ABSTRACT—We determined whether chronic treatment with nipradilol, a $\beta$-blocker with vasodilating action, reduces left ventricular cavity dilation (LV remodeling) following myocardial infarction and improves cardiac performance. Myocardial infarction was produced by coronary artery ligation in 16-week-old female rats and then the rats were treated for 3–4 months with nipradilol (10 mg/kg/day) or vehicle (0.5% carboxymethylcellulose). The effect of nipradilol on LV remodeling was evaluated by assessing the left ventricular end-diastolic volume index (LVEDVI) and passive pressure-volume relation curve. Since LVEDVI depends on the infarct size, LVEDVI was compared between the vehicle- and nipradilol-treated rats with similar infarct size (10–40%). At 3–4 months after myocardial infarct production, the left ventricular end-diastolic volume index in the vehicle-treated rats with myocardial infarction was significantly increased, compared with that in the sham-operated rats without infarction. The nipradilol-treated rats had a significantly smaller left ventricular volume index than the vehicle-treated rats (2.04 ± 0.16 ml/kg in the vehicle-treated group vs 1.36 ± 0.10 ml/kg in the nipradilol-treated group, $P < 0.01$). The maximum cardiac index achieved by volume loading as an index of cardiac performance was significantly greater in the nipradilol group than the vehicle group (254.5 ± 12.6 ml/min kg in the vehicle group vs 347.9 ± 20.2 ml/min kg in the nipradilol group, $P < 0.01$). These results suggest that chronic treatment of nipradilol attenuated left ventricular cavity dilation after myocardial infarction and improved cardiac performance.

Keywords: Remodeling, Myocardial infarction, Cardiac function, Nipradilol, Left ventricular diastolic volume

In experimental (1) and clinical (2) studies, it has been shown that the left ventricular (LV) cavity dilates progressively following acute myocardial infarction (MI), namely, LV remodeling. LV remodeling is a major risk factor for mortality and morbidity after MI (3). It has been reported that angiotensin-converting enzyme inhibitors such as captopril suppress remodeling in experimental (4) and clinical (5) studies. Furthermore, recent studies have demonstrated that angiotensin II type 1 receptor blockers (6) and nitrates (7, 8) may attenuate LV remodeling in some animal models of MI. The reduction of LV remodeling by these three different types of drugs is believed to result from LV unloading due to their vasodilatation.

$\beta$-Adrenergic blockers are often used in the treatment of patients with acute MI and have been shown to reduce morbidity and mortality at the acute and chronic stage of MI, presumably by preventing myocardial ischemia in the jeopardized myocardium and arrhythmia (9, 10). However, previous studies in rats have suggested that propranolol may promote LV dilation following MI (11, 12), which may adversely affect LV function.

Nipradilol (3,4-dihydro-8-(2-hydroxy-3-isopropylamino) propoxy-3-nitroxy-2H-1-benzopyran) is a $\beta$-blocker that has a vasodilating action partly mediated by the nitrate moiety of the chemical structure (13, 14), in addition to the non-selective $\beta$-adrenergic blocking action. Nipradilol, but not propranolol, has been demonstrated to increase venous compliance and show an LV unloading in clinical (15, 16) and animal (14) studies.

From these observations, we considered that nipradilol may reduce the LV remodeling through LV unloading. Therefore, we performed this study to determine whether chronic treatment of nipradilol favorably affects LV...
remodeling and cardiac performance following MI in rats.

MATERIALS AND METHODS

The rats used in this study were handled according to the animal welfare regulations of our institution, and the protocol was approved by the Animal Use Committee of the institution. These regulations are in accordance with the principles of animal use of the American Physiological Society.

Experimental MI

MI was produced in 16-week-old female Wistar rats (n=150) by the previously described method (17). In brief, the rats were anesthetized with ether and a left-sided thoracotomy was performed. The heart was exteriorized and a coronary artery was ligated with a 5/0 braided silk suture. The heart was returned to the chest cavity and the wound was rapidly closed. Two days after the ligation, the surviving rats were randomly divided into two groups: nipradilol- (n=46) and vehicle- (n=48) treated groups. Imposed oral administration of nipradilol (10 mg/kg, suspended in 2 ml/kg of 0.5% carboxymethylcellulose (CMC), once daily) or vehicle (2 ml/kg/day of 0.5% CMC, once daily) to the respective treatment group began on the second day of MI production and continued for 3-4 months. The dose used in this study has been reported to lower arterial pressure in spontaneously hypertensive rats (approximately 10 mmHg) after single oral administration, which was associated with reduction of peripheral vascular resistance (13). In another set of experiments, age- and sex-matched Wistar rats (n=9) were sham-operated and treated daily with the vehicle.

The rats were maintained under a room temperature of 23±2°C, a room humidity of 60±10%, 12-hr light/dark cycle, and allowed food and water ad libitum.

Measurements of hemodynamics

On the day after the final administration, the rats were anesthetized lightly with pentobarbital sodium (30 mg/kg, i.p.). A micromanometer-tipped catheter transducer (CTC-047N; Nihon Kohden, Tokyo) was inserted into the right carotid artery, advanced into the aorta to measure aortic blood pressure, and then inserted into the LV cavity to measure LV pressure. The rate of change of LV pressure divided by simultaneous LV pressure (dP/dt/P) was measured by a pressure processor (EQ600-G, Nihon Kohden). Peak positive and negative dP/dt/P, (+dP/dt/P)max and (−dP/dt/P)max, were used as indices of LV contractility and relaxation, respectively. A lead II electrocardiograph was recorded and the heart rate (HR) was measured. A thoracotomy was then performed and ventilation was maintained with a positive pressure respirator (Rodent Respirator 680; Harvard Apparatus, South Natick, MA, USA) at 60 strokes/min and a tidal volume of 1 ml/100 g body weight. An electromagnetic flow probe (FT-025T, Nihon Kohden) was placed around the ascending aorta to measure baseline cardiac output. We waited for at least 30 min before recording hemodynamic variables, by which time they had become stable. To assess the maximum output-generating capacity (Cl max) of the heart, we measured maximal cardiac output by the previously described method (4). In brief, Tyrode’s solution bubbled with 95% O2 and 5% CO2 and maintained at 37°C was infused rapidly at the rate of 30.6 ml/min through the cannula inserted into the right jugular vein, to produce a rise in cardiac output to the maximal and plateau levels. We recorded mean arterial blood pressure (MAP), LV pressure, LV dP/dt/P, HR and cardiac output in each rat. The cardiac index (CI) was derived by normalizing the cardiac output by the body weight (in kilograms), and the systemic vascular resistance (SVR) before saline loading was calculated from the baseline cardiac output and MAP.

Isolated LV pressure-volume relationships

After the completion of all hemodynamic measurements, 1.0 ml of 2 mM KCl was rapidly injected intravenously to arrest the heart in diastole. The LV pressure-volume relation was assessed by the previously described method (18). Briefly, the heart was removed and the right ventricle was incised. A double-lumen catheter, attached to a pressure transducer (Statham P50; Gould Instruments Co., Cleveland, OH, USA) and an infusion pump (A-2; Truth, Tokyo), was passed into the LV and tied with a ligature at the atrioventricular groove to isolate the LV from the left atrium. After gentle aspiration to reduce the pressure to about −5 mmHg, saline was infused at 0.68 ml/min into the LV, while LV pressure was continuously recorded until it reached 30 mmHg. The pressure-volume curves were generated over the pressure range of 0–30 mmHg. Ventricular volumes at 0, 3, 5, 10, 15, 20, 25 and 30 mmHg were calculated from the infusion rate and time. The volumes normalized to body weight were used for analysis. As a measure of the LV cavity volume, the LV end-diastolic volume index (LVEDVI) was estimated from the measured left ventricular end-diastolic pressure (LVEDP) and the LV pressure-volume curve in each heart, as described by Pfeffer et al. (4). In short, the LV volume was determined by finding the volume on the recorded postmortem pressure-volume curve that corresponded to the end-diastolic pressure obtained in the hemodynamic measurements in vivo.
LV chamber stiffness

The chamber stiffness constant, $K_c$, was determined as reported previously (19, 20). Pressure-volume curves at the LV pressure range above 3 mmHg were fitted to the following exponential function:

$$P = b \exp(K_cV) + c \quad \text{for } 3 \leq P \leq 30 \text{ mmHg}$$

where $P$ is the LV pressure and $V$ is the ventricular volume index.

$K_0$ at the pressure range of 3–30 mmHg is the overall chamber stiffness constant. $K_1$ at the pressure range of 3–10 mmHg; $K_2$, 10–20 mmHg; and $K_3$, 20–30 mmHg were calculated as the slope from the curvilinear relation in the respective pressure range according to the formula:

$$\frac{dP}{dV} = K_cP \quad \text{for } c = 0 - 3.$$  

Infarct size measurement

After assessment of the pressure volume curve, 10% formalin solution was infused into the LV until the pressure achieved 20 mmHg, and then the heart was fixed with this pressure for more than 48 hr. The LV was then weighed, embedded in paraffin, and cut into serial 4-μm sections at 2-mm intervals from the apex to the base. These specimens were stained with Azan and the infarct size was determined in each animal by using the techniques described earlier (4). In short, the perimeter of the scar and that of the non-infarcted muscle for both the endocardial and epicardial surface of each section were measured three times with a microcomputer-controlled curvimeter (S-type; Uchida Yoko, Tokyo) and averaged. The circumferential lengths of the scar at the endocardial and epicardial surfaces in all histological sections were numerically summed separately. The ratio of the sum of the scar circumferences to the sum of the surface circumferences defined the infarct size.

Data analyses

The MI size is known to influence the magnitude of LV cavity volume expansion (21). To assess the effects of n pipradilol on LV remodeling, the comparison of LV volumes was made between rats with similar MI size (10%–40%) of the vehicle- and the n pipradilol-treated groups. By the previously reported criteria of MI size classification (4), 10–40% of MI was classified into “small” and “medium” groups and >40% “large” and “extensive large”. On the basis of this, we used the rats with 10–40% of MI in this study. In rats with infarcts greater than 40%, however, we could not obtain a sufficient number of animals to compare the variables between the vehicle- and n pipradilol-treated rats.

All values are expressed as means±S.E.M. Analysis of variance (ANOVA) was applied to compare mean values among the groups. When ANOVA showed statistical significance by the F-test, intergroup comparisons among the sham-operated, the vehicle-treated and the n pipradilol-treated groups were made by Tukey multiple comparison test. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS

Table 1 shows the number of animals, body weight (BW), LV weight per 100 g of body weight (LV/body weight) and the treatment period. The treatment period did not differ among the sham-operated, the vehicle-treated and the n pipradilol-treated rats. BW of the sham-operated and the n pipradilol-treated rats were significantly greater than that of the vehicle-treated rats. Values of the LV/body weight of the vehicle- and the n pipradilol-treated rats were significantly greater than that of the sham-operated rats. The mean infarct size of the n pipradilol group used in this study was slightly but significantly greater than that of the vehicle group.

Table 2 shows the baseline hemodynamics in these three groups. Among the three groups, there were no differences in MAP and HR. The CI in the vehicle and the n pipradilol groups were significantly lower than that in the sham group. LVEDP in the vehicle-treated rats with MI was significantly greater than that in the sham-operated

| Group                | n  | BW (g)   | Inf (%) | LV/body weight (mg/100 g) | Treatment period (day) |
|----------------------|----|----------|---------|--------------------------|------------------------|

n, Number of animals; BW, body weight; Inf, myocardial infarct size; LV/body weight, left ventricular weight per body weight ratio. *$P<0.05$, **$P<0.01$ vs the sham-operated rats without myocardial infarction. $^*P<0.05$, $^*P<0.01$ vs the vehicle-treated rats with myocardial infarction.
Of the rats with MI, LVEDP in the nipradilol group was significantly smaller than that in the vehicle group. The SVR in the vehicle group was greater than that in the sham group (P<0.01). (+dP/dt/P)max and (-dP/dt/P)max in the vehicle group with MI were significantly smaller than those in the sham-operated group. In the nipradilol group, (+dP/dt/P)max was significantly greater than in the vehicle group.

n, Number of animals; MAP, mean arterial blood pressure; HR, heart rate; CI, cardiac index; LVEDP, left ventricular end-diastolic pressure; (+dP/dt/P)max, maximum rate of rise of left ventricular pressure normalized by simultaneous left ventricular pressure; (-dP/dt/P)max, maximum rate of decline of left ventricular pressure normalized by simultaneous left ventricular pressure; SVR, systemic vascular resistance.

Fig. 1. Left ventricular pressure-volume (per kg) relationship of the sham-operated (○, n=9), the vehicle-(●, n=22) and the nipradilol-treated (□, n=20) rats. Each point and horizontal bar indicate the mean±S.E.M. *P<0.05, **P<0.01 vs the sham-operated rats without myocardial infarction, ^P<0.05, ^P<0.01 vs the vehicle-treated rats with myocardial infarction.

The LV pressure-volume relation obtained by passive volume loading is shown in Fig. 1. The curve of pressure-volume relation in the vehicle-treated rats with MI was significantly shifted to the right from that in the sham-operated rats without MI. The curve of the nipradilol-treated rats with MI was rightward-shifted from that of the sham-operated rats without MI and leftward-shifted from that of the vehicle-treated rats with MI.

Table 3 shows the LV chamber stiffness constants calculated from the curve-analysis of the LV pressure-volume curve. The stiffness constants in all of the pressure ranges in the vehicle group were significantly smaller than that in the sham-operated group. Of the infarcted rats, K3 of the nipradilol-treated group was significantly greater than that in the vehicle-treated group and the other stiffness constants of the nipradilol group tended to be greater than those of the vehicle group.

LVEDVI, a measure of LV cavity volume, in each group is shown in Fig. 2. LVEDVI in the vehicle-treated rats with MI was significantly greater than that in the
sham-operated rats without MI. LVEDVI in the nipradilol group was significantly smaller than that in the vehicle group.

The CI_max, an index of the capacity of maximum cardiac output-generation, in the vehicle group with MI was significantly smaller than that in the sham-operated rats. CI_max in the nipradilol group was significantly greater than that in the vehicle group and did not differ from that in the sham-operated group (Fig. 3).

DISCUSSION

The purpose of this investigation was to examine the chronic effects of a β-adrenergic blocker with vasodilating action, nipradilol, on LV dynamics and compliance in rats with MI. The results indicate that LV cavity dilation following MI was reduced by chronic therapy with nipradilol; this effect was associated with the improvement in LV cardiac performance.

The effects of chronic MI on cardiac and hemodynamic function can be assessed by comparing the findings in the vehicle-treated rats with MI and those in the sham-operated rats without MI. The rightward shift of the LV pressure-volume curve and the greater LVEDVI in the rats with MI in comparison with the rats without MI suggest that 3–4 months MI caused LV remodeling. The LVEDVI in the MI rats was more than two times greater than that in the non-infarcted rats, indicating that LV cavity dilation occurred in not only infarcted but non-infarcted regions of the heart. In analysis of the pressure-

volume curves, the smaller LV stiffness constants observed in the MI rats means that there is a smaller increase in LV pressure for any given volume during saline loading, which may also reflect an eccentric LV chamber dilation by MI. Of the baseline hemodynamics, LVEDP in the MI animals was higher than that in the non-infarcted animals, which indicates that LV preload increased after MI. The smaller values of CI, CImax, LV(+dP/dt/P)max and (-dP/dt/P)max in the rats with MI suggest that MI caused cardiac dysfunction and impaired LV contractility and relaxation.

The effects of nipradilol on LV remodeling and hemodynamics may be assessed by comparing the findings between the vehicle- and nipradilol-treated rats with MI. In a previous study (13) using hypertensive rats, nipradilol given in a dose of 10 mg/kg has been reported to show a hypotensive effect after a single oral administration, which was associated with reductions of HR and SVR. Thus, we used the dose assumed to be enough to show such cardiovascular effects in this study. However, MAP and HR in the nipradilol-treated rats did not differ from those in the vehicle-treated rats. These hemodynamic discrepancies might depend on the disappearance of significant cardiovascular effects of nipradilol because the hemodynamic measurements were performed more than 24 hr after the last administration and/or on difference of the experimental conditions, i.e., the lineage difference between hypertensive and normotensive rats. Nipradilol shifted the LV pressure-volume curve to the left and reduced LVEDVI. Several factors are known to influence LV cavity volume after MI, including the location of the ligature in the coronary artery, the onset of the drug treatment, the time after MI (1, 2) and the infarct size (21). Among these factors, the ligature location and the onset of treatment were the same in the vehicle and nipradilol-treated animals. The time after MI may not be a factor either in this study because the treatment days did not differ between these two groups. The difference in the degree of LV dilation was unlikely to be related to such non-specific factors. LV cavity enlargement after MI has been reported to increase in proportion to the size of MI (21). In the present study, the mean size of MI in the nipradilol rats was slightly but significantly greater than that in the vehicle rats. Despite the larger MI size, the nipradilol-treated rats had a significantly smaller LV cavity volume than the vehicle-treated rats. These observations suggest that nipradilol reduced the LV remodeling following MI. The greater stiffness constants in the nipradilol rats may also reflect the reduction of LV chamber dilation by nipradilol. Of the baseline hemodynamics, the cardiac contractility was improved by nipradilol because (+dP/dt/P)max in the nipradilol rats was greater than that in the vehicle rats. Nipradilol increased CI_{max} and decreased LVEDP, suggesting that...
chronic therapy with nipradilol improves the cardiac dysfunction and reduces the preload.

Several reports, investigating the effects of propranolol on the MI-induced LV remodeling in rats, have demonstrated that propranolol facilitated or did not reduce the LV remodeling after MI (11, 12). These reports suggest that the beneficial effects of nipradilol on LV remodeling following MI in rats did not result from its β-blocking action. The mechanisms by which nipradilol reduced LV remodeling after MI in Wistar rats are not known from our study. However, it has been demonstrated that angiotensin-converting enzyme inhibitors (4) and angiotensin II type 1 receptor blocker (6) reduce LV cavity enlargement after MI through reduction of preload and afterload and/or through suppression of the renin-angiotensin-aldosterone system. The former leads to LV unloading, and the latter system has been shown to play an important role in the development of reactive hypertrophy and fibrosis accompanied by LV remodeling (22). Hirai et al. (23) have reported that the long-term administration of nitrates may also reduce LV remodeling in a canine model of MI and suggested that the decreases of preload and afterload and/or the increase of collateral blood flow contribute to its reduction of LV remodeling. Raya et al. (24) have demonstrated the importance of reduction of preload in inhibition of LV remodeling since hydralazine, a reducer of afterload, did not alter LV remodeling in their study. Thus, the decrease in the preload appears to be an important mechanism to reduce the LV remodeling. Moreover, LV wall stress is believed to be causally related to progressive LV dilation following MI. Histological studies suggested that the increased wall stress by the increased LV radius due to the wall thinning after MI produces progressive cell elongation (25) and side-to-side cell slippage (26) of the non-infarcted myocardium. The explanation for the mechanism of LV remodeling is provided by these histological changes in the non-infarcted region of the MI heart due to increased wall stress. These also suggest that the alleviation of LV wall stress is important in the therapy of the remodeling after MI. In the present study, nipradilol failed to decrease SVR and alter LV afterload. On the other hand, preload was reduced by nipradilol. Nipradilol has been reported to produce venodilation and increase venous compliance in experimental (14) and clinical (15, 16) studies, which may contribute to the preload reduction observed in this study. A decrease in preload can lead to both LV unloading and a decline in wall tension, which are suggested to be related to the progression of LV remodeling after MI. Thus, it is conceivable that the preload reduction by nipradilol attenuated the LV loading condition, relieved geometrical stress in the LV wall, and reduced the LV remodeling following MI.

In conclusion, chronic nipradilol treatment for 3–4 months after MI attenuated LV remodeling and improved cardiac function. It was considered that the preload reduction by nipradilol may contribute to the beneficial effects on LV remodeling after MI.
