**Abstract**

**Background:** Cerebral palsy (CP) is the most common type of permanent movement and postural disorder in childhood that occurs because of a lesion in the developing brain (1). These children may experience a wide range of movement, postural, coordination, sensory, and cognitive disorders throughout their lives (2). Various treatment and rehabilitation interventions are performed to maximize the performance of these children (3, 4). Many efforts have been made to investigate the effect of these interventions on children with CP by employing appropriate outcome measures. In recent years, quality of life (QOL), as a manifestation of health and well-being, has been proposed as an outcome measure for evaluating the effectiveness of interventions (5). In the International Classification of Functioning (ICF), QOL has been proposed as the ultimate goal of interventions (6). QOL can also be considered as a predictor of a child's health status (7).

According to the definition of the World Health Organization, QOL is an individual's understanding of his or her situation and circumstances in life, which is based on their culture, value system, goals, expectations, standards, and priorities. Therefore, QOL is completely individualized and subjective and is based on people's understanding of different aspects of their lives (8, 9). Although QOL has a multidimensional structure, many researchers agree that it is equal to person's performance or is highly dependent on their performance (10).

Studies showed impaired QOL in children with CP. This degree of impairment is associated with the level of independence in daily activities, mobility, clinical limitations, and social interactions (11). Shelley and colleagues (12) examined the relationship between the QOL of children with CP and their level of performance. In their study, the CPQOL questionnaire was used to evaluate the QOL of children with CP, and Gross Motor Function Classification System (GMFCS) was used to evaluate their level of gross motor function. A significant relationship was found between the subscales of QOL and gross motor function. However, this association was more related to the physical subscale than the psychosocial subscale. The relationship between performance and QOL is not limited to walking performance and a positive relationship between physical activity and QOL has also been reported (11).

Park and co-workers (13) used path analysis to assess the relationship between strength, spasticity, gross motor function, and QOL on 62 children with spastic CP. There was a significant and direct relationship between spasticity, strength, and gross motor function, and between gross motor function and health-related QOL, as well as between strength and children's QOL. In another study, Kolman and colleagues (14) examined the predictors of health and QOL. They found that factors related to comfort, emotions, communication, and social interactions predicted QOL more than mobility and self-care. Maher and co-workers (15) also reported that physical activity significantly predicted the quality of physical and social life. However, in a systematic review of studies on the QOL of children and adolescents with CP in the middle- and low-income countries, it was reported that the physical subscale of QOL of children with CP was highly affected, and this physical subscale was strongly correlated with motor function (15). However, these children have a high QOL in the psychosocial subscale even if they have low performance (12).

It seems that gross motor function and manual and cognitive ability could predict the QOL of children with CP. Therefore, we aimed to investigate the relationship between performance of children with CP in terms of gross motor function, manual ability, and cognitive function with their QOL.

**Methods**

In this cross-sectional study with non-probability sampling, 200 children with CP were enrolled from eight rehabilitation centers and three schools for children with physical disabilities. We included children aged 4-12 years diagnosed with CP according to their medical records or their therapists' report, whose parents were literate and agreed with their participation. Children were classified topographically and physiologically according to the Surveillance of Cerebral Palsy in Europe (SCPE) (16).

**Tools and Measures**

The data for this study were collected using a socio-demographic characteristics questionnaire, the Persian version of the CPQOL-parent, GMFCS, Manual Ability Classification System (MACS), and the SPARCLE cognitive level estimation form.

The socio-demographic questionnaire includes 46 questions divided into four sections: questions related to the child, the parents, the child's caregiver, and the child's health status.

The CPQOL-parent version measures condition-specific QOL and is completed by the parents. This questionnaire has 66 items and is appropriate to assess the QOL of children with CP aged 4-12 years. The answer to each question is divided into a 9-point Likert scale, which the parent either selects or draws a line around.
CPQOL has seven subscales, including (1) social well-being and acceptance; (2) functioning; (3) participation and physical health; (4) emotional well-being; (5) pain and impact of disability; (6) access to services; and (7) family health. The Persian version of the CPQOL-parent version questionnaire was validated according to the protocol provided by the developers (19), and had acceptable reliability (ICC=0.47-0.84) and the subscales had appropriate internal consistency (α=0.61-0.87) (19).

Gross motor function was assessed according to the GFMCS and based on spontaneous gross movement such as the child's head control, sitting, standing, and transferring (20). In this system, the gross motor function of children with CP is classified into five levels. In level one, children have the most, and in level five, children have the least independent motor function. This scale has acceptable validity and reliability (20, 21).

The MACS assesses children's manual ability based on how their hands are used to control objects in everyday life (22). This system is defined in five levels similar to the GFMCS. Children in level one have the highest manual ability function, and children in Level five have the least control over the objects. MACS has been validated in Persian and has an acceptable level of validity and reliability (23).

Cognitive function in children with CP was estimated and classified into three levels including: >70, 70-50, <50. This classification was prepared and used by SPARCLE in Europe (24). Parents with children with CP are asked to answer four questions. Then, based on their responses, the children's cognitive level is identified.

Procedures

Following the recruitment of the participants, the aims and steps of completing the questionnaires were explained to them. Then, upon their willingness, written consent was obtained from the parents. In the next steps, the questionnaires of the study were completed according to the following order. First, CPQOL and socio-demographic questionnaires were completed consecutively by the parents. Then, the children's GFMCS, MACS, and level of cognition were identified by an assessor (three occupational therapists) by interviewing the parents. On average, the whole process took about 60 minutes. This study was approved by the Ethical Committee of the University of Social Welfare and Rehabilitation Sciences (ID: 801/4/88/58).

Data analysis

Data were analyzed using SPSS software, version 19. Descriptive statistics were used to determine the characteristics of the participants. Linear regression was used to investigate the relationship between the subscales of CPQOL and children's functions, including gross motor function, manual ability, and cognitive function.

Results

The mean ± SD age of the 200 children participating in this study was 7.7 ± 2.40 years. The distribution of various levels of manual ability function was almost close to each other in five levels according to MACS. Levels four and three had the highest percentage with 23% and 20%, respectively, and the other levels were 19% each. The distribution of gross motor function according to the GFMCS was different from MACS. Levels four and two were the highest with 30.5%, and 24.5% respectively. The lowest percentage was at level one with 11% (Table 1).
Table 1
Demographic characteristics of children with CP

|                        | Number | Percent |
|------------------------|--------|---------|
| **Sex:**               |        |         |
| Female                 | 97     | 48.5    |
| Male                   | 103    | 51.5    |
| **Cerebral Palsy Type:**|       |         |
| Spastic (Unilateral)   | 36     | 18.0    |
| Spastic (Bilateral)    | 125    | 62.5    |
| Ataxic                 | 10     | 5.0     |
| Dyskinetic             | 14     | 7.0     |
| Not Classified         | 15     | 7.5     |
| **Manual Ability Classification System (MACS):** | | |
| Level 1                | 38     | 19.0    |
| Level 2                | 38     | 19.0    |
| Level 3                | 40     | 20.0    |
| Level 4                | 46     | 23.0    |
| Level 5                | 38     | 19.0    |
| **Gross Motor Function Classification System (GMFCS):** | | |
| Level 1                | 22     | 11.0    |
| Level 2                | 49     | 24.5    |
| Level 3                | 31     | 15.5    |
| Level 4                | 61     | 30.5    |
| Level 5                | 37     | 18.5    |
| **Cognitive function:** |       |         |
| 50 >                   | 36     | 18.0    |
| 50–70                  | 46     | 23.0    |
| 70 <                   | 118    | 59.0    |

Using linear regression, the relationship between CPQOL subscales and gross motor function did not show a statistically significant difference in any of the subscales. However, this relationship with the functioning subscale was close to a significant level (P = 0.071) (Table 2). Because of the similarity of the scale of variables with respect to non-standardized coefficients B, the most effective relationships were obtained with the subscales of functioning and participation and physical health. Negative relationships indicate an inverse relationship between severity of disability and QOL.
Discussions

In this study, the relationship between CPQOL subscales and children with CP’s functions (gross motor function, manual ability, and cognitive level) were investigated. The main question of this study was: do children with a high level of function (i.e., gross motor, manual ability, and cognitive level) have a higher quality of life? According to the result of this study, the relationship between CPQOL subscales and gross motor function did not show a statistically significant in any of the subscales. Also, the relationship between the CPQOL subscales and the children’s manual ability was not statistically significant except for the functioning subscale. The relationship between CPQOL subscales and the children's cognitive level showed a statistically significant relationship only with the functioning subscale (P < 0.05) (Table 2). The relationship with other subscales was not statistically significant.

In previous studies, it has been concluded that despite the relationship between performance and physical subscales of QOL, there is no relationship between performance and psychosocial subscales of QOL or this relationship is weak. It should be noted that in these studies, questionnaires used assessed the activities that the child can do more than the general well-being of children. In other words, they were more related to performance than well-being (25, 26). Well-being is a broader term than performance and is a more appropriate term to describe health. Well-being includes the presence of positive emotions and moods, the absence of negative emotions, satisfaction with life, fulfillment, and positive functioning. In our study, we use CPQOL questionnaire that evaluates well-being along with functioning and participation. Shelley and colleagues (12) investigated the QOL of children with CP based on CPQOL as well as its relationship with gross motor function. We used this questionnaire not only for gross motor function but for manual ability and cognitive function as well. We found that not only the relationship between QOL subscale of functioning and gross motor function was closed to a significant level, but this relationship was also significant for the child’s manual ability and cognitive level. This is a confirmation of previous studies, adding that regarding performance, not only gross motor performance but also the manual ability and cognitive level should be considered. In a study on children who were ambulated, Omura and co-workers (27) found a significant relationship between walking abilities and the physical subscale of CPQOL. They also reported that there was a positive correlation between physical function, gait function, and a child's level of communication with physical subscales of QOL. However, this study was performed on children who were able to walk.

Delicate motor function, including speed and mastery of the upper limbs and visual-motor control, were named as the most important motor factors affecting the QOL of children with CP in a study by Chen and colleagues (28). In Kolman and co-workers’ study (7), inability to walk or understand the caregiver, being unhappy or sad, and not going to school were significant predictors of their poor QOL in children with CP.

The results of this study also demonstrated a significant relationship between the functioning aspects of CPQOL and children’s manual ability. The results of this study are different from Shelly and colleagues’ (12) that showed a significant relationship between all CPQOL subscales (except “access to health services” subscale). In their study, the relationship between the physical subscales of CPQOL was stronger than the psychosocial one. Teuscherco-
workers(2019)reported that manual ability and QOL were associated with health in a five-year follow-up study of children with CP. However, despite the significant relationship between children's function and physical subscale of QOL, this relationship was not significant with other subscales(29). It maybe concluded that a child with CP with poor performance has the potential to report a high QOL. What has been mentioned in studies as a reason for this is that the person with CP has the ability to adapt to the conditions of disability. This needs more evidence for elaboration.

Limitations

Due to the lack of a proper registry system for recording information on children with CP, access to these children through randomization was not possible. Therefore, this study applied the convenient sampling procedure. One of the strengths of our study was our large sample size with appropriate distribution in various levels of gross motor function and manual ability.

Declarations

Ethics approval and consent to participate

This study was approved by the Ethical Committee of the University of Social Welfare and Rehabilitation Sciences (ID: 801/4/88/58). Informed written consent was obtained from participant parent. All methods were carried out in accordance with relevant guidelines and regulations under Ethics approval and consent to participate

Consent for publication
