{40}\text{Ca}^+$, $^{88}\text{Sr}^+$ and $^{138}\text{Ba}^+$, which are commonly used species for optical qubits [4], are low at the respective magic wavelengths [77] and, therefore, high light intensities are required to achieve sizeable optical trapping potentials. Unfortunately, the concomitant increase of spontaneous scattering rates leads to relatively high infidelities.

In particular, magic wavelengths in between the $S_{1/2} \leftrightarrow P_{1/2}$ and the $S_{1/2} \leftrightarrow P_{3/2}$ transitions have small detunings from broad transitions, which leads to scattering rates in the regime of hundreds of kHz. Performing gates with typical gate times $\tau$ on the order of tens to hundreds of $\mu\text{s}$ is therefore rendered impossible.

For the abovementioned species, there also exists a set of magic wavelength that is red detuned from all relevant transitions [77]. For $^{40}\text{Ca}^+$, this wavelength is at 1271 nm and therefore has a detuning of over 400 nm to the nearest relevant transition. Using tweezers at this magic wavelength yields lower scattering rates of hundreds of Hz. However, the resulting infidelities are still in the $10^{-1}$ regime.

An alternative way to reduce the infidelity due to scattering is to use two superimposed tweezer beams at different wavelength to trap each of the two qubit states individually. On the one hand, the gained flexibility with regard to the choice of wavelength could allow for low
scattering rates while keeping the required power reasonable, but on the other hand additional experimental challenges would come into play. In particular, to avoid gate errors due to decoherence of the qubit induced by differential trapping potential fluctuations of the two qubit states, precise control over both the power in the tweezer beams as well as the positioning of the tweezers is required.

Appendix C: Tweezer misadjustments

In section IV D in Eq. (22) we state the optical potential that is generated by a misadjusted optical tweezer. Here we describe how we calculate the effect of the shifts of the tweezer focuses. First note that since the optical potential is at most quadratic in the shifts of the tweezers, these shifts affect the modes of the ions only through the corresponding shifts in the equilibrium positions of the ions. We determine these shifts numerically up to second order in the shifts before averaging over several Gaussian realizations as before. To this end we expand the gradient of the total potential for a total number of $N$ ions

$$
\nabla \xi V = \sum_m \delta_m (\partial_{\delta_m} \nabla \xi V) \mid_{\xi_0} + \frac{1}{2} \sum_{m,n} \delta_m \delta_n (\partial_{\delta_m} \partial_{\delta_n} \nabla \xi V) \mid_{\xi_0} \quad (C1)
$$

where $\xi = \xi_0 + X_1 \delta + (\delta^T X_2 \delta)$ with $\xi^{(0)} = (x_1^{(0)}, x_2^{(0)}, \ldots, y_1^{(0)}, \ldots, y_N^{(0)})$ the equilibrium positions of the ions without tweezers, $\delta = (\delta_{x1}, \delta_{x2}, \ldots, \delta_{x_N})$ the shifts of the tweezer focuses and $3N \times 3N$-matrices $X_1$, $(X_2^n)_{n=1}^{3N}$ that determine the new equilibrium positions from the shifts. From the condition $\nabla \xi V = 0$ to all orders we obtain

$$
D = 0 \iff X_1 = H^{-1} P 
$$

where $H_{ij} = (\partial_{\xi^i} \partial_{\xi^j} V) \mid_{\xi_0}$ and $P_{ij} = (\partial_{\xi^i} \partial_{\xi^j} V) \mid_{\xi_0}$. The second order yields

$$
W = 0 \iff X_2 = H^{-1} b 
$$

where $X_2 = (X_2^n)_n$ and $b = (\frac{1}{2} X_1^T \partial_x H_n X_1)_n$ are vectors whose elements are matrices with $H_r = \partial_{\xi^r} H$. Hence the multiplication with $H^{-1}$ gives a linear combination of matrices for each element of $X_2$.

Appendix D: Adiabatic switching of tweezer arrays

Here we derive an estimate, based on adiabatic perturbation theory, for the excitation of phonons due to the switching of optical tweezers. We consider the switching protocol described by the phonon Hamiltonian (A6) with time-dependent local oscillation frequencies,

$$
\tilde{\omega}_{\alpha,i}^2 = \omega_{\alpha,i}^2 - \frac{s_n e^{2\zeta}(3)}{2\pi \epsilon_0 d^3 m} \left( 1 - x \right) \delta_{i,1} + \delta_{i,2} + \delta_{i,3},
$$

(D1)

which depend linearly on the parameter $s = t/\tau_s$ that varies between zero and one, and where $\tau_s$ denotes the switching time. At the beginning of the protocol at $s = 0$, the ions at positions $i = 1, 2$ are pinned. At the end of the protocol, the optical potential on the ion at site $i = 1$ is switched off, and the ions at positions $i = 2, 3$ are pinned.

The instantaneous eigenstates and energies of the phonon Hamiltonian obey $H_{ph}(s) \mid n(s) \rangle = E_n(s) \mid n(s) \rangle$, where for simplicity we label the states with a single index $n \in \mathbb{N}_0$. To obtain an estimate of the excitation of phonons, we assume that all phonon modes are initially cooled to their ground state. The transition probability to an excited state $n > 0$ is given by [78]

$$
P_{0 \rightarrow n} \sim \frac{1}{\tau_s^2} \left( \left| \langle n \mid \partial_s H_{ph}(0) \rangle \right|^2 + \left| \langle n \mid \partial_s H_{ph}(0) \rangle \rangle \left( E_n - E_0 \right)^4 \right|_{s=0}^{s=1} \right),
$$

(D2)

and the total probability to excite phonon modes is $P = \sum_{n \neq 0} P_{0 \rightarrow n}$. By evaluating the matrix elements of the phonon Hamiltonian explicitly, we find

$$
P = \frac{1}{2} \left( \frac{\omega_x}{\tau_s} \right)^2 \times \sum_{\alpha \in \{x,z\}} \int_0^\pi \frac{dk}{2\pi} \sum_{n,n'=1}^N A_{n,n'}^2 \left( A_{n,k}^{(s=0)} + A_{n,k}^{(s=1)} \right),
$$

(D3)

where, for $\alpha \in \{x, z\}$,

$$
A_{n,n'} = \frac{\omega_x^2}{(\omega_x + \omega_{x,n})^4} \sum_{\lambda,\lambda'=1}^{2} \left( c_{\alpha,\lambda,\lambda'} \right)^2,
$$

(D4)

and

$$
c_{\alpha,\lambda,\lambda'} = \frac{\omega_x^2}{2\sqrt{\omega_{x,n}\omega_{z,n}}}(W_{\alpha,3}^{\lambda,\lambda',k,n,n'} - W_{\alpha,1}^{\lambda,\lambda',k,n,n'}),
$$

(D5)

with

$$
W_{\alpha,3}^{\lambda,\lambda',k,n,n'} = \frac{\omega_x}{\omega_{x,n}} \frac{\omega_{z,n}}{\omega_{z,n}} \frac{\omega_{z,n}}{\omega_{z,n}} \frac{\omega_{z,n}}{\omega_{z,n}}
$$

(D6)

These expressions yield the estimates stated in the main text in Sec. IV E.

Appendix E: Entangling gates with time-modulated Rabi frequencies

Here we specialize Eqs. (5) and (6) which determine the entangling gate Eq. (3) to time-modulated Rabi frequencies [42].
1. Finite chains

The qubit-phonon coupling (5) can be written as \( \alpha_i^n = A_i^n \cdot R_i \), where the dimensionless Rabi frequency is given by \( R_i = \eta_0 \Omega_i / \omega_x = (R_1, \ldots, R_N) \) with the parameter \( \eta_0 \) defined in Eq. (20), and where \( A_i^n = -i \sqrt{\omega_x / \omega_n} \Omega_i^\dagger g_{i,n} \). Further, the qubit-qubit coupling (6) can be written as \( A_{i,i'} = R_i^\dagger X_{i,i'} R_{i'} \), where \( X_{i,i'} = \sum_{n=1}^N (\eta_0^i \eta_0^{i'})^p g_{i,n} g_{i',n}^\dagger \). \( A_{i,i'} \) is an \( S \times S \) matrix with elements

\[
A_{i,i'} = \sum_{n=1}^N (\eta_0^i / \eta_0^{i'}) g_{i,n} g_{i',n}^\dagger \quad \text{for } s' > s,
\]

\[
A_{i,i'}^F = \sum_{n=1}^N (\eta_0^i / \eta_0^{i'}) g_{i,n} g_{i',n}^\dagger \quad \text{for } s' = s
\]

In terms of the vectors \( A_i^n \), the infidelity per gate Eq. (11) can be written as \( \delta F = \frac{1}{2} \sum_{i=1}^N R_i^\dagger \Phi_i R_i \), where \( \Phi_i^{s,s'} = \frac{8}{5} \sum_{n=1}^N \text{Re} \left( (A_i^n)^* A_i^n_{s,s'} \right) \).

2. Infinite chains

In infinite ion chains, the qubit-qubit coupling can be written as \( \chi_{i,i'}^{k,n} = R_i^\dagger X_{i,i'}^k R_{i'}^{n,n} \), where

\[
X_{i,i'}^{k,n} = 2 \int_0^\pi \frac{dk}{2\pi} \sum_{n=1}^P \frac{\omega_x}{\omega_k} \left[ \cos(k (l - t')) \left( \xi_{i,k,n,1}^k \xi_{i,k,n,2}^k + \xi_{i,k,n,1}^k \xi_{i,k,n,2}^k \right) \right] f_{i,n}^{i,k,n} \]

To obtain \( X_{i,i'}^{k,n} \), we approximate the integral over \( k \in [0, \pi] \) by a discrete Riemann sum, and we calculate the matrices \( \Xi_{i,k,n}^{k,n} \) and the phonon mode frequencies \( \omega_k \) for each discrete value of \( k \) numerically as described in Appendix A.

Similarly, for the matrix \( \Phi_i^{k,n} \) which determines the infidelity per gate we find

\[
\Phi_i^{k,n} = \frac{32}{5} \sum_{n=1}^N \sqrt{\omega_k} \sum_{k,n}^2 (\Xi_{i,k,n}^{k,n,2})^2 \times \text{Re} \left( (g_{i,n}^{k,n} g_{i,n}^{k,n})^* \right). \]
