ABSTRACT

We present high time resolution (1.09 s) photometry of GRB 080210 obtained with ULTRASPEC mounted on the ESO/3.6-m telescope, starting 68.22 min after the burst and lasting for 26.45 min. The light curve is smooth on both short (down to 2.18 s) and long time scales, confirmed by a featureless power spectrum. On top of the fireball power-law decay, bumps and wiggles at different time scales can, in principle, be produced by density fluctuations in the circumburst medium, substructures in the jet or by refreshed shocks. Comparing our constraints with variability limits derived from kinematic arguments, we exclude under-density fluctuations producing flux dips larger than 1 per cent with time scales $\Delta t > 9.2\, \text{min}$ (2 per cent on $\Delta t > 2.3\, \text{min}$ for many fluctuating regions). In addition, we study the afterglow VLT/FORS2 spectrum, the optical-to-X-ray spectral energy distribution (SED) and the time decay. The SED is best fit with a broken power law with slopes $\beta_{\text{opt}} = 0.71 \pm 0.01$ and $\beta_X = 1.59 \pm 0.07$, in disagreement with the fireball model, suggesting a non-standard afterglow for GRB 080210. We find $A_V = 0.18 \pm 0.03$ mag optical extinction due to SMC-like dust and an excess X-ray absorption of $\log (N_{\text{H}}/\text{cm}^{-2}) = 21.58^{+0.18}_{-0.26}$ assuming Solar abundances. The spectral analysis reveals a damped Ly$\alpha$ absorber ($\log (N_{\text{H}}/\text{cm}^{-2}) = 21.90 \pm 0.10$) with a low metallicity $([\text{X/H}] = -1.21 \pm 0.16)$, likely associated with the interstellar medium of the GRB host galaxy ($z = 2.641$).

Key words: gamma-rays: bursts - instrumentation: detectors - dust, extinction - ISM: kinematics - ISM: abundances

1 INTRODUCTION

Long ($> 2\, s$) soft gamma ray bursts (GRBs) are the most powerful explosions known in the Universe. After the discovery of GRB optical \cite{vanParadijs1997} and X-ray \cite{Costa1997} afterglows in 1997, we have learned that they mainly occur in distant galaxies and their connection to core-collapse supernovae is now widely accepted \cite{Woosley2006}. The diversity amongst individual GRB events, as well as the difficulty in observing such transient sources, challenges the-
(i) Density fluctuations can arise from interstellar turbulence or can be generated, before the GRB event, by a variable wind from the progenitor star (see e.g., van Marle et al. 2003). Linear density fluctuations with $dn/n < 1$ on a length scale of $10^3$ AU could induce fluctuations in the afterglow light curve with a fractional amplitude of up to $\sim 30$ per cent over time scales of tens of minutes in the optical and near-ultraviolet (Wang & Loeb 2000). (ii) Substructures in the jet can form if the bulk Lorentz factor evolves within the emitting surface, which is expanding in a self-similar way, once the fireball has been decelerated by the external medium. The refreshed shocks will boost the luminosity of the emitting surface (patchy-shell; Mészáros & Piran 1998). As the emitting region evolves through this patchy-jet, the flux varies in intensity. (iii) Angular inhomogeneity of the relativistic ejecta can separate the emitting surface into different causally disconnected regions (patchy-shell; Kumar & Piran 2000; Nakar & Oren 2004). These wiggles evolve within the emitting surface, which is expanding in time with the blast-wave deceleration, causing variability in the radiation. (iv) If the ejecta have a range of bulk Lorentz factors, the slower shells will catch up with the leading blast wave, once the fireball has been decelerated by the external medium. The refreshed shocks will boost the luminosity of the afterglow (Rees & Mészáros 1998). (v) The GRB engine could contribute to the variability at late times: as debris accretes onto the black hole in the period following the burst, its extended activity could heat the environment or produce new outflows, giving rise to a detectable component of emission which, like any accretion-powered source, would be variable (Rees & Mészáros 2004). Thus, the detection (and even the non-detection) of time variability within several minutes to a couple of hours after the burst can provide important constraints on the different proposed scenarios, and therefore on the physics of the evolution of the fireball.

Temporal variations in GRB afterglow light curves were first observed, on time scale as short as $\sim 1$ hour, in GRB 011211 (Holland et al. 2003; Jakobsson et al. 2004), induced either by inhomogeneities in the medium surrounding the GRB, or by a patchy jet. Lazzati et al. (2003) have argued that the deviations in the afterglow of GRB 021004 are due to the interaction of the GRB fireball, or jet, with density enhancements in the ambient medium. However, time-resolved polarimetry of the same burst suggested that the variations were produced by a refreshed shock (Björnsson, Gudmundsson & Jóhannesson 2004; Granot, Nakar & Piran 2004) have also interpreted the variations seen in the light curve of GRB 030329 as due to refreshed shocks.

Several limitations challenge the detection of late-time variability in GRB light curves. First, the amplitude of most of the fluctuations that can possibly be expected decays with time. Moreover, different processes (e.g., density fluctuations, patchy shell or refreshed shocks) will physically constrain the variability over only certain time scales at one observation time (Ioka, Kobayashi & Zhang 2003). In particular, the fastest variability is the hardest to detect, partly because it is intrinsically weaker, but also because the readout noise and dead time of classical CCDs usually limits the time resolution of the observation itself. High-speed photometry can now be achieved thanks to the fast read-out with zero-noise of the frame-transfer electron-multiplying CCDs (EMCCDs). The ULTRASPEC camera (Dhillon et al. 2007) adopts such a CCD to amplify the signal, rendering the read-out noise negligible. In addition, the frame transfer architecture allows the EMCCD to read out a completed exposure whilst the next exposure is being obtained, virtually eliminating the dead time between exposures.

We observed GRB 080210 with ULTRASPEC mounted on the ESO 3.6-m telescope in La Silla, allowing 1.09 s time resolution imaging. The highest speed photometry

Table 1. GRB 080210 observation log on date 2008 February 10. $^a$ $\delta t$ is the mid-exposure time after the BAT trigger (07:50:06 UT).
obtained for a GRB afterglow so far is the TORTORA observations of the extremely bright “naked eye” GRB 080319B (Greco et al. 2009; Beskin et al. 2010), with a 0.3 s time bin, from 10 to 100 s after the burst trigger. However, the ULTRASPEC observations of GRB 080210, presented in this paper, probes the afterglow phase, providing the lowest $\Delta t/t$ so far. This opens a new window on the fast-variability study of the afterglow itself. Comparing the variability limits given by Ioka et al. (2005) with the ULTRASPEC observations, we can constrain the properties of the circumburst medium and the shock structure.

In addition, we investigate the GRB 080210 host galaxy environment in another way, through ESO-VLT/FORS low- and medium-resolution spectroscopy, as well as optical-to-X-ray spectral energy distribution (SED) modelling. Lyα and metal absorption systems, often observed in GRB lines of sight, can be used to derive physical properties of the absorbing gas clouds, such as kinematics, densities and metallicities (Vreeswijk et al. 2006; Ledoux et al. 2009). On the other hand, the SED provides information on both the dust inside the host galaxy and the spectral properties of the GRB afterglow itself (e.g., Starling et al. 2007). Overall, interpreting the combined optical and X-ray spectra and light curves within the context of the fireball model can provide a probe of the blast-wave physics, as well as the GRB environment (Sari, Piran & Narayan 1998; Zhang et al. 2006).

The paper is organized as follows: observations and data reduction are presented in Sec. 2, while their analysis is reported in Sec. 3: first the ULTRASPEC light curve, then the optical spectroscopy, the SED modelling and finally the optical and X-ray afterglow temporal decay. We discuss our results in Sec. 4 and summarize them in the last section. Throughout the paper we use the convention $F_\nu(t) \propto t^{-\alpha} \nu^{-\beta}$ for the flux density, where $\alpha$ is the temporal slope and $\beta$ is the spectral slope. Hereafter we assume a standard ΛCDM cosmology with $H_0 = 70.4$ km s$^{-1}$ Mpc$^{-1}$, $\Omega_M = 0.27$ and $\Omega_{\Lambda} = 0.73$ (Jarosik et al. 2010).

2 OBSERVATIONS AND DATA REDUCTION

2.1 Swift detection

The Swift Burst Alert Telescope (BAT) triggered on GRB 080210 on February 10th, 2008 at $T_{0} = 07:50:06$ UT (Grupe et al. 2008). The duration spanning 90 per cent of the GRB emission (15–350 keV) was 45 ± 11 s and its 15–150 keV fluence was $1.8 \times 10^{-6}$ erg cm$^{-2}$. The time integrated BAT spectrum is best fit by a simple power law with photon index $\Gamma = 1.77 \pm 0.12$ (Ukwatta et al. 2008). An X-ray afterglow was observed with the Swift X-Ray Telescope (XRT), starting 161 s (240 s) after the trigger in windowed timing (photon counting) mode. An optical afterglow was detected by the Swift Ultra-Violet/Optical Telescope at a position R.A. = $16^h 45^m 04.01^s$ and Decl. = $+13^\circ 49' 35.9''$ (J2000, estimated 90 per cent confidence error radius of 0.6″). Marshall & Grupe (2008). We retrieved the X-ray light curve and spectra from the Swift repository.
2.3 VLT/FORS2 observations

Starting at 08:32 UT on 2008 February 10th (42 min post-burst), a series of 600 s spectra were obtained with VLT/FORS2 in long-slit spectroscopy mode with a 1′0 wide slit, North-South oriented and centered with an R-band acquisition image. The sequence of grisms used was 300V, 600z+OG590, 1400V, 1200R+GG435 and finally 300V again. This allowed us to both cover a larger wavelength window with the lower resolution grism (300V) and obtain mid-resolution spectroscopy for different regions of the spectrum. The individual spectra were cleaned of cosmic rays and 1.09 s sampled ULTRASPEC light curves (V band). The whole observation (4093–5680 s after the trigger) is displayed in the three upper panels, while the first 100 s are shown in the bottom panel (1σ errors over-plotted). The raw GRB (solid) and the comparison star (dotted) light curves are shown in the first and second panels, respectively. The GRB light curve, flux calibrated display in the three upper panels, while the first 100 s are shown in the bottom panel.

Figure 2. The fast (1.09 s) sampled ULTRASPEC light curves (V band). The whole observation (4093–5680 s after the trigger) is displayed in the three upper panels, while the first 100 s are shown in the bottom panel (1σ errors over-plotted). The raw GRB (solid) and the comparison star (dotted) light curves are shown in the first and second panels, respectively. The GRB light curve, flux calibrated display in the three upper panels, while the first 100 s are shown in the bottom panel.

While the mid-resolution spectra were mainly used for the spectral analysis, we aimed to flux-calibrate the low-resolution 300V spectra for the SED study. However, the two 300V spectra were obtained at high airmass (2.3 and 1.8 respectively) where the difference between the slit position angle and the parallactic angle was 126.6° and 133.4°, respectively. Thus, slit losses influence the continuum level of the spectra, particularly in the blue. In order to correct for this, we computed the slit throughput in the following way. A theoretical model of the point spread function (PSF) as delivered by an 8.2 m diameter Unit Telescope, including the central obscuration caused by the secondary mirror, was built using a piece of IDL code graciously made available by Enrico Fedrigo (private communication). In particular, this model includes the dependence of the diffraction-limited theoretical PSF as a function of wavelength. This model PSF was then convolved with a Gaussian whose wavelength-dependent FWHM follows Roddier’s formula, i.e. \( \propto (\lambda/\lambda_{\text{ref}})^{-0.2} \), normalized to the value measured on each observed spectrum at the effective wavelength of the R filter used for the centering of the target (\( \lambda_{\text{ref}} = 6600 \) Å).

For each spectrum, the distance of the PSF centre to the slit centre at a given wavelength was assumed to be the differential refraction between this wavelength and \( \lambda_{\text{ref}} \) multiplied by the cosine of the difference between the parallactic angle at the time of the observation and the parallactic angle at the time when the object would be at an airmass of 1.41, converted to degrees (25° and 18°). Here we assumed that the Longitudinal Atmospheric Dispersion Corrector (LADC) of FORS2 (Avila, Rupprecht & Beckers 1997) performs optimally up to airmass of 1.41. For the calculation of the differential refraction, we assumed the usual atmospheric conditions at Paranal (temperature \( T = 12^\circ C \), pressure \( P = 743 \) mbar). The integrated value of the flux along the spatial direction entering the spectrograph can then be calculated for each wavelength. The factor representing the slit throughput is then the ratio between this integrated value and the total flux at that wavelength. The top panel of Fig. 4 shows the estimated slit throughputs as a function of wavelength for the two 300V FORS2 spectra. The bottom panel shows the ratio between the throughputs compared with the ratio between the two spectra. The agreement indicates that the slit throughputs have been reasonably well calculated.

The response curve correction was performed using observations of the standard star LTT3864. The flux calibration was rescaled using R-band VLT/FORS2 images. R-band photometry was secured with VLT/FORS2, before and after our spectroscopic observation. Calibration was...
carried out by observing the Landolt standard fields SA 100 and Rubin 149, which allowed us to obtain a photometric accuracy of 0.02 mag. The GRB observations were carried out at large airmass (1.7–2.5), but so was also one of the two standard fields, which allowed a reliable extinction coefficient to be computed, in agreement with the value tabulated in the ESO web page. The photometric conditions were excellent according to the Paranal night logs.

3 DATA ANALYSIS

3.1 ULTRASPEC light curve

The ULTRASPEC light curve is plotted in Fig. 2. We Fourier transformed the ULTRASPEC light curve in order to investigate the variability and possible periodicities over all time scales. We exclude the flux variation due to the afterglow natural evolution by first correcting the light curve with the power-law fit to the decay. Figure 3 shows the power spectra of the unbinned light curve. Thanks to the fast sampling of ULTRASPEC, we can monitor the power spectrum down to 2.18 s time scales. The power spectrum of the light curve shows a peak at 2.8 s, likely due to random noise. Indeed, the peak height is not significant (3 per cent of the flux, corresponding to log (∆F/F) = −1.57, (log ∆t/t) = −3.2 at 81.4 min), well below the instrument detection limit, see Sec. 4.2. We performed a Monte Carlo type generation of 100,000 light curves with random variability equal to the measured GRB variability and found peaks of this height and greater to occur in 6 per cent of cases. In addition, the phase-folded light curve does not show any evidence for periodicity. Thus, no frequency is preferred in the power spectrum. The ULTRASPEC light curve is smooth and follows a pure power law within the statistical fluctuations.

3.2 VLT/FORS2 spectral analysis

In the 300V combined spectrum (averaged from the two 300V flux calibrated spectra), we identify a damped Lyα absorber (DLA) in addition to a number of absorption lines at z = 2.641 ± 0.001, associated with the host galaxy of the burst. We also identify an intervening system at z_{int} = 2.509 ± 0.001 from SiIV and CIV transitions. A list of the lines detected in the low resolution 300V spectrum and their equivalent widths (EWs) is reported in [15]. We measured the EWs for both 300V epochs and find no evidence for spectral variability in the absorption. For the H1 DLA fit, we derived log (NH1/cm^2) = 21.90 ± 0.10 (Fig. 3). The tentative detection of Lyα emission inside the DLA, as seen from the 1D spectrum [17], is most likely noise, since it is not detected in the 2D frame.

A good metallicity estimator is usually the weak transition Zn II λ2026, but for GRB 080210 this line is only covered by the low resolution 300V spectrum, allowing only a crude metallicity estimate. From the simultaneous Voigt-profile fit of the Zn II λ2026 with the Si II λ1526, λ1808 and Fe II λ1608, λ1611 lines in the low resolution spectrum, performed with the MIDAS/FITLYMAN software [21], we derive a log (NZn II/cm^2) = 13.53 ± 0.14 cm^2 (i.e. [Zn/H] = −0.93 ± 0.18, Doppler thermal broadening b_{th} = 0 km s^{-1}, and turbulent broadening b_{tur} = 39.4 ± 6.8 km s^{-1}). The analysis seems to show that the Zn II λ2026 line is on the linear part of the curve of growth (i.e. unsaturated), despite the low spectral resolution of the data. The metallicities refer to the solar abundances reported by [16].

Several lines are also identified in the medium resolution 1400V, 1200R and 600R spectra with the EWs listed in Table 2. Many of the lines associated with the GRB host galaxy system show evidence for a two-component profile (component “a” and “b”). In order to derive reliable column densities and to study the kinematics of the gas, we select the FeII, SiII, AlII and AIIII lines in the higher resolution grisms 1400V and 1200R that are neither too

Table 3. The ionic column densities estimated from a simultaneous Voigt profile fit to the lines in the 1400V and 1200R medium resolution grism spectra. a Al ii λ1670 line is saturated, the lower limit on N_{Al ii} is derived from the EW (Table 2). b The Si ii λ1526 line is only included in a first stage to model the line profiles; the Si abundance is computed using only the weaker and non-saturated Si ii λ1808 line. c Zn abundance estimated from the low resolution 300V spectrum ($b_{turk}$=39.4, $b_{th}$=0 km s$^{-1}$).

saturated or blended with other transitions, and model them simultaneously with a two-component Voigt profile, using the VPFIT software. In this way, the line profile of all the species is modelled with the same redshift $z$ and $b_{turk}$ for a given component, resulting in different column densities for different ions. We expect the Fe ii, Si ii, Al ii and possibly Al iii to be co-spatial and therefore to show a similar line profile. This is what we observe in the

1 Available at [http://www.ast.cam.ac.uk/~rfc/vpfit.html](http://www.ast.cam.ac.uk/~rfc/vpfit.html)
the line-of-sight to GRB 080210. The Si II λ1304 transition was excluded from the analysis because it is blended with the possibly dominating O I* λ1304 line. The 600z spectrum was not included in the Voigt profile fit because of its poorer spectral resolution. The two components that model the line profiles are separated by 148±25 km s$^{-1}$ in velocity: $z_a = 2.6386\pm0.0003$, $z_b = 2.6416\pm0.0003$ (dotted lines), $b_{\text{urb, a}} = 38 ± 7$ km s$^{-1}$, $b_{\text{urb, b}} = 23 ± 6$ km s$^{-1}$, $b_{\text{hi}} = 0$ km s$^{-1}$. The dashed curves show the 1σ errors.

Figure 5. The line profiles in the medium resolution 1400V and 1200R spectra are best modelled with two components separated by 148±25 km s$^{-1}$ in velocity: $z_a = 2.6386\pm0.0003$, $z_b = 2.6416\pm0.0003$ (dotted lines), $b_{\text{urb, a}} = 38 ± 7$ km s$^{-1}$, $b_{\text{urb, b}} = 23 ± 6$ km s$^{-1}$, $b_{\text{hi}} = 0$ km s$^{-1}$. The dashed curves show the 1σ errors.

3.3 Spectral energy distribution

In order to fit the optical-to-X-ray SED, we combine the averaged 300V optical with the X-ray spectra. We choose to include the 300V spectrum in the SED to investigate the significant dust reddening reported by Fynbo et al. (2009). Also, the larger spectral window coverage of the 300V as compared to the higher resolution spectra makes it more suitable to investigate the SED. The SED time is chosen at the logarithmic mean between the two 300V observations (3945 s). Using the Swift spectrum repository (Evans et al. 2007, 2009), we extract the X-ray spectrum from a narrow time interval (3690–4200 s, logarithmically centred on the SED time), and use its count rate to scale the X-ray spectrum extracted from a larger time window (3690–106130 s) and with a better signal-to-noise (S/N). This approach assumes no spectral evolution in the X-ray spectrum, as confirmed by extracting spectra for different time windows and by the constant hardness ratio. This allows the optical and the X-ray spectra to be compared in flux. The 300V averaged spectrum was cleaned (absorption lines removed and frequencies bluer than Ly$\alpha$ excluded) and corrected for Galactic extinction. The optical spectrum was then binned into 22 bands (192 Å) in order to obtain the same number of data points as in the X-ray spectrum. The statistical errors were calculated from the variance in the spectrum. A systematic error introduced by the response function was calculated by measuring the amplitude of the spurious wiggles introduced by the flux calibration process. This uncertainty and the error due to the calibration against the VLT photometric measurement were then added in quadrature to the formal error. The total resulting error on the optical spectrum is about 8 per cent of the flux. The optical-to-X-ray SED is shown in Fig. 6.

We model the SED from the optical to the X-rays with a single power law (PL), a broken power law (BPL) and a tied broken power law (TBPL), where the spectral slopes are tied to differ by $\Delta \alpha = 0.5$ to reproduce the spectral break (cooling frequency) expected for a synchrotron spectrum. The fit was performed with the Interactive Spectral Interpretation System (ISIS; Houck & Denicola 2004) software, which allows all the data to be compared directly in count space. Working in count space has the advantage of not requiring any a priori model for the X-rays, otherwise needed for the conversion of the X-rays into flux (see e.g. Starling et al. 2009). The host galaxy dust extinction was modelled with Small Magellanic Cloud (SMC), Large Magellanic Cloud (LMC) or Milky Way (MW) extinction curves (Pei 1992) and the X-ray absorption (in excess of the Galactic $N_{\text{H, Gal}} = (5.59 ± 0.02) \times 10^{20}$ cm$^{-2}$, Kalberla et al. 2004) is measured from a zphabs model in ISIS, assuming Solar metallicity. Table 3 summarizes the fit results.

The best fitting model is a BPL with spectral slopes $\beta_X = 1.59 ± 0.11$ and $\beta_{\text{opt}} = 0.71 ± 0.02$, with the cooling frequency occurring at $E_{\text{break}} = 1.40_{-0.13}^{+0.09}$ keV in the soft X-ray range. These values are derived for SMC-like extinction (lowest $\chi^2 = 191.6$, for 37 degrees of freedom), while the LMC extinction curve provides a very similar fit, resulting in consistent parameter values. The MW extinction curve and its related 2175 Å bump can be excluded. The optical spectrum is reddened by dust grains at the redshift $z = 2.641$ of the host galaxy, with $E(B-V) = 0.06 ± 0.01$ mag, or $A_V = 0.18 ± 0.03$ mag (rest-frame), modelled with an SMC-like extinction curve. We find an excess X-ray absorption of $N_{\text{H}} = 0.38_{-0.17}^{+0.19} \times 10^{22}$ cm$^{-2}$ assuming Solar metallicity, whereas $N_{\text{H}} = 2.04_{-0.95}^{+1.03} \times 10^{22}$ cm$^{-2}$ for $Z/Z_\odot = 0.06$. The above errors refer to a 90 per cent confidence level. The SED results should be treated with caution,
because they are dependent on the slit loss correction of the 300V spectra. In particular, the same SED analysis, but for the optical spectrum that has not been corrected for slit losses, provides a 4 per cent change in the optical slope and 68 per cent in the $E(B-V)$, for the best fit model.

### Table 4

| Extinction type | Model | $\chi^2$ [dof] | $E(B-V)$ | $N_H$ | $\beta_1$ | $\beta_2$ | $E_{\text{break}}$ (keV) |
|-----------------|-------|----------------|----------|-------|-----------|-----------|---------------------------|
| SMC             | PL    | 517.2[39]     | 0.10 ± 0.01 | $<0.03$ | 0.82 ± 0.02 | -         | -                         |
|                 | BPL   | 191.6[37]     | 0.06 ± 0.01 | 0.38$^{+0.19}_{-0.17}$ | 0.71 ± 0.02 | 1.59 ± 0.11 | 1.40$^{+0.09}_{-0.13}$ |
|                 | TBPL  | 232.0[38]     | 0.07 ± 0.01 | 0.27$^{+0.17}_{-0.17}$ | 0.72 ± 0.02 | 1.55 ± 0.11 | 1.50$^{+0.09}_{-0.13}$ |
| LMC             | PL    | 434.9[39]     | 0.17 ± 0.02 | $<0.22$ | 0.91 ± 0.02 | -         | -                         |
|                 | BPL   | 194.4[37]     | 0.10 ± 0.02 | 0.48$^{+0.19}_{-0.18}$ | 0.77 ± 0.03 | 1.59$^{+0.11}_{-0.10}$ | 1.41$^{+0.10}_{-0.12}$ |
|                 | TBPL  | 238.7[38]     | 0.10 ± 0.02 | 0    | 0.72 ± 0.02 | 1.53 ± 0.11 | 1.35 ± 0.11 |
| MW              | PL    | 546.9[39]     | 0.21 ± 0.02 | $<0.25$ | 0.91 ± 0.03 | -         | -                         |
|                 | BPL   | 265.0[37]     | $<0.02$ | 0.20$^{+0.18}_{-0.16}$ | 0.63$^{+0.03}_{-0.01}$ | 1.59 ± 0.11 | 1.39$^{+0.09}_{-0.12}$ |
|                 | TBPL  | 323.1[38]     | 0.05 ± 0.03 | 0    | 0.72 ± 0.02 | 1.20 ± 0.03 | 1.20 ± 0.10 |

All the errors refer to a 90 per cent confidence level. $^a$ $N_H = 2.04^{+1.03}_{-0.95} \times 10^{22}$ cm$^{-2}$ for $Z/Z_\odot = 0.06$.

**Figure 6.** The SED of the optical 300V spectrum (×) and the X-ray spectrum (+), at 66 min after the burst. The solid line shows the best fitting model, a broken power law with spectral slopes $\beta_X = 1.59 \pm 0.11$ and $\beta_{\text{opt}} = 0.71 \pm 0.02$, for an SMC-type dust extinction, see Table 4. The residuals are displayed in the bottom panel.

3.4 Afterglow evolution

Figure 7 shows the afterglow time evolution in the X-ray and optical bands. We converted the X-ray light curve into monochromatic flux at 1.73 keV, the logarithmic average of the XRT band, assuming a spectral slope $\beta_X = 1.59$ as derived from the SED (see Section 3.3). Early (< 12 min) X-ray data were excluded from the fit to avoid the influence of flares. The last XRT data points were also excluded in order to avoid the contribution from a possible break at
late time that cannot be constrained. We fit the X-ray light curve with a single power law with temporal slope $\alpha = 1.24 \pm 0.07$ (reduced $\chi^2 = 3.67$ for 23 dof), noting that a broken power law does not improve the fit. The high $\chi^2$ could be produced by the wiggles observed in the X-ray light curve, possibly originated by micro-variability. However, the poor sampling of the X-ray light curve does not allow us to investigate this further.

The V-band temporal decay was derived from a power-law fit to the ULTRASPEC light curve $\alpha_V = 0.74 \pm 0.07$, see Section 3.1. We collected the R-band photometric data points from our VLT/FORS2 acquisition images and the Keck-I/LRIS data, reported in Table 5, corrected them for Galactic extinction ($A_V = 0.276$ mag; Schlegel, Finkbeiner & Davis 1998), and converted them to flux density. A temporal decay with slope $\alpha_{\text{VLT+Keck}} = 1.07 \pm 0.07$ can be derived by a poor power-law fit to the three R-band data points (reduced $\chi^2 = 26.5$), in disagreement with the V-band decay. This suggest the presence of a break in the light curves at late times. Thus, the Keck data point was excluded from the temporal decay study to avoid the contribution from the possible break. The R-band decay derived from the two VLT data points has a temporal slope $\alpha_R = 0.75 \pm 0.09$, consistent with the V band, where the error was calculated from the minimum and maximum slopes between the two points.

### 4 DISCUSSION

#### 4.1 Modelling the afterglow

In order to investigate the physics of the GRB 080210 afterglow, we attempt to model it within the synchrotron scenario. In Table 5, the temporal slope $\alpha$ and the spectral slope $\beta$ are collected from both the optical and X-ray analysis (where $F_\nu \propto \nu^{-\alpha} \nu^{-\beta}$), as derived above. We first note that the $\beta_{\text{opt}} - \beta_{\text{X}} = 0.88 \pm 0.07$ disagrees with the $\Delta \beta = 0.5$ expected from the fireball model. In particular, this implies that the spectral break is not a cooling break and that the optical and the X-ray emission are not produced by a coherent synchrotron process. Possibly, the optical radiation and the X-rays were emitted in different regions, the overall SED resulting from a composition of two synchrotron spectra. Alternatively, different radiative processes must be invoked to explain the SED.

For the X-rays, we attempt to model it within the synchrotron scenario (where $F_\nu \propto \nu^{-\alpha} \nu^{-\beta}$), as derived above. We first note that the $\beta_{\text{opt}} - \beta_{\text{X}} = 0.88 \pm 0.07$ disagrees with the $\Delta \beta = 0.5$ expected from the fireball model. In particular, this implies that the spectral break is not a cooling break and that the optical and the X-ray emission are not produced by a coherent synchrotron process. Possibly, the optical radiation and the X-rays were emitted in different regions, the overall SED resulting from a composition of two synchrotron spectra. Alternatively, different radiative processes must be invoked to explain the SED.

We further test fireball model predictions calculating the electron energy distribution index, $p$, from the temporal and spectral indices, see Table 5. We assume a simple ISM, slow cooling scenario, with no extra energy injection (Zhang et al. 2006) and the cooling frequency in the soft X-rays, as derived by the SED fit. The electron indices derived from the temporal and spectral slope show a poor agreement ($3.5\sigma$) for the optical band, and disagreement ($5.2\sigma$) for the X-rays. Although the optical and X-ray temporal slopes provide a similar $p(\alpha)$ (within $2.1\sigma$), the electron indices derived from the spectral slopes disagree at a $5.3\sigma$ level between the optical and the X-rays.

Thus, the closure relations are not satisfied for the case of GRB 080210. In particular, the X-ray spectral slope seems too steep to be produced by the synchrotron electron cooling expected in the model. One possible reason for this is that the X-ray spectral slope was overestimated due to the degeneracy with the spectral break and the X-ray absorb-

| Time since GRB (hr) | Instrument | Magnitude |
|---------------------|------------|-----------|
| 0.61                | VLT/FORS2  | 18.74±0.05|
| 1.69                | VLT/FORS2  | 19.57±0.05|
| 55.70               | Keck-I/LRIS | 23.97±0.07|

Table 5. The R-band photometry, not corrected for Galactic extinction (1σ errors). a Perley & Bloom, private communication.
Table 6. The optical and X-ray temporal and spectral indices α and β as observed and expected from the fireball model. We assume here an ISM scenario, with no extra energy injection and the slow cooling regime (e.g., Zhang et al. 2006). The errors are 1σ. The electron energy distribution indices p(α), derived from the temporal slope, agree within 2.1σ between optical and X-rays, while p(β) disagree at a 5.3σ level. The level of agreement between p(α) and p(β) is indicated by σ_{p(α),p(β)}.

|                | α_{obs} | β_{obs} | Regime | α(β)_{exp} | β(α)_{exp} | p(α)       | p(β)       | σ_{p(α),p(β)} |
|----------------|---------|---------|--------|------------|------------|-------------|-------------|----------------|
| Optical        | 0.75 ± 0.09| 0.71 ± 0.01| ν < ν_e| 1.07 ± 0.02| 0.50 ± 0.06| 2.00 ± 0.12| 2.43 ± 0.02| 3.5            |
| X-rays         | 1.24 ± 0.07| 1.59 ± 0.07| ν_e < ν | 1.88 ± 0.11| 1.16 ± 0.05| 2.32 ± 0.09| 3.18 ± 0.14| 5.2            |

4.2 Variability

The ULTRASPEC capability of observing at 1 s time resolution is a new frontier in the GRB afterglow variability study. But do we expect to see variability on those short time scales? How strong? And what processes can produce such variations? Answering these questions is essential to interpret not only the current light curve but also future observations with ULTRASPEC or any equivalent instrument. In order to address these questions and investigate the ULTRASPEC possibility of detecting fast variability, we analyze here the variability limits, derived by Ioka et al. (2005), based on kinematic arguments, showing that only certain time-scale fluctuations are physically allowed, at a particular observing time. These authors consider: (a) dips in the light curve, (b) bumps produced by density fluctuations, (c) a patchy-shell and (d) a refreshed shock. For the sake of clarity, we report below the limits from Ioka et al. (2005) that are relevant for this paper.

(a) The fluctuations that could produce dips in the light curve are limited to

$$\frac{\Delta F_\nu}{F_\nu} \leq 4 \frac{\Delta t}{5t}$$

as derived from geometric constraints on the evolving emitting surface, considering causality arguments, relativistic effects and assuming a sudden shut off of the emission to obtain the upper limit on the variability.

(b) Regardless of their properties, the density enhancements can decelerate the emitting matter, limiting the variability to

$$\frac{\Delta F_\nu}{F_\nu} \leq 8 \frac{\Delta t}{5t}$$

assuming the same geometric and causality arguments as above, and that the kinetic energy $E_{\text{kin}}$ is uniformly distributed in the variable volume.

(c) In case of a patchy shell, the time scale of the fluctuations is initially constrained to grow linearly in time ($\Delta t \sim t$ Nakar & Oren 2004), limiting the variability time scales to

$$\frac{\Delta t}{t} \geq 1$$

for persistent angular fluctuations.

(d) Refreshed shocks can produce bumps with time scales

$$\frac{\Delta t}{t} \geq \frac{1}{4}$$

if the acceleration of the GRB ejecta is hydrodynamic, as a slow shell will expand with its co-moving sound speed and collide with the decelerating leading shock-front.

If the emitting region is observed off-axis, i.e. when the line of sight is not aligned with the jet axis, and many regions ($> 10^3$) contribute to the variability, the dips and density fluctuations, respectively, are limited to

$$(a^*) \quad \frac{\Delta F_\nu}{F_\nu} \leq \frac{6 \sqrt{2}}{\exp(\sigma)} \left(\frac{\Delta t}{t}\right)^{3/2}$$

$$(b^*) \quad \frac{\Delta F_\nu}{F_\nu} \leq \frac{24}{5} \frac{\Delta t}{t}$$

as derived by Ioka et al. (2005) from cases (a) and (b) above.

The variability limits discussed above are plotted in Fig. S (adapted from Ioka et al. 2005), where the regions of allowed variability are indicated by the arrows, for each process. We also indicate the ULTRASPEC observation time domain (outlined by the dashed lines) at mid-exposure time (81.44 min), considering the covered time scales above 2.18 s (0.03 min < $\Delta t$ < 26.45 min) and the instrument detection limit. This limit is calculated from the light curve S/N over a single data point (time bin unit $dt = 1.09$ s) and extended to longer time scales ($\Delta F/F(\Delta t_{\text{bins}}) = \Delta F/F(1 \text{ bin}) / \sqrt{\Delta t_{\text{bins}}}$), where $\Delta t_{\text{bins}}$ is the number of time bins for each time scale. It is this detection limit that defines which fluctuations could possibly have been detected in the ULTRASPEC observations. The region where the allowed variability overlaps with the ULTRASPEC monitoring is highlighted in Fig. S. Given the smoothness of the GRB080210 light curve, we can exclude...
dips (a and a* lines). These limits on the variation amplitude can be interpreted in terms of under-density of the circumburst region within the fireball model. However, we cannot apply this to the case of GRB 080210 because of its non-standard afterglow physics. Finally, with the current ULTRASPEC dataset, refreshed shocks could in principle have been detected on time scales 20.00 min < Δt < 26.45 min, but they were not observed.

4.3 Host galaxy environment

4.3.1 Gas location, metallicity and dust

The spectroscopy of the optical afterglow reveals a number of absorption lines due to neutral and low-ionization species, i.e. O i, Si ii, C ii, Fe ii, Al iii and Zn ii, which can be used to investigate the properties of the absorbing region. The ionization potential of O i (13.618 eV) is very close to that of H i (13.598 keV); this already suggests that the two species could be co-spatial. Indeed, in low ionization media O i and H i tend to couple due to charge exchange (Field & Steigman 1971). The ionization potentials of neutral Si, C, Fe, Al and Zn are well below 13.618 eV. Thus, all the observed species may, in principle, coexist in the same region. However, since the oxygen and hydrogen lines that we detect in the spectrum are saturated, their profiles cannot be used to compare the kinematics. On the other hand, the Voigt profile fit to the Fe ii, Si ii and Al iii transitions indicates that these ions share the same two-component profile. Furthermore, they have comparable ionization potentials. These two pieces of evidence strongly suggest that these species are co-spatial. Al iii is mildly ionized, and therefore belonging to a different gas-phase; however, its double velocity profile indicates that Al iii is still related to the rest of the gas, possibly surrounding the bulk of the H i.

Regarding the distance of the burst to the absorber, to first order, we can exclude that the lines are produced in the close vicinity of the GRB, as ionization is expected to occur inside ~10 pc (see e.g. [Ledoux et al. 2009]). The Mg i is a possible distance limit indicator (> 50 pc; Prochaska, Chen & Bloom 2000), but none of its transitions were covered by the observations. The actual distance of the bulk of the gas may be much larger. Indeed, absorption systems have been found up to several kpc from the burst (Vreeswijk et al. 2002; D’Elia 2003; Ledoux et al. 2009), where the distance was computed using a photo-excitation (UV pumping) model of the fine-structure line variability. We also detect fine structure lines (i.e. Si ii*, C ii* and Fe ii* in the 1400V and 300V grisms, see also [Fynbo et al. 2009]), but the low resolution of the FORS spectra does not allow any further modelling.

From the DLA profile fit, we derived a neutral hydrogen column density, \( \log (N_{\text{H}}} / \text{cm}^{-2}) = 21.90 \pm 0.10 \). This fairly high column density, compared to the low-resolution afterglow sample analysed by [Fynbo et al. 2009], causes the neutral hydrogen to screen heavier elements (present in the same gas with much lower abundances) from ionization. Thus, we assume that no ionization effects...
can significantly influence the metallicity estimate. The best metallicity indicator between the optical absorption lines that we detected is Si II A1808, for which we find [Si/H] = −1.21 ± 0.16 (Z/Z⊙ = 0.06−0.02). This suggests a chemically poor environment, quite common for GRBs with bright optical afterglows, where metallicities fall below 0.3Z⊙ for most absorbers (Fynbo et al. 2006).

From the X-rays, we derive an equivalent hydrogen column density of log (N_H/cm^2) = 21.58±0.18 assuming Solar abundances, whilst log (N_H/cm^2) = 22.31±0.15 for Z/Z⊙ = 0.06. The soft X-ray absorption is normally produced by metals in the line-of-sight, e.g., carbon and oxygen (Wilms et al. 2000). The equivalent hydrogen column density measured from the X-ray absorption in GRB 080210 is comparable to the neutral hydrogen column density log (N_H/cm^2) = 21.90 ± 0.10 from the Lyα. However, in general the equivalent and neutral hydrogen column densities correlate extremely poorly (Watson et al. 2007).

We find a visual extinction, A_V = 0.18 ± 0.03 mag, from the SED fitting and interpret it as due to dust. This value is quite common in GRB afterglows (Kann et al. 2011; Schaelv et al. 2011; Zafar et al., in preparation.). An SMC extinction law best reproduces the dust extinction that affects the GRB 080210 afterglow spectrum and a MW extinction law can be excluded. Consistent with this, we do not observe the 2175 Å bump (7919 Å in the observer frame), which is a typical signature of the Galactic dust absorption (Pei 1992). Even though such a structure has been observed in GRB afterglows (Kruhler et al. 2008; Elasdottir et al. 2009; Perley et al. 2010), it has been shown that in most GRB host galaxies, dust typically displays an SMC extinction curve (e.g., Starling et al. 2007; Kann et al. 2011). While a Galactic extinction law requires roughly the same amount of graphite and silicate grains, the SMC curve can be produced by silicate grains alone (Pei 1992). Thus, we infer a low graphite dust content for the GRB 080210 host galaxy. Although the presence of dust is expected in DLAs (Pettini et al. 2009; Perley et al. 2010), it has been shown that in most GRB host galaxies, dust typically displays an SMC extinction curve (e.g., Starling et al. 2007; Kann et al. 2011). While a Galactic extinction law requires roughly the same amount of graphite and silicate grains, the SMC curve can be produced by silicate grains alone (Pei 1992). Thus, we infer a low graphite dust content for the GRB 080210 host galaxy. Although the presence of dust is expected in DLAs (Pettini et al. 1997), the low metallicity disfavours the production of dust grains, as shown by the relation between dust and metallicity (Vladilo 1998).

4.4 Origin of the intervening system

The intervening system at z = 2.508 would require a relative velocity v ≈ 11,000 km s^−1, if associated with the GRB host galaxy. Velocities up to 3,000 km s^−1 have been observed in GRB afterglow spectra (e.g., Mirabal et al. 2003) or expected by Wolf Rayet wind models (van Marle et al. 2004). However, none of the proposed scenarios seems to be able to reproduce ∼ 10,000 km s^−1.

An intriguing possibility is that such an outflow could be accelerated by an active galactic nucleus (AGN). About half of the C IV and Mg II narrow-line absorbers towards QSOs with apparent outflow velocities of 3,000–12,000 km s^−1 are actually intrinsic to the QSO/host (Wild et al. 2008). We cannot exclude the possibility that the host galaxy of GRB 080210 is a low-luminosity AGN, since its emission would fall well below the detectability limit of X-ray telescopes. However, it is unlikely that a ∼ 10,000 km s^−1 fast outflow could remain as narrow in velocity as we observe (b_turb ∼ 30 km s^−1). In addition, if the faster outflows occur in the polar direction of an axisymmetric accretion geometry, it might be difficult to locate a star forming region hosting the burst between the nucleus and the accelerated absorbing material without invoking a fine tuned geometry. Moreover, the fastest outflows are typically located very close to the AGN itself and the burst location is unlikely to cross them on the line of sight.

Thus, the most favoured origin of the intervening system at z = 2.509 is an absorber on the line of sight, a cloud or a galaxy ∼ 43 Mpc from the GRB host galaxy and unrelated to it. Statistically, a significant incidence of intervening systems is expected. Given the number density per unit redshift interval of intervening absorbers, not associated with the host galaxy, the probability of detecting at least one random C IV absorber of rest-frame EW(λ1548) > 0.4 Å is 34 per cent (Chen et al. 2007).

5 SUMMARY

We searched for short-term variability, down to 2.18 s, in the ESO 3.6-m/ULTRASPEC observations of the GRB 080210 optical afterglow. The light curve decays as a power law (α = 0.74 ± 0.07) and appears smooth on all time scales. Nevertheless, the time-monitoring allows us to investigate the circumburst environment and the blast-wave propagation. Comparing our observation with the variability limits derived by (oka et al. 2002), we can exclude dips in the light curve with amplitude stronger than 1 per cent of the flux on time scales Δt > 9.2 min and stronger than 2 per cent on time scales Δt > 2.3 min, for a single or many under-dense regions respectively.

The GRB 080210 optical and X-ray late afterglows decay with temporal slopes α_opt = 0.75 ± 0.09 and α_X = 1.24 ± 0.07. The spectral slopes β_opt = 0.71±0.01 and β_X = 1.59 ± 0.07 are derived from the joint optical-to-X-ray SED fit with a broken power law (1σ errors). We evaluate these observations with the theoretical expectation of the standard model and find no agreement within 5.3σ, suggesting that the GRB 080210 afterglow cannot be produced with the fireball model physics.

From the SED analysis, we find that the spectral break is located in the soft X-ray at E_bREAK = 1.40 ± 0.13 keV, while the X-rays absorption indicates an excess equivalent hydrogen absorption of log (N_H/cm^2) = 21.58±0.18 assuming Solar abundances, and log (N_H/cm^2) = 22.31±0.15 for Z/Z⊙ = 0.06. This establishes that the soft X-ray emission is likely produced by metals in the line-of-sight, e.g., carbon and oxygen (Wilms et al. 2000). The equivalent hydrogen column density measured from the X-ray absorption in GRB 080210 is comparable to the neutral hydrogen column density log (N_H/cm^2) = 21.90 ± 0.10 from the Lyα. However, in general the equivalent and neutral hydrogen column densities correlate extremely poorly (Watson et al. 2007).

In the optical VLT/FORS2 spectra, we detect several metal absorption lines associated with the GRB host galaxy (z = 2.641), as well as a DLA (log (N_HI/cm^2) = 21.90 ± 0.10). We find [Si/H] = −1.21 ± 0.16.
reveals a two-component profile, separated by 148 km s\(^{-1}\), possibly associated with two major clouds along the line of sight within the host galaxy.

GRB 080210 represents one of the first attempts to study fast variability in GRB afterglows. Although this particular case must be treated with caution, due to its non-standard afterglow physics, our analysis demonstrated that the expected short-term can be detected by using the high speed read-out of the ULTRASPEC camera, specially for bright afterglows with higher S/N.

ACKNOWLEDGEMENTS
ADC acknowledges support from the University of Iceland Research Fund. PJ acknowledge support by a Marie Curie European Re-integration Grant within the 7th European Community Framework Program and a Grant of Excellence from the Icelandic Research Fund. The Dark Cosmology Centre is funded by the Danish National Research Foundation. ULTRASPEC was funded by the EU-OPTICON programme. This work made use of data supplied by the UK Swift Science Data Centre at the University of Leicester.
