We analyze the quantum discord $Q$ throughout the low-temperature phase diagram of the quantum XY model in transverse field. We first focus on the $T = 0$ order-disorder quantum phase transition both in the symmetric ground state and in the symmetry broken one. Besides it, we highlight how $Q$ displays clear anomalies also at a non critical value of the control parameter inside the ordered phase, where the ground state is completely factorized. We evidence how the phenomenon is in fact of collective nature and displays universal features. We also study $Q$ at finite temperature. We show that, close to the quantum phase transition, $Q$ exhibits quantum-classical crossover of the system with universal scaling behavior. We evidence a non trivial pattern of thermal correlations resulting from the factorization phenomenon.

I. INTRODUCTION

Correlations provide a characterization of many-body systems. In the quantum realm both classical and non local quantum correlations (like entanglement) are relevant. Although entanglement completely describes quantum correlations for pure states, it is in general subter to characterize the pattern of correlations for mixed states. Indeed the quantitative interplay between classical and quantum correlations has been formulated only recently with the introduction of the quantum discord, operatively defining quantum correlations in composite systems. In this context, intense research activity has been devoted to spin models, generically displaying non trivial patterns of correlations in different interesting regimes.

Two peculiarities are relevant here: on one hand, the order-disorder Quantum Phase Transitions (QPT) occurring at zero temperature as long as the control parameter $h$ is tuned across a critical value $h_c$. It is worth noting that the quantum order arises because superselection rules lead to a symmetry breaking. Besides QPT, spin systems may exhibit a further remarkable phenomenon occurring at $h = h_f$ located within the ordered symmetry-broken phase, where the ground state is exactly factorized, and therefore correlations are exclusively classical. Such factorization consists in a quantum transition exclusively for entanglement and is rigorously not accompanied by any change of symmetry.

In this article we provide the details of the analysis of the quantum discord arising in the quantum XY spin-1/2 system, both at zero and at finite temperature. In particular we consider the ground state with broken symmetry. We analyze the quantum discord both at the QPT and close to $h_f$. We evidence how the quantum criticality affects the quantum discord at low-temperature, allowing to define the quantum cross-over phenomena in an operative way. Close to the factorizing point, the finite-temperature quantum discord displays characteristic traits.

The structure of this paper is as follows. In Sec. I we give an overview on the notions of quantum and classical correlations in a general quantum system. In Sec. II we introduce a many body system that is suitable for our type of analysis: the XY model in an external transverse field. We also present some features related to its physics and to the way in which correlations are evaluated. The analysis of our results is carried out in the subsequent sections, first for the zero-temperature case and then when the temperature is switched on. Finally in Sec. VII we draw our conclusions.

II. QUANTUM, CLASSICAL AND TOTAL CORRELATIONS

In a bipartite quantum system $AB$ the total amount of correlations between $A$ and $B$ is given by the mutual information

$$I(A : B) \equiv S(\hat{\rho}^A) + S(\hat{\rho}^B) - S(\hat{\rho}^{AB}),$$

where $S(\hat{\rho}) = -\text{Tr}[\hat{\rho} \log_2 \hat{\rho}]$ is the von Neumann entropy. In classical information, using the Bayes rule, an equivalent formulation of the mutual information is

$$\mathcal{J}(A : B) \equiv S(A) - S(A|B),$$

where the conditional entropy $S(A|B) = S(AB) - S(B)$ quantifies the ignorance on part $A$ once a measurement on $B$ is performed. In the quantum realm, a measurement generally perturbs the system and part of the information itself is lost. Therefore, when we consider a quantum composite system, Eq. (2) differs from Eq. (1). This difference allows us to estimate the relative role of quantum and classical correlations in composite systems.

As a matter of fact, if we describe a measurement on part $B$ by a set of projectors $\{\hat{B}_k\}$, then

$$\hat{\rho}_{(k)}^{AB} = \frac{1}{p_k} (\mathbb{1}_A \otimes \hat{B}_k) \hat{\rho}^{AB} (\mathbb{1}_A \otimes \hat{B}_k)$$

arXiv:1112.0361v1 [cond-mat.stat-mech] 1 Dec 2011
is the composite state conditioned to the k-th outcome with probability $p_k = \text{Tr}[(\mathbb{1}_A \otimes B_k) \hat{\rho}^{AB}(\mathbb{1}_A \otimes B_k)]$. This conditioned state is the key ingredient which allows to distinguish between classical and quantum correlations: in fact it generally differs from the pre-measurement state $\hat{\rho}^{AB}$, as well as the mutual information differs from classical correlations. A reasonable definition of classical correlations $C$ then comes by finding the set of measurements on $\{B_k\}$ that disturbs the least the part A, i.e. by maximizing $[2, 3]$:

$$C(\hat{\rho}^{AB}) \equiv \max_{\{B_k\}} \left[ S(\hat{\rho}^A) - S(\hat{\rho}^{AB}|\{B_k\}) \right]. \quad (4)$$

The difference between mutual information and classical correlations defines the so called quantum discord:

$$Q(\hat{\rho}^{AB}) \equiv \mathcal{I}(A : B) - C(\hat{\rho}^{AB}). \quad (5)$$

In the estimate of quantum correlations between subsystems of a bipartite system, entanglement has been playing a leading role, in particular about the relevance of correlations in many body systems. However in general quantum discord differs from entanglement: for example, even if they are the same for pure states, they can display a very different behavior in mixed states.

III. THE XY MODEL IN TRANSVERSE FIELD

Hereafter we will focus on an interacting pair of spins 1/2 in the anti-ferromagnetic XY chain with transverse field $h$. The Hamiltonian of the model

$$\hat{\mathcal{H}} = -\sum_j \left( \frac{1 + \gamma}{2} \hat{\sigma}_j^x \hat{\sigma}_{j+1}^x + \frac{1 - \gamma}{2} \hat{\sigma}_j^y \hat{\sigma}_{j+1}^y + h \hat{\sigma}_j^z \right) \quad (6)$$

describes the competition between two parts: the nearest neighbor anisotropic interaction on the $xy$ plane, with an anisotropy tuned by varying $\gamma \in (0, 1]$, and the coupling with external magnetic field $h$ along the $z$ direction (throughout this paper we set $h = k_B = 1$). Using a set of successive transformations (Jordan-Wigner, Bogoliubov, Fourier [17]), the Pauli matrices operators $\hat{\sigma}_j^\alpha$ ($\alpha = x, y, z$) on sites $j$ can be expressed in terms of operators such that the Hamiltonian takes the diagonal form

$$\hat{\mathcal{H}} = -\sum_k \Lambda_k \hat{\eta}_k^i \hat{\eta}_k + \text{const}. \quad (7)$$

The system is thus described as a gas of non interacting fermionic quasiparticles, where $\eta_k^i$ ($\eta_k$) is the creation (annihilation) operator of a fermion with momentum $k$. Furthermore, the Jordan-Wigner transformation allows an analytic expression for the correlation functions $g_{\alpha\alpha}(r) = \langle \hat{\sigma}_j^\alpha \hat{\sigma}_{j+r}^\alpha \rangle$ of any two spins in the chain far $r$ sites from each other [18].

The exact solution of the XY model encouraged a plethora of studies concerning its critical phenomena [18] [19]. In particular, during the last decade, new insight has been made in the description of the physics of the system through the analysis of quantum correlations (i.e. entanglement) [4].

A. The Phase Diagram

The phase diagram of the XY model is marked by two peculiar values of the applied field $h$ [3] [11] [13]. For $\gamma \in (0, 1]$ the system displays a zero-temperature ($T = 0$) continuum QPT at $h_c = 1$, of the Ising universality class with critical indices $\nu = z = 1$, $\beta = 1/8$ [11]. In fact, for strong enough external fields ($h \geq h_c$) all the spins tend to be aligned along the $z$ direction, while the opposite limit ($h \ll h_c$) gives rise to a spontaneous magnetization (with $Z_2$ symmetry broken) along a direction on the $xy$ plane, that is $\gamma$-dependent. At zero temperature, on the left side $h < h_c$ of the phase diagram the system is an ordered ferromagnet and the $Z_2$ symmetry is broken, while on the right side $h > h_c$ quantum fluctuations lead to a disordered phase where the system is a quantum paramagnet. At finite temperature $T > 0$ the physics of the whole system is still affected by the QCP $h = h_c$ at zero temperature. A $V$-shaped diagram in the $h - T$ plane emerges, characterized by the straight lines $T = |h - h_c|$ that mark the crossover region between the so called quantum critical region ($T > |h - h_c|$) and the quasi-classical regions surrounding it [11].

Besides the QCP, there is another value of the transverse field that characterizes the zero-temperature phase diagram of the XY model. Indeed it has been found that, at zero temperature and at a certain anisotropy $\gamma$, for $h = h_f = \sqrt{1 - \gamma^2}$ the ground state is exactly factorized [13]:
physics involved and hence in our understanding of it. In particular it seems that the interplay of correlations when the field is tuned across $h_f$ is the only accessible way, so far, to tackle the puzzling physics that leads to the factorized state of Eq. [5]. Here we show that the quantum discord allows a fine structure of the phase diagram around $h_c$, and, most remarkably, it displays a non trivial scaling law at the factorization field $h_f$.

IV. CLASSICAL AND QUANTUM CORRELATIONS IN THE XY MODEL

In order to compute $Q_r$ between any two spins $A$ and $B$ at distance $r$ along the chain, the key ingredients are the single-site density matrices $\hat{\rho}^A, \hat{\rho}^B$ and the two-site density matrix of the composite subsystem $\hat{\rho}^{AB}$ [see Eq. (5)]. Due to translational invariance along the chain, single-site density matrices are the same for any spin and they are given by

$$\hat{\rho}^A = \hat{\rho}^B = \frac{1}{2} \left( \begin{array}{cc} 1 + g_z & g_x \\ g_x & 1 - g_z \end{array} \right),$$

(9)

where $g_a = \langle \hat{\sigma}_a \rangle$ are the local expectation values of the magnetization along the three different axes. On the other hand, the expression of $\hat{\rho}^{AB}$ may be cumbersome. In fact, the general two-site reduced density matrix for a Hamiltonian model with global phase flip symmetry has the following form [21]:

$$\hat{\rho}_r = \frac{1}{4} \left( \begin{array}{cccc} A & a & a & F \\
a & B & C & b \\
a & C & B & b \\
F & b & b & D \end{array} \right)$$

(10)

in the basis $\{|00\}, |01\}, |10\}, |11\}$, where $|0\rangle$ and $|1\rangle$ are eigenstates of $\hat{\sigma}^z$ (because of translational invariance, this density matrix depends only on the distance $r$ between the two spins: $\hat{\rho}_r \equiv \hat{\rho}^{AB}$). The various entries in Eq. (10) are related to the two-point correlators $g_{ij}(r) = \langle \hat{\sigma}_{ij} \hat{\sigma}_{j+r} \rangle$ and to the local magnetizations, according to the following:

$$A = 1 + g_z + g_{zz},$$

$$D = 1 - g_z + g_{zz},$$

$$B = 1 - g_z,$$

$$C = g_{xx} + g_{yy},$$

$$F = g_{xx} - g_{yy}$$

(11)

express the parity coefficients, while

$$a = g_x + g_{zz},$$

$$b = g_x - g_{zz}$$

(12)

explicit the contribution from the symmetry breaking.

As long as the system is in the $Z_2$-symmetric phase, matrix elements in "low case" are null ($a = b = 0$). The symmetry breaking manifest itself in $a, b \neq 0$ [21].

In the former case, the remaining non vanishing "upper case" entries in Eq. (11) can be evaluated analytically [15], therefore we could use a fully analytical approach to compute the quantum discord in the so called thermal ground state [6]. In this state the system approaches the ground state by lowering the temperature towards the limit $T = 0$; for this reason the symmetry is conserved and the state is not in the "true" degenerate ground state. In the latter case, the $Z_2$ symmetry is lost and beside the spontaneous magnetization $g_z$, also the non trivially computable $g_{zz}(r)$ correlation appears [22]. In that case we resort to the numerical Density Matrix Renormalization Group (DMRG) method for finite systems with open boundaries [24].

Once we have access to the density matrices through the correlation functions, we can compute the explicit form of the mutual information and the classical correlation in order to distill the amount of pure quantum correlations in Eq. (5). Since the reduced density matrix of the single spin is the same for any site, the mutual information is given by:

$$I(A : B) = 2S(\hat{\rho}^A) - \sum_{\nu=0}^{3} \lambda_{\nu} \log_2 \lambda_{\nu},$$

(13)

where $\lambda_{\nu}(r)$ are eigenvalues of $\hat{\rho}_r^{AB}$. If one further specializes to $Z_2$-symmetric states, Eq. (13) can be readily evaluated by using the following two ingredients: i) the single-site density matrix in Eq. (9) turns out to be diagonal, therefore its von Neumann entropy is $S(\hat{\rho}^A) = S_{\text{bin}}((1 + g_z)/2)$, where $S_{\text{bin}}(p) = -p \log_2 p - (1-p) \log_2 (1-p)$ is the binary Shannon entropy; ii) in terms of the correlation functions, the eigenvalues of $\hat{\rho}_r^{AB}$ turn out to be $[6]$:

$$\lambda_{0/1} = \frac{1}{4} \left(1 + g_{zz} \pm \sqrt{g_{zz}^2 + (g_{xx} - g_{yy})^2}\right)$$

$$\lambda_{2/3} = \frac{1}{4} \left(1 - g_{zz} \pm |g_{xx} + g_{yy}|\right)$$

(14)

Once the mutual information (13) is known in terms of the correlation functions, one needs to perform a suitable measurement on spin $B$ in order to compute classical $C(\hat{\rho}_r)$ and eventually quantum $Q(\hat{\rho}_r)$ correlations, as stated in Eq. (5). Following a procedure similar to Refs. [5, 6, 24], we use a set of projectors $\{\hat{B}_k\}$ as local measurements on the spin $B$. In particular, working on the computational basis $\{|0\}, |1\}$ in the Hilbert space $H_B$ associated to the spin $B$, our general set of projectors is

$$\{\hat{B}_k = V\hat{\Pi}_k V^\dagger\} \quad k = 0, 1$$

(15)

where $\hat{\Pi}_k = |k\rangle \langle k|$ is related to the basis vectors and $V \in U(2)$ gives the generalization to any type of projector on $B$. As suggested in Ref. [6], $V$ can be parametrized as follows:

$$V = \left( \begin{array}{cc} \cos \frac{\theta}{2} & \sin \frac{\theta}{2} e^{-i\phi} \\
\sin \frac{\theta}{2} e^{i\phi} & -\cos \frac{\theta}{2} \end{array} \right)$$

(16)
where \( \theta \in [0, \pi] \) and \( \phi \in [0, 2\pi) \) are respectively the azimuthal and polar axes of a qubit over the Bloch sphere in \( \mathcal{H}_2 \). After a measurement has been performed on \( B \), the reduced density matrix \( \rho_{AB}^B(\tilde{B}_k) \) will be in one of the following states:

\[
\hat{\rho}_{0/1} = \frac{1}{2} \left( \hat{I}_A + \sum_{\alpha=1}^{3} q_{0/1,\alpha} \hat{\sigma}_A^{\alpha} \right) \otimes \left( V\Pi_{0/1}V^\dagger \right)_B .
\] (17)

This expression gives the explicit dependence of the system \( A \) with respect to the projective measurement performed on the spin \( B \). The coefficient \( q_{k,\alpha} = q_{k,\alpha}(\theta, \phi) \) in the expansion depends on the projectors used to perform the measure on \( B \) (see Ref. [3] for the explicit form).

Finally, the maximization over all possible \( \tilde{B}_k \) embedded in Eq. (1) is equivalent to find those values \((\theta_{\text{opt}}, \phi_{\text{opt}})\) that disturb the least the spin \( A \) when we make a measure on \( B \). For \( Z_2 \)-symmetric states we analytically found \( \theta_{\text{opt}} = \frac{\pi}{2}, \phi_{\text{opt}} = 0 \), in accordance with Refs. [6, 8]. This eventually leads to a simple closed expression for the classical correlations:

\[
C(\hat{\rho}_r) = S_{\text{bin}}(p_1) - S_{\text{bin}}(p_2) ,
\] (18)

where \( S_{\text{bin}}(p) \) is the Shannon entropy and

\[
p_1 = \frac{1 + g_x}{2} ; \quad p_2 = \frac{1}{2} + \sqrt{\frac{g_z^2 + g_x^2}{4}} .
\] (19)

By taking the difference between the mutual information [13] and Eq. (18) for the classical correlations, one gets the following simplified expression for the quantum discord between any two spins in the XY chain in transverse field, valid for \( Z_2 \)-symmetric states [6]:

\[
Q(\hat{\rho}_r) = S_{\text{bin}}(p_1) + S_{\text{bin}}(p_2) - \sum_{\nu=0}^{3} \lambda_\nu \log_2 \lambda_\nu .
\] (20)

V. QUANTUM DISCORD AT T = 0

In this section we analyze quantum correlations both in the thermal ground state and in the symmetry broken one. In particular we remark differences and similarities between them, and highlight the interesting features occurring at the QCP and at the factorizing field (if not specified, the \( xy \) anisotropy is set to \( \gamma = 0.7 \) in every picture).

We start by showing the behavior of quantum discord at zero temperature, over a wide range of external field values \( h \) centered around the critical value \( h_c \), where the QPT occurs. In Fig. 1 we plot the quantum discord \( Q_r \), for both the XY model (main panel, \( \gamma = 0.7 \)) and the Ising model (right inset, \( \gamma = 1 \)), in the true ground state obtained by means of DMRG simulations (dotted lines with symbols) and in the thermal ground state evaluated analytically (solid lines without symbols). In the disordered phase \( h > h_c \) no difference occurs between the two state, while in the opposite regime \( h < h_c \) two different patterns come out. In fact, in the latter case the order in the system is really achieved only when the symmetry of the system is lost. We achieve this condition by introducing a tiny longitudinal field \( (h_x \ll 1) \) in the DMRG computations that leads to the symmetry breaking and gives out the true ground state, where quantum correlations are very small as long as \( h < h_c \). It is remarkable that they start to increase once the field is tuned immediately upper the factorizing field (where all quantum correlations must vanish), eventually reaching a cuspid-like maximum at the QCP. On the other hand, the quantum discord on the thermal ground state is a smooth function with respect to the field. In general it depends on the distance \( r \) between the two spins, but at the factorizing point it gets the same value for any length scale, as witnessed by the left inset [25].

To go deeper in the analysis, let us first focus on \( h_c = 1 \). The QPT is in general marked by a divergent derivative of the quantum discord, with respect to the field. In particular such divergence is present for any \( \gamma \) in the symmetry-broken state, while on the thermal ground state it holds as long as \( \gamma < 1 \) (see Fig. 2); for \( \gamma = 1 \), \( \partial_h Q_r \) is finite at \( h_c \), although the \( \partial_h^2 Q_r \) diverges [6]. This divergence suggests that a scaling analysis at the QCP
is feasible. In particular in Fig. 3 we show the finite size scaling $\partial h Q_1$ for the symmetry-broken ground state in the XY model, in proximity of the critical point $h_c$. The first derivative of the quantum discord is a function of $L^{-\gamma}(h - h_m)$ only, and satisfies the scaling ansatz $\partial h Q_1 \sim L^{-\gamma} \times F[L^{-\gamma}(h - h_m)]$, where $h_m$ is the renormalized critical point at finite size $L$ and $\omega = 0.472$. We found a universal behavior $h_c - h_m \sim L^{-1.28 \pm 0.03}$ with respect to $\gamma$.

Turning into the factorizing field $h_f$ we underline that, for the thermal ground state, it is the only value where the curves with different $r$, intersect with each other (see up-left inset in Fig. 1 [25]). Besides this, in the broken symmetry state, not only we found that all curves vanish in $h_f$, but we numerically estimated the following dependence of $Q_r$ close to it:

$$Q_r \sim (h - h_f)^2 \times \left(\frac{1 - \gamma}{1 + \gamma}\right)^r.$$  \hfill (21)

Such behavior is consistent with the expression of correlation functions close to the factorizing line obtained in Ref. [26], and here appears to incorporate the effect arising from the non vanishing spontaneous magnetization. Most remarkably, we found a rather peculiar dependence of $Q_r$ on the system size, converging to the asymptotic value $Q_r^{(L \to \infty)}$ with an exponential scaling behavior (see Fig. 4).

VI. QUANTUM DISCORD AT FINITE TEMPERATURE

Even if both the QCP and the factorizing field occur at $T = 0$, they influence the physics of the system even if the temperature is switched on. Close to $h_c$, the physics is dictated by the interplay between thermal and quantum fluctuations of the order parameter. As we stated before, the cross-over temperature $T_{\text{cross}} = |h - h_c|^2$ fixes the energy scale [11]. For $T \ll T_{\text{cross}}$ the system is described by a quasi-classical theory, while inside the “quantum critical region” ($T \gg T_{\text{cross}}$), it is impossible to distinguish between quantum and thermal effects. Here the critical properties arising from the QCP at $T = 0$ are
highly dominating the dynamics of the system; as a matter of fact, we expect that quantum correlations display some particular pattern as well as they do at $h_c$. In fact close to $h_f$ and at small $T$, the bipartite entanglement remains vanishing in a finite non linear cone in the $h-T$ plane \cite{20,27}. Thermal states, though, are not separable, and entanglement is present in a multipartite form \cite{27}. In this regime the bipartite entanglement results to be non monotonous, and a reentrant swap between parallel and antiparallel entanglement is observed \cite{20}. At finite temperature, the $Z_2$ symmetry is preserved all over the values of $h$ (there is no longer a symmetry broken phase). This means that if the system lies in the ground state at $T=0$ (symbols lines in Fig. 1), once the temperature is switched on we get a jump of $Q_r$ all along the phase $h < h_c$. After that it behaves as a smooth function decaying with increasing the temperature (Fig. 5). Such discontinuity is also observed in the entanglement, even if in that case it is much less pronounced and it occurs only for $h < h_f$ \cite{21}. Let us now analyze how criticality and factorization modify the fabric of pure quantum correlations in the $h-T$ plane. We start by focusing on the finite-temperature scaling of the quantum discord close to the critical point $h_c$. In the first place we verified the logarithmic scaling $\partial_h Q_r |_{h_c} \sim x \ln(T) + k$ along the critical line, $h = 1$, in the $h-T$ plane (see Fig. 9), where the value of $x$ depends on the degree of anisotropy $\gamma$. Once $x$ is given (for example we found $x = 0.065$, for $r = 1$ and $\gamma = 0.7$ - Fig. 6), by properly tuning the ratio $T/T_{\text{cross}}$, where $T_{\text{cross}} = |h - h_c|$, we verified the scaling ansatz

$$\partial_h Q_r = T^x F\left(\frac{T}{T_{\text{cross}}}\right).$$  \hspace{1cm} (22)

In particular in Fig. 6 we show how different curves, related to different values of $T/T_{\text{cross}}$, collapse when approaching the critical point. Remarkably in the Ising case (inset) the scaling is verified as well, even if the derivative $\partial_h Q_1$ is finite at $h_c$. To explore the behavior of correlations along the $h-T$ plane, we studied how the quantum discord varies on the phase diagram just above the QCP. In the first place we analyze how the derivative with respect to field behaves along the directions fanning out from $h_c$. In Fig. 7 we sketch a cartoon to describe the directional derivative $D_u Q_r = |\partial_T Q_r \sin \alpha + \partial_h Q_r \cos \alpha|$ we used to describe how $Q_1$ varies close to the QCP. From the pattern of $D_u Q_1$ at low temperature (Fig. 8) we see how the presence of the QPT characterizes the whole phase diagram. The black vertical line starting from the QCP highlights the fact that the quantum discord remains constant along the critical line $h = 1$: in a sense, close to such region $h \approx 1$, quantum correlations are particularly “rigid”. This explains their robustness up to finite temperatures, particularly along slopes within the quantum critical region. On the other hand, out of the quantum critical region, the variation of $Q_1$.
FIG. 8: Density plot of $D_u Q_1$ close to $h_c$, in the $h - T$ plane. The vertical line fanning out from the QCP shows that $Q_1$ tends to be constant inside the quantum critical region.

FIG. 9: Density plot in the $h - T$ plane of $\partial_T [Q_1/C_1]$ close to $h_c$; along the critical line the ratio $Q_1/C_1$ is constant with respect to the temperature. The solid straight line ($T = |h - h_c|$) marks the boundary of the quantum critical region.

is drastically increased. We also point out the peculiar asymmetric behavior between the two semiclassical regions (in the ordered phase $D_u Q_1$ is generally higher than in the paramagnetic phase). Furthermore, to make a more accurate analysis we look at the interplay between quantum discord and classical correlations. In particular we analyze how the ratio $Q_1/C_1$ varies with the temperature, exploiting the respective sensitivity to thermal fluctuations arising at finite temperature. Accordingly with the phase diagram related to the QPT, a $V$ shaped pattern comes out (see Fig. 9). In particular along the critical line, inside the quantum critical region, we found $\partial_T [Q_1/C_1] = 0$. Then apparently the ratio between correlations is constant even though the temperature is switched on, as long as the field is tuned at the critical value $h_c$. Besides this, the whole crossover region from a phase to another one is marked as the highest variation in the nature of correlations in the system.

Finally we concentrate on how the factorizing field affects the finite-temperature physics of the system. As we stressed before, the $Z_2$ symmetry is preserved on the thermal state. In particular, for the thermal ground state, the factorizing field is the unique value where the quantum discord is the same at any length scale $r$. Here we show that this feature is present even after the temperature is switched on. In Fig. 10 we propose the quantity

$$\Delta Q_r = \frac{2}{m(m-1)} \sum_{i,j=1}^{m} |Q_{r_i} - Q_{r_j}|$$

as a measure of the robustness of this characteristic at non zero temperature. We consider different distances between the couple of spins $A$ and $B$, and take the average of the difference between the respective quantum discord. Our results strongly support that, for a finite range of temperature, this difference is still zero (i.e. the quantum discord for different $r$ preserves its scale invariance only at $h \approx h_f$).

We emphasize that the robustness and sensitivity of the quantum discord to non zero temperature, encourage the implementation of suitable experiments that could give good feedback of our analysis.

VII. DISCUSSION

We studied pure quantum correlations quantified by the quantum discord $Q_r$ in the quantum phases involved in a symmetry-breaking QPT.

In the ordered phase, although $Q_r$ results relatively small in the symmetry-broken state as compared to the thermal ground state, it underlies key features in driving both the order-disorder transition across the QPT at $h_c$, and the correlation transition across the factorizing field $h_f$. The critical point is characterized by a non analyticity of $Q_r$ found in the Ising universality class. Close to
that $h_f$, $Q_r$ displays uniquely non trivial properties: in the thermal ground state quantum correlations are identical at all scales; for the symmetry-broken state the factorization can be interpreted as a collective reshuffling of quantum correlations. We point out that $h_f$ marks the transition between two “phases” characterized by a different pattern of entanglement [15][20]. Accordingly our data provide evidence that such a correlation transition phenomenon is of collective nature, governed by an exponential scaling law. We observe that the scaling close to $h_f$ cannot be algebraic, because the correlation functions drop exponentially in the gapped phases. Nonetheless we ascribe this specific scaling behavior to the peculiar drop exponentially in the gapped phases. For finite $L$ different ground states for the two parity sectors intersect [28]. The ground state energy density is diverging for all $L$ (such divergence, though, vanishes in the thermodynamic limit). Indeed we found that the factorization occurs without any violation of adiabatic continuity. Accordingly, the ground state fidelity $F(h)$, which can detect both symmetry breaking and non-symmetry breaking QPT, is a smooth function at $h_f$ [29]. We remark that this can occur without closing a gap and changing the symmetry of the system, as a signature of the fact that quantum phases and entanglement are more subtle than what the symmetry-breaking paradigm says. Such a behavior is particularly relevant in the context of QPTs involving topologically ordered phases where a QPT consists in the change of the global pattern of entanglement, instead of symmetry [30].

We also analyzed the phase diagram at low $T$. A discontinuity of $Q_r$ with $T$ is evidenced in the whole ordered phase $h < h_c$. We proved that $Q_r$ displays universal features, identifying the quantum critical region as the one where the quantum discord (relatively to classical correlations) is frozen out to the $T = 0$ value. In particular in each phase the ratio between correlations is stable with respect to the temperature, while the highest variations develop in the crossover region on the right of $h_c$, where the system is running out of the critical region into the quasi-classical one just above the disordered phase of the paramagnet. This type of quantum correlations therefore allows a fine structure of the phase diagram, according to the behavior of the gap $\Delta \lesssim 0$. In the low temperature limit $T < |\Delta|$: as a matter of fact, two different mechanisms lead to the two corresponding semiclassical regimes driven by quantum ($\Delta > 0$) or thermal ($\Delta < 0$) fluctuations [11]. Finally, a non trivial pattern of quantum correlations fans out from the factorization of the ground state, as well: we identified a finite portion of the low-temperature phase diagram where the quantum discord is nearly constant at any range, despite of the thermal fluctuations.

Acknowledgments

We thank A. De Pasquale, R. Fazio, S. Montangero, D. Patané, M. Zannetti, J. Quintanilla for useful discussions. The DMRG code released within the PwP project (www.dmrgr.it) has been used. Research at Perimeter Institute for Theoretical Physics is supported in part by the Government of Canada through NSERC and by the Province of Ontario through MRI. DR acknowledges support from EU through the project SOLID.
