Isolated thylakoids from halophytic Eutrema salsugineum (Thellungiella salsuginea) produces more H$_2$O$_2$ in comparison to glycophytic Arabidopsis thaliana. The first objective of this study was to verify whether this feature is relevant also to the intact chloroplasts and leaves. Enhanced H$_2$O$_2$ levels in chloroplasts and leaves of E. salsugineum were positively verified with several methods (electron microscopy, staining with Amplex Red and with diaminobenzidine). This effect was associated with a decreased ratio of O$_2$−/H$_2$O$_2$ in E. salsugineum in comparison to A. thaliana as detected by electron paramagnetic resonance method. As a next step, we tested how this specific ROS signature of halophytic species affects the antioxidant status and down-stream components of ROS signaling. Comparison of enzymatic antioxidants revealed a decreased activity of ascorbate peroxidase (APX), enhanced activity of glutathione peroxidase, and the presence of thylakoid-bound forms of iron superoxide dismutase (FeSOD) and APX in E. salsugineum. These cues were, however, independent from application of salt stress. The typical H$_2$O$_2$-dependent cellular responses, namely the levels of glucosinolates and stress-related hormones were determined. The total glucosinolate content in E. salsugineum water-treated leaves was higher than in A. thaliana and increased after salinity treatment. Treatment with salinity up-regulated all of tested stress hormones, their precursors and catabolites [abscisic acid (ABA), dihydrophaseic acid, phaseic acid, 1-aminocyclopropane-1-carboxylic acid, salicylic acid, jasmionic acid, cis-(+)-12-oxo-phytodienoic acid and jasmonoyl-L-isoleucine] in A. thaliana, whereas in E. salsugineum only a stimulation in ethylene synthesis and ABA catabolism was noted. Obtained results suggest that constitutively enhanced H$_2$O$_2$...
INTRODUCTION

Reactive oxygen species (ROS) are intriguing molecules, which are toxic to the biological structures but also play a signaling role in controlling plant growth, development and stress responses (for a recent review, see Suzuki et al., 2012; Baxter et al., 2014). They accompany the basal metabolic fluxes of aerobic organisms during the whole ontogeny. Considering the precise and multilevel control of metabolic changes it might not be surprising that ROS coming from the various cellular and extracellular sites seem to have their specific signaling targets (Op den Camp et al., 2003; Avsian-Kretchmer et al., 2004; Gadjev et al., 2009; Geisler et al., 2006; Laloi et al., 2007). In plants several ROS, such as H2O2, O2•− and 1O2, are formed in chloroplasts aside the photosynthetic electron transport. They, in turn, affect the nuclear gene expression to adjust the photosynthesis to changing environment. The most stable form, which is assumed to leave this organelle and evoke the effects on the nuclear genes, is H2O2 (Mubarakshina et al., 2010; Borisova et al., 2012).

In an attempt to recognize the signaling effects of H2O2 originating from chloroplasts, Arabidopsis mutant overexpressing glycolate oxidase in chloroplasts (GO5 plants) has been developed (Fahrenstich et al., 2008). In the photorespiratory conditions GO5 mutants produce H2O2 in chloroplasts instead of in peroxisomes. Transcript profiling of GO5 plants (Balazadeh et al., 2012) identified the H2O2 regulated genes and transcription factors, whereas further work of Sewelam et al. (2014) underpinned the top 20 genes specifically up-regulated by H2O2 produced in chloroplasts. These studies proved that H2O2 can trigger different responses depending on the subcellular site of its production.

Recently, we demonstrated that thylakoids isolated from a highly stress resistant species Eutrema salsugineum (Thellungiella salsuginea) are capable of the enhanced production of H2O2, in comparison to Arabidopsis thaliana, already in the absence of stress (Wiciarz et al., 2015). This creates the opportunity to unravel the signaling action of chloroplast H2O2 generation in the natural system. E. salsugineum tolerates extreme salinity, cold, drought, ozone and over the last years this species became a plant model of stress resistance well-comparable with the Arabidopsis genome (Inan et al., 2004; Li et al., 2006; Amtmann, 2009; Hou and Bartels, 2015). So far, several studies focused on the discovery of transcriptomic footprints of high stress resistance in E. salsugineum. These studies showed that several stress-associated genes in E. salsugineum have a constitutively higher expression in comparison with Arabidopsis thaliana already in the absence of stress (Inan et al., 2004; Taji et al., 2004; Gong et al., 2005). The group of up-regulated genes includes, for example, those involved in abscisic acid (ABA) biosynthesis and signaling (Taji et al., 2004; Gong et al., 2005). In contrast, after stress treatment, only a slight change in gene expression was detected in E. salsugineum in comparison with a great activation of transcription in A. thaliana plants (Taji et al., 2004; Li et al., 2006; Wong et al., 2006). Also, a comparative proteomics of A. thaliana and E. salsugineum salt responses revealed more changes in protein abundance in Arabidopsis than in Eutrema (Pang et al., 2010). Combined, these results indicate so called ‘stress preparedness’ of E. salsugineum, which supports its halophytic nature. Comparison of metabolite profiles of these two species following salt stress revealed a significant differences (Arbona et al., 2010). This suggests, that an adjustment of metabolism and activation of the already present enzymatic machinery serves as a faster and more efficient strategy to cope with stress than synthesis of new proteins.

A goal of this study was to verify whether enhanced generation of H2O2 in thylakoids of halophytic Eutrema in comparison to glycophytic A. thaliana is significant also in vivo. As a next objective, it was tested how this situation influences oxidative damage, antioxidant system and hormonal signaling in the control conditions and after a salinity stress.

MATERIALS AND METHODS

Plant Material and Growth Conditions

Arabidopsis thaliana (Col-0) and E. salsugineum (T. salsuginea, salt cress) ecotype Shandong were grown from seeds in the soil culture under irrigation with tap water. Seeds were obtained from the Nottingham Arabidopsis Stock Centre, UK. Plants were cultivated in the phytotron chamber at temperatures of 18°/16°C day/night, photoperiod 10/14 h, irradiance of ab. 220 µmol m−2 s−1 and RH ~50%. Both species were adapted to these conditions for at least three generations. Because of delay in growth of E. salsugineum in comparison to A. thaliana, as reported earlier (Inan et al., 2004; Stepien and Johnson, 2009), to compare rosettes at the same developmental stage, 4-weeks-old A. thaliana and 5-weeks-old E. salsugineum plants were taken for experiments. To evoke a mild salinity-stress plants were irrigated with 0.15 and 0.3 M NaCl solutions for A. thaliana and E. salsugineum, respectively, while watered plants served as controls. After 7 days of NaCl treatment complete rosettes were collected, frozen in liquid nitrogen and stored at −80°C until further use (unless stated otherwise).

Thylakoid Membrane Preparation

Thylakoids were isolated as described earlier (Wiciarz et al., 2015). Shortly, leaves were homogenized in medium containing 50 mM HEPES-KOH (pH 7.6), 330 mM sorbitol (control plants)
and 495 mM sorbitol (NaCl-treated plants) respectively, 1 mM MgCl₂, 2 mM Na₂EDTA, 5 mM sodium ascorbate and 0.01% (w/v) fatty acid-free bovine serum albumine. After centrifugation for 4 min at 4000 × g the pellet was resuspended in 50 mM HEPES-KOH (pH 7.6), 5 mM sorbitol, 5 mM MgCl₂ and centrifuged again. Then the pellet was washed and resuspended in 50 mM HEPES-KOH (pH 7.6), 330 mM sorbitol, 10 mM MgCl₂, 20 mM NaCl, 2.5 mM Na₂EDTA, 10 mM NaHCO₃. The chlorophyll concentration was estimated spectrophotometrically according to Lichtenthaler and Buschmann (2001).

**Electron Paramagnetic Resonance (EPR) Measurements**

Production of O₂⁺ and H₂O₂ by thylakoids from *A. thaliana* and *E. salsugineum* water-treated plants was detected by electron paramagnetic resonance (EPR) spin-trapping spectroscopy using DMPO (5,5-dimethyl-pyrroline N-oxide; Sigma-Aldrich, USA) and POBN [α-(4-pyridyl-1-oxide)-N-tertbutyl nitronitrone; Sigma-Aldrich] as the spin trap, respectively, as described earlier (Jajić et al., 2015). Shortly, for O₂⁺ detection, isolated thylakoids (chlorophyll concentration 200 µg mL⁻¹) were mixed with DMPO to a final concentration 50 mM, transferred to a flat cell and illuminated for 5 min at 500 µmol quanta m⁻² s⁻¹ within the EPR spectrometer MiniScope MS300 (Magnettech GmbH, Germany). For H₂O₂ detection, the H₂O₂-produced hydroxyl radical after the initiation of the Fenton reaction was measured. Isolated thylakoids (concentration of chlorophyll 150 µg mL⁻¹) in a reaction medium pH 7.6 containing 0.4 M sucrose, 20 mM NaCl, 5 mM MgCl₂, 10 mM Hepes-KOH were illuminated with white light source LS2 (Hansatech, UK) for 3 min at 500 µmol quanta m⁻² s⁻¹. Next, 50 mM POBN, 50 µM FeEDTA and 4% ethanol were added and incubated for 3 min, transferred to glass capillaries and measured using an EPR spectrometer. To check the influence of enzymatic scavengers on H₂O₂ production, measurements were performed in presence and absence of 5 mM sodium azide (inhibitor of heme containing enzymes).

**H₂O₂ Detection**

Ultrastructural localization of H₂O₂ was visualized in transmission electron microscopy (TEM) via electron-dense precipitates of cerium perhydroxides [Ce(OH)₂OOH and Ce(OH)₃OOH] formed after the reaction of cerium chloride (CeCl₃) with endogenous H₂O₂ (Bestwick et al., 1997). After 1 h of light leaves of *A. thaliana* and *E. salsugineum* from water-treated plants were cut into small pieces (~5 mm). Leaf fragments were immediately infiltrated and then incubated for 1 h with a 0.5 M morpholinepropanesulfonic acid (MOPS) buffer (pH 7.0), containing 5 mM CeCl₃ (Libik-Konieczny et al., 2015). The controls were tissue samples incubated in MOPS buffer. Then, tissues were quickly washed in the 0.5 M MOPS and fixed in 2.5% (w/v) formaldehyde (prepared from paraformaldehyde) and a 2.5% (v/v) glutaraldehyde in 50 mM cacodylate buffer (pH 7.0) for 4 h at room temperature. The procedure for preparing the samples for TEM was as described earlier (Kozieradzka-Kiszkurno and Pfachno, 2012). The material was dehydrated in a series of graded acetone and embedded in Spurr Low-Viscosity Embedding Kit (Polysciences, Germany). Ultrathin (60–90 nm) sections were cut with a diamond knife on a Leica EM UC7 ultramicrotome. The sections were stained with uranyl acetate and lead citrate and then viewed using a Philips CM 100 TEM at 75 kV.

Histochemical localization of H₂O₂ production in leaves was determined using the DAB (3,3-diaminobenzidine) staining technique according to Libilk-Koniczny et al. (2015). Leaves of *E. salsugineum* and *A. thaliana* water-treated plants were infiltrated with a solution of 1 mg mL⁻¹ DAB (Sigma-Aldrich) prepared in water. Incubation was carried for 4 h in the dark at room temperature.

**SDS-PAGE and Immunoblot Analysis**

Leaf soluble proteins were extracted with 0.1 M phosphate buffer pH 7.5 containing 1 mM dithiothreitol, 2% (w/v) polyvinylpolypyrrolidone and protease inhibitor cocktail (Sigma-Aldrich). Homogenates were centrifuged 10 min at 10000 × g. Protein concentration in supernatant was estimated using Roti-Protein assay kit (Carl Roth, Germany). SDS-PAGE as well as immunoblotting were performed as described earlier (Niewiadomska et al., 2009). Thylakoid membranes (TMs) and soluble proteins were dissolved in denaturing buffer and heated 20 min at 99°C (soluble proteins) or 5 min at 75°C (TMs). After electrophoresis, the separated proteins were blotted onto nitrocellulose membranes and probed with polyclonal antibodies raised against: ascorbate peroxidase (APX; anti-APX); glutathione peroxidase (GPX; anti-GPX); iron superoxide dismutase (FeSOD; anti-FeSOD); gamma glutamylcysteine synthase, γ -ECS (anti-γ -ECS); peroxiredoxins Q, PrxQ (anti-PrxQ). All antibodies were purchased from Agrisera (Sweden).

**Determination of Lipid Peroxidation**

Lipid peroxidation in leaves and isolated thylakoids of *A. thaliana* and *E. salsugineum* water-treated plants was assessed by measuring the malondialdehyde (MDA) content using high-performance liquid chromatography (HPLC) as described by Rastogi et al. (2014). Shortly, leaf samples were ground in a mortar with chilled 80% (v/v) ethanol. The extract was then centrifuged (10000 × g for 2 min) and the supernatant was further used. Samples were mixed with equal amount of reaction mixture containing 20% (w/v) trichloroacetic acid, 0.01% (w/v) butylated hydroxytoluene and 0.65% (v/v) thiobarbituric acid (TBA). After heating at 95°C for 20 min and centrifugation the MDA-(TBA)₂ adduct was separated and quantified by the HPLC. The elution buffer was 50 mM KH₂PO₄ (pH 7.0)/methanol (65:35, v/v). The retention time was 5 min and flow rate of 0.5 mL min⁻¹ with detection at 530 nm. Tetraethoxy-propane (Sigma-Aldrich) was used as a standard.

**Quantification of H₂O₂ Concentration**

An Amplex® Red Hydrogen Peroxide/Peroxidase Assay Kit (Life Technologies/Thermo Fisher Scientific, USA) was used to measure H₂O₂ content in *A. thaliana* and *E. salsugineum* leaves after water irrigation. Leaves (0.1 g) frozen in liquid
nitrogen were ground with 0.5 M sodium phosphate buffer, pH 7.4, and centrifuged 10 min at 10,000 × g. Proteins were removed from the extracts using Amicon Ultra Centrifugal Filters (Merck Millipore, USA) and the filtrate (25 μL) was incubated for 30 min in dark conditions with 50 mM Amplex Red reagent and 0.2 units mL⁻¹ horseradish peroxidase. Excitation was measured at 530 nm and fluorescence detection at 590 nm with a microplate reader Synergy 2 (BioTek, USA). The hydrogen peroxide concentration was estimated by comparison with standard curve (0–10 μM) of H₂O₂. The experiments were repeated three times independently, each time in triplicate.

Determination of Antioxidant Enzyme Activities
Soluble leaf proteins were extracted with 0.1 M phosphate buffer pH 7.5 [catalase (CAT); SOD], 50 mM phosphate buffer pH 7.0 (GPX) or 0.1 M phosphate buffer pH 7.8 with 1 mM ascorbic acid (APX), in each case containing protease inhibitor cocktail (Sigma-Aldrich). After centrifugation 10 min at 10,000 × g at 4°C soluble proteins were desalted using Amicon Ultra Centrifugal Filters (Merck Millipore). Protein concentration was estimated using Roti®-Nanoquant Protein quantitation assay (Carl Roth).

Catalase activity was measured according to the method described by Aebi (1984). The decomposition of 10 mM H₂O₂ in phosphate buffer (50 mM phosphate buffer pH 7.0) was monitored for 2 min at 240 nm. Calculations used an absorbance coefficient of 43 M⁻¹ cm⁻¹.

Ascorbate peroxidase activity was determined according to Nakano and Asada (1981). The decrease in absorbance at 290 nm due to ascorbate oxidation was recorded. The assay mixture contained 20 μg proteins, 0.1 mM EDTA, 0.5 mM ascorbic acid, 50 mM and 0.1 mM H₂O₂ in phosphate buffer (pH 7.0). The absorbance was recorded after 3 min. The APX activity was calculated using the absorbance coefficient of 2.8 mM⁻¹ cm⁻¹.

Glutathione peroxidase activity was determined as the decrease in absorbance at 340 nm due to the oxidation of NADPH (ε = 6.22 mM⁻¹ cm⁻¹) according to Hopkins and Tudhope (1973). The reaction mixture consisted of 50 mM phosphate buffer (pH 8.0) containing 0.5 mM EDTA, 0.125 mM NADPH, 1 mM reduced glutathione, 0.5 U/mL glutathione reductase (Sigma-Aldrich), 300 μM tert-butyl hydroperoxide and 20 μg proteins. The reaction was monitored for 3 min.

Glucosinolate Content
The total glucosinolates were extracted and assessed basically as described by Aghajanazadeh et al. (2014). Leaf samples (0.1 g) were boiled for 2 min in 3 ml 90% methanol. The extract was centrifuged (2500 × g for 2 min) and the residues were extracted again. The determination of total glucosinolate content was based on color complex formation between glucosinolates and sodium tetrachloropalladate (II). The 60 μl of extract was incubated for 30 min in 1800 μl 2 mM Na₂PdCl₄ and absorbance of developed color was measured at 450 nm. The glucosinolate content was calculated using standard curve of sinigrin (0–3 mM; Sigma-Aldrich).

Plant Hormone Determination
For hormone analysis A. thaliana and E. salsugineum leaf samples were collected at midday. Extraction and analysis were performed according to Dobrev and Kaminke (2002) and Dobrev and Vankova (2012). Briefly, approximately 100 mg fresh samples were homogenized and extracted with methanol/water/formic acid (15/4/1, v/v/v). The following labeled internal standards (10 pmol per sample) were added: 2H₄-ABA, 3H₃-PA, 2H₅-SA, 2H₅-JA (Olchemim, Czech Republic). Extracts were purified using SPE-C18 column (SepPak-C18, Waters, Milford, MA, USA) and separated on a reverse phase-cation exchange column (Oasis-MCX, Waters). The hormone fraction was eluted with methanol, separated by HPLC (Ultimate 3000, Dionex/Thermo Fisher Scientific, Austria) and the hormones were quantified using a hybrid triple quadrupole.linear ion trap mass spectrometer (3200 Q TRAP, Applied Biosystems/MD SCIEX, Foster City, CA, USA). The analyses were carried out in three biological replicates. The analysis of ABA and its catabolites DPA (dihydrophaseic acid) and PA (phaseic acid); ACC (1-aminocyclopropane-1-carboxylic acid), SA (salicylic acid), jasmonic acid (JA) and jasmonoyl precursor cis-OPDA [cis-(+-)12-oxo-phytodienoic acid] and jasmonoyl-1-isoleucine (JA-Ile) was performed.

Statistical Analysis
All analysis were calculated with Student’s 𝑡-test. Significant differences are marked at 𝑃 ≤ 0.05.

RESULTS
Production of H₂O₂ in Isolated Thylakoids and in Leaves
In thylakoids from A. thaliana and E. salsugineum an opposite patterns of ROS production were demonstrated by EPR method (Figure 1). Illuminated thylakoids of E. salsugineum generated more H₂O₂, as detected indirectly with POBN spin trap which reacts with H₂O₂-derived hydroxyl radical (Figures 1A,B), but less O₂⁻⁻, as detected with DMPO spin trap (Figures 1C,D), in comparison to the thylakoids of A. thaliana. Addition of NaN₃ strongly increased the production of H₂O₂, but did not significantly influence generation of O₂⁻⁻, the superoxide anion radical.

To verify unequivocally, whether a difference in H₂O₂ generation between the two species is significant also for chloroplasts and leaves we used several methodological approaches. The presence of H₂O₂ in the chloroplasts has been tested with a specific CeCl₃ staining visualized by TEM. Chloroplasts of mesophyll cells from water-treated A. thaliana revealed no cerium perhydroxide deposits (Figure 2A), while salt stress associated H₂O₂ accumulation was visible as black precipitate spots (Figure 2B), mainly at the edges of granal thylakoids (Figure 2C). In contrast, in chloroplasts of E.
salsugineum an electron-dense precipitates were detectable already in control (Figure 2D), while more pronounced dark spots were visible after salt stress (Figures 2E,F). Another difference between A. thaliana and E. salsugineum detected by TEM was that a salinity-induced thylakoid swelling was detected only in A. thaliana chloroplasts (Figure 2B), while in E. salsugineum chloroplasts no signs of such destruction occurred (Figures 2E,F). Staining controls without CeCl₃ showed no electron-dense deposits in both species (data not shown).

Similarly, in leaves, enhanced content of H₂O₂ was documented in E. salsugineum than in A. thaliana (Figure 3A, staining with Amplex Red, and Figure 3B- staining with DAB). However, in spite of the high availability of this ROS a very low level of MDA was detected in E. salsugineum leaves, indicating a low extent of oxidative damage to membrane lipids (Figure 4A). This difference between the two species disappeared when isolated TMs were compared (Figure 4B). On this basis we formulated a hypothesis that enhanced leakage of H₂O₂ from plastids keeps the antioxidant system up-regulated, thereby preadapting plants to the salinity stress.

**Comparison of Antioxidant System in Arabidopsis and Eutrema**

The capacity of antioxidant system was compared in leaves of A. thaliana and E. salsugineum in the control conditions and after salinity stress. Due to the disturbed kinetics of enzymatic assays observed in crude leaf extracts (LEs) from E. salsugineum, the activities of H₂O₂ scavenging enzymes were analyzed in purified protein fractions. The activities of CAT were similar in both species in the control conditions and remained unchanged after salinity stress (Figure 5A). The activity of APX was lower in the E. salsugineum both in control and after salinity stress (Figure 5B). In contrast, the activity of thiol-dependent GPX was higher in E. salsugineum both in control and after a salinity stress (Figure 5C).

Considering the chloroplastic generation of H₂O₂ in E. salsugineum, the antioxidant system in this organelle might be of particular importance for this species. Therefore, we compared the antioxidant enzymes present at TMs and in the soluble fraction (LEs; Figure 6). The stromal form of APX (sAPX) was present in similar amount in both species, while distribution of thylakoid bound APX (tAPX) showed a clear difference between A. thaliana and E. salsugineum. This form was much more abundant in Eutrema both in controls and in salinity-treated plants, while it was barely detected in A. thaliana. Another differences between these two species was related to FeSOD. In E. salsugineum, FeSOD was less abundant in LEs, while it was much more abundant in TMs, when compared with A. thaliana (Figure 6). To get an insight into the level of thiols and thiol-dependent enzymes we compared the
FIGURE 2 | Transmission electron microscopy (TEM) images of H$_2$O$_2$ accumulation in chloroplasts of A. thaliana and E. salsugineum plants treated with water and NaCl solution (0.15 and 0.3 M, respectively). The black spots (white arrows) represent H$_2$O$_2$ forming electron-dense cerium perhydroxide precipitates. A. thaliana chloroplasts from water-treated (A) and salt-stressed plants (B,C). Black arrow in (B) points to the swelling of thylakoids. E. salsugineum chloroplasts from water-treated (D) and salt-stressed plants (E,F). t, thylakoids; s, stroma. Bars = 1 µm (A,B,D,E); Bars = 0.5 µm (C,F).

amount of stromal peroxiredoxins Q (PrxQ) and the enzyme of reduced glutathione (GSH) synthesis, gamma glutamylcysteine synthase (γ-ECS). In E. salsugineum PrxQ were more abundant than in A. thaliana, and a slight decrease was noted after salinity treatment in both species, whilst γ-ECS was present at similar amount in both species (Figure 6). These pronounced differences between E. salsugineum and A. thaliana in the amounts of various ROS scavengers in chloroplasts suggest that there is a stronger need to protect photosynthetic membranes against ROS in the former species, already in the absence of stress.

Signaling Pathways Associated with ROS

It is well-documented that ROS signaling is interconnected with stress hormones (Baxter et al., 2014). Therefore, we analyzed the endogenous levels of stress-related hormones in A. thaliana and E. salsugineum plants grown in control conditions and changes evoked by salt-treatment. In control conditions, the concentrations of ABA and its catabolite PA were similar in leaves of both species (Figures 7A,B), while the level of another ABA catabolite, DPA was twofold lower in E. salsugineum (Figure 7C). Salt treatment caused an increase in ABA (twofold), DPA (twofold) and PA (threefold) in A. thaliana, whereas no significant changes (ABA, DPA), and a slight increase in (PA), were detected in E. salsugineum (Figures 7A–C). Concentrations of ethylene precursor ACC were similar in the two species in control conditions and underwent a similar increase due to salinity (Figure 7D). Concentrations of SA and jasmonates were much lower in the control E. salsugineum in comparison to A. thaliana: SA almost fourfold, JA by 4.5-fold, Ja-Ile by 2.4-fold and cisOPDA by 5.5-fold (Figures 7E–H). NaCl-treatment increased the levels of these hormones in A. thaliana (1.7-, 2.6-, 6.6-, 1.8-fold, respectively) but not in E. salsugineum, where their decreased concentrations were found (1.8-, 4-, 4-, 3.2-fold, respectively).

One of the highlights of H$_2$O$_2$ signaling from chloroplasts seems to be enhanced synthesis of glucosinolates, as demonstrated in GO5 plants (Balazadeh et al., 2012; Sewelam et al., 2014). To check this cue in our wild type model, we measured the total concentration of leaf glucosinolates. The total level of glucosinolates was enhanced in leaves of E. salsugineum in comparison with A. thaliana in control conditions, and a stronger increase was detected in E. salsugineum after salinity treatment (Figure 8).
DISCUSSION

In this work, we compared a halophytic E. salsugineum with glycophytic A. thaliana in regard to the chloroplastic H$_2$O$_2$ signature on the salt stress tolerance. As a first step, we verified whether a chloroplastic H$_2$O$_2$ signal, previously reported with use of isolated TMs (Wiciarz et al., 2015), persists in the relatively undamaged organelle and tissue.

Enhanced generation of H$_2$O$_2$ within the chloroplasts of control and stress-treated Eutrema was visualized by TEM, suggesting that a higher level of H$_2$O$_2$ persists in the whole chloroplasts. However, it is not uniformly distributed but spotted in the proximity of granal thylakoids, where it is produced. TEM images also revealed, that NaCl treatment caused thylakoid swelling only in A. thaliana. Thylakoid dilation is a well-documented symptom of salinity stress in plants (Niewiadomska et al., 2011; Yamane et al., 2012; Pottosin and Shabala, 2016), while structural integrity of E. salsugineum chloroplasts under mild NaCl-stress was previously shown by Chang et al. (2015). This lack of swelling might be attributed to the activity of thylakoid ion channels, and/or K$^+$/Na$^+$/H$^+$ antiporters which control the ion homeostasis under salinity-stress (Pottosin and Shabala, 2016).

Although we did not find any direct evidence for an export of H$_2$O$_2$ from plastids, the total H$_2$O$_2$ level in leaf extracts was also elevated in Eutrema leaves. Hence, it is likely that a chloroplast H$_2$O$_2$ generation contributes considerably to this phenomenon. Our speculation is based on a well-accepted phenomenon that illuminated chloroplast is a major site of ROS production in the mesophyll cells (Asada, 2006). Moreover, a considerable leakage of H$_2$O$_2$ from healthy chloroplasts has been shown experimentally (Mubarakshina et al., 2010; Borisova et al., 2012).

Here, performed study revealed that an increased generation of H$_2$O$_2$ in halophytic species is associated by a decreased generation of O$_2^{*-}$. Considering a much higher reactivity of O$_2^{*-}$ than H$_2$O$_2$, this pattern of ROS production might shape a specific ROS signature important for so called stress-preparedness of Eutrema. This speculation is supported by a much lower oxidative damage (MDA) in leaves of E. salsugineum than in A. thaliana. As argued by Tiwari et al. (2013), superoxide, but not H$_2$O$_2$, is required to evoke oxidative damage in photosynthetic membranes. This damage is mediated by the hydroxyl radical and is manifested by the appearance of carbon-centered radical. Experiments with the flu A. thaliana mutant and the flu overexpressing TAPX, enabled to demonstrate that H$_2$O$_2$ antagonizes the 1O$_2$-mediated cell death response and growth inhibition, which might be particularly advantageous under stress (Laloi et al., 2007). A rapid conversion of a more harmful ROS (such as O$_2^{*-}$) into a longer-living and less toxic H$_2$O$_2$ has previously been concluded for halophytic plants on the basis of enhanced activity of superoxide dismutase (Bose et al., 2014). In halophytic E. salsugineum an operation
of the protective electron cycling around PSII (Stepien and Johnson, 2009; Wiciarz et al., 2015) seems to support that view. Such a cycle could be beneficial for plants in several ways. Firstly, it may create a more safe electron sink in comparison to the production of superoxide and its toxic derivatives. Secondly, an abundance of H$_2$O$_2$ may play a signaling role.

A growing body of data indicate that H$_2$O$_2$ triggers defense responses in plant cells (for a recent review, see Suzuki et al., 2012; Baxter et al., 2014; Bose et al., 2014; Ismail et al., 2014). In this respect, ROS formation in chloroplast may also act indirectly via strengthening or amplifying retrograde redox signals (Galvez-Valdivieso and Mullineaux, 2010). One of the targets of ROS signaling route under stress is an up-regulation of antioxidants (Fryer et al., 2003; Geisler et al., 2006). However, the activity of a major H$_2$O$_2$ scavenger CAT was similar in *E. salsugineum* and *A. thaliana* in controls and in salinity-treated plants, whereas APX activity was even decreased in *E. salsugineum*. This is in agreement with numerous reports on salt cress. The transcript profiling analysis with two *E. salsugineum* ecotypes did not detect any antioxidant genes among those specifically up-regulated by salinity (Taji et al., 2004; Wong et al., 2006). Also, a proteomic data did not detect any salinity-dependent stimulation of antioxidant enzymes in
FIGURE 7 | Average content of stress-related hormones in leaves of A. thaliana and E. salsugineum plants treated with water and NaCl solution (0.15 and 0.3 M, respectively) assessed by LC–MS/MS. (A) ABA (abscisic acid). (B) DPA (dihydrophaseic acid). (C) PA (phaseic acid). (D) ACC (1-aminocyclopropane-1-carboxylic acid). (E) SA (salicylic acid). (F) JA (jasmonic acid). (G) JA-l-le (jasmonyl-L-isoleucine). (H) cisOPDA (cis-12-oxo-phytodienoic acid). Each data point represents the mean ± SD (n = 5). ‘Asterisk’ indicates significant difference from A. thaliana from the same treatment. ‘Diamond’ indicates a significant difference between control and salinity-treated plants.

FIGURE 8 | Total glucosinolates content in leaves of A. thaliana and E. salsugineum plants treated with water and NaCl solution (0.15 and 0.3 M, respectively). Each data point represents the mean ± SD (n = 3). ‘Asterisk’ indicates significant difference from A. thaliana from the same treatment. ‘Diamond’ indicates significant difference between control and salinity-treated plants.

Among the enzymatic H$_2$O$_2$ scavengers only GPX was enhanced in E. salsugineum. This points to the importance of redox active thiols. GPXs reduce not only H$_2$O$_2$ but also organic hydroperoxides using reducing power of GSH. Hence, they may contribute to the dramatically reduced MDA level. A noteworthy stimulation of antioxidant defense associated with glutathione has previously been revealed in E. salsugineum by transcript profiling of Gong et al. (2005). This was represented by GPXs (GPX2 and GPX6), glutaredoxins and glutathione-S-transferases (GSTZ1 and GSTU7). Four out of eight GPXs found in E. salsugineum have been shown to respond to salt and osmotic stresses at both transcript and protein level (Gao et al., 2014). It is worthy to note here, that GPX may serve as a specific sensor and transducer of H$_2$O$_2$ signal. A dual function of GPX associated with both scavenging of ROS and transferring the H$_2$O$_2$ signal has been pointed out repeatedly (Delaunay et al., 2002; Miao et al., 2006). Moreover, a specific activation of GPX1 promoter in tobacco by a chloroplast-generated H$_2$O$_2$ was documented by Avsian-Kretchmer et al. (2004). Whereas, study with Arabidopsis gpx3 mutant demonstrated that GPX3 participates in the ABA and H$_2$O$_2$ signaling pathway regulating the stomatal aperture and resistance to drought (Miao et al., 2006).
Considering an enhanced generation of H$_2$O$_2$ and changed O$_2^·$/H$_2$O$_2$ ratio in chloroplasts, a major role might be attributed to the anti-oxidative protection within this organelle. Indeed, TMs of *Eutrema* appeared to be better protected against ROS in comparison with *Arabidopsis*, as indicated by a higher abundance of tAPX and FeSOD. This corresponds with enhanced level of FeSOD transcripts in the control *E. salsugineum*, reported by Taji et al. (2004). In regard to chloroplast stroma, we found an enhanced amount of PrxQ in *E. salsugineum*. These above-mentioned features of chloroplast antioxidant system are constitutive in *E. salsugineum*, which supports earlier conclusions on the stress preparedness of this species (Inan et al., 2004; Taji et al., 2004; Gong et al., 2005; Wong et al., 2006). They are also in line with the view that components of redox homeostasis in chloroplasts are crucial for salinity tolerance (Niewiadomska and Wiciarz, 2015; Uzilday et al., 2015). So far, recognized chloroplast redox players highly engaged in *E. salsugineum* are: adenosine 5′-phosphosulfate reductase involved in sulfate assimilation (Gong et al., 2005); thioredoxin CDSP32 (M’rah et al., 2007); 2-cys peroxiredoxin BAS1 (Gao et al., 2009) and plastid terminal oxidase (PTOX), an enzyme of chlororespiratory pathway (Stepien and Johnson, 2009; Wiciarz et al., 2015). In addition to these, also proteins associated with the Calvin-Benson cycle, such as a more active Rubisco (Wiciarz et al., 2015) and a more abundant glyceraldehyde 3-phosphate dehydrogenase (Pang et al., 2010; Chang et al., 2015) are likely to contribute to the improved redox balance in *E. salsugineum* by efficient recycling of ADP and NADP$^+$. A very weak response to salinity stress at the level of tested antioxidants may raise a question: whether *E. salsugineum* (and *A. thaliana*) senses the salinity stress at all? This has been clarified by analysis of stress hormones. A massive increase in stress-related hormones (ABA, SA, JA, and ethylene precursor) was detected in salinity-treated *A. thaliana*. These hormones are responsible for several stress effects in plants, among them stomatal closure and retardation of growth, although, their action is quite complex and may lead either to survival or to cell death. In contrast, in *Eutrema* the only indicator of salinity-evoked stress was a stimulation of ethylene synthesis. Although, some enhancement in ABA catabolite PA, may suggest a previous ABA induction. Earlier study of Ellouzi et al. (2014) documented that levels of ABA, JA, and ACC were increased in *E. salsugineum* after 2 days of salt stress, while 400 mM NaCl treatment for more than 5 days caused minimal changes in ABA and JA concentrations (Taji et al., 2004; Arbona et al., 2010). In *E. salsugineum* the levels of lipid-based active jasmonates (JA and JA-Ile) were low and even decreased due to salinity-treatment. This effect seems to be closely related to salt-resistance of *Eutrema*. As shown by Ismail et al. (2014), an interplay between ABA and JA is of particular importance for plant’s survival or death under salinity stress. A comparison of the two *Vitis* species differing in salt-stress tolerance revealed that in the more salt-tolerant *Vitis rupestris* ABA accumulated early and strongly suppressed the formation of JA-Ile, while in the salt-sensitive *V. vinifera* the accumulation of ABA was delayed and correlated which allow for accumulation of JA-Ile up to the high levels. A suppression of jasmonates in *E. salsugineum* might also be explained in accordance with the data obtained with AtGO5 mutant overproducing H$_2$O$_2$ in chloroplasts, in which a stimulated expression of several repressors of JA signaling pathway has occurred (Balazadeh et al., 2012). A very weak response to salinity at the level of ABA in *E. salsugineum* in contrast to *A. thaliana* is surprising in view of data on a higher expression of genes for ABA-biosynthesis and signaling (Taji et al., 2004; Gong et al., 2005; Wu et al., 2012) and an increased number of genes involved in ABA synthesis pathway in *Eutrema* genome (Wu et al., 2012). Possibly, in *E. salsugineum* the increased level of ABA is confined to the early stage of development or this hormone is very rapidly modulated in response to stress (indicated by slight increase in PA). A weak response of stress hormones to salinity in *E. salsugineum* supports the earlier conclusion of Hou and Bartels (2015), that comparing with *A. thaliana* the higher NaCl levels (600 mM) are required in *E. salsugineum* to trigger some defense reactions, such as increased transcription of two aldehyde dehydrogenase genes. On the other hand, the importance of glucosinolates for stress-resistance of *E. salsugineum* is depicted by their enhanced level and a strong salinity-dependent increase. A great variation in the patterns of aliphatic, aromatic, and indole glucosinolate was documented in *E. salsugineum*, depending on the organ and developmental stage (Pang et al., 2012). However, a precise role of these compounds in stress tolerance is not clarified yet. An up-regulation of the synthesis of indole glucosinolates and phytoalexin camalexin was found as a specific feature of increased H$_2$O$_2$ signaling from chloroplasts in studies with AtGO5 mutant made by Balazadeh et al. (2012) and Sewelam et al. (2014). However, *E. salsugineum* does not produce camalexin, but wasalexins A and B and methoxybrassenin B (Pedras and Adio, 2008). Intriguingly, as another support for a constitutive stress-preparedness of *Eutrema*, the three phytoalexins (indolyl-3-acetonitrile, caulilexin C, and arvelexin) are found as phytoanticipins, i.e., they are constitutively produced in this species (Pedras and Adio, 2008).

**CONCLUSION**

In this paper we provided evidence for a specific pattern of ROS formation and accumulation in halophytic *Eutrema* in comparison to glycophytic *Arabidopsis*. In concert with that, a pronounced changes in the antioxidant system were revealed in *E. salsugineum*, such as a decreased activity of APX, an increased activity of GPX, an increased level of PrxQ, and the presence of thylakoid-bound forms of FeSOD and APX. All these cues allow for enhanced H$_2$O$_2$ signaling from chloroplasts of *E. salsugineum* already in the control conditions, at decreased level of oxidative damage in the same time. This signaling led to enhanced level of glucosinolates in *Eutrema* and decreased levels of stress hormones (SA and jasmonates). Salinity-stress evoked a strong up-regulation of all tested stress hormones in *A. thaliana* whereas in *E. salsugineum* only a stimulation in ethylene synthesis and ABA catabolism was noted. On this basis we hypothesize that H$_2$O$_2$ signaling is engaged in the halophytic species to modulate a hormonal responses in such a way to minimize the triggering of jasmonate pathway which leads to cell death.
AUTHOR CONTRIBUTIONS

MP performed analysis of antioxidants, staining and quantitation of H$_2$O$_2$, determination of glucosinolates, participated in TEM analysis and in preparation of the manuscript. MW measured MDA, participates in the analysis of antioxidants and ROS. IJ measured ROS with EPR. MK-K performed TEM analysis. PD and RV measured stress hormones, and RV participated in writing of the text. EN designed the experiment and wrote the manuscript. All authors have read and approved the manuscript.

FUNDING

This work was supported by the Polish National Science Centre project (2011/03/B/NSZ/01619 EN, MP, MW).
