ABSTRACT

Context. Carbon, nitrogen, and oxygen (CNO) are key elements in stellar formation and evolution, and their abundances should also have a significant impact on planetary formation and evolution.

Aims. We present a detailed spectroscopic analysis of 74 solar-type stars, 42 of which are known to harbour planets. We determine the nitrogen abundances of these stars and investigate a possible connection between N and the presence of planetary companions.

Methods. We used VLT/UVES to obtain high-resolution near-UV spectra of our targets. Spectral synthesis of the NH band at 3360 Å was performed with the spectral synthesis codes MOOG and FITTING.

Results. We identify several spectral windows from which accurate N abundance can be obtained. Nitrogen distributions for stars with and without planets show that planet hosts are nitrogen-rich when compared to single stars. However, given the linear trend between [N/Fe] vs. [Fe/H], this fact can be explained as being due to the metal-rich nature of planet hosts.

Conclusions. We conclude that reliable N abundances can be derived for metal-rich solar type stars from the near UV molecular band at 3360 Å. We confirm a linear trend between [N/Fe] and metallicity expected from standard models of Galactic chemical evolution.

Key words. stars: abundances – stars: chemically peculiar – planetary systems

1. Introduction

The study of C, N, and O in stars is crucial because they are the most abundant elements after H and He. These elements play an important role in stellar interiors because they generate energy through the CNO cycle, thereby affecting the lifetime of the stars (Liang et al. 2001)

Nitrogen is created in a different nucleosynthetic process from that giving rise to carbon and oxygen. Whereas for carbon and oxygen the dominant production modes are the \( \alpha \)-chain reactions, for nitrogen the dominant production mode lies in the rearrangement of nuclei during the CNO cycle (see Maeder 2009).

One important question regarding N is its origin. Since N needs C and O to be formed, if it is formed from pre-existing C and O in the star, it is called “secondary”. If, instead, the carbon and oxygen are produced in the star itself and then used to produce nitrogen, then the nitrogen is called “primary”. Several studies have proved that production of nitrogen at low metallicities comes from primary rather than secondary sources (Pagel & Edmunds 1981; Bessell & Norris 1982; Carbon et al. 1987; Henry et al. 2000; Israelian et al. 2004). At higher metallicities, secondary processes dominate.

Two main sources for primary production have been proposed:

1. Rotating massive stars, implying detached N and Fe abundances and overabundance of N regarding Fe (Maeder & Meynet 2000).
2. Intermediate-mass stars (4–8 \( M_\odot \)) during their thermally pulsing AGB phase through CNO processing in the convective envelope (Marigo 2001; van den Hoek & Groenewegen 1997). The contribution by massive stars is negligible (Liang et al. 2001; Pettini et al. 2002), so dominant contributors are intermediate- and low-mass stars (ILMS). These ILMSs are also a source for secondary production.

Gonzalez (1997) and Santos et al. (2001) discovered that, on average, planet hosts are more metal-rich than “single” stars (stars with no known companion planet; from now on designated as single stars). Two hypotheses have been suggested to explain this anomaly:

1. Self enrichment: this scenario should be triggered by the action of hot jupiters migrating from outside the protoplanetary disc. During this migration, planetesimals from the disc are accreted on to the star. This mechanism would be efficient only during the first 20–30 Myr or later when the surface convection layers of the star for the first time attains its minimum size configuration (Chavero et al. 2010). Israelian et al. (2001, 2003) found evidence of pollution,
suggesting the infall of a planet, in HD 82943 (see, however, Mandell et al. 2004; Ghezzi et al. 2009).

The self-enrichment scenario could lead to a relative over-abundance of refractories, such as Si, Mg, Ca, Ti, and the iron-group elements, compared to volatiles, such as C, N, O, S, and Zn. The accretion of small planets may affect the composition of the convective layer of the stars (see Théado & Vauclair 2012, and references therein). To how great an extent this affects the accretion of volatiles such as C, N, and O (see González Hernández et al. 2013) remains unanswered.

2. Primordial cloud: Santos et al. (2001, 2002, 2003) proposed that this over-abundance most probably is caused by a metal-rich primordial cloud. They claimed that the observed abundances are representative of the primordial cloud where the star was formed. This idea is supported by models of planet formation and evolution based on the core-accretion process (e.g. Ida & Lin 2004; Mordasini et al. 2012).

Later abundance studies on stars with and without planets confirmed the primordial cloud as the most likely reason for the metal-rich nature of planet-host stars (Santos et al. 2004, 2005; Valenti & Fischer 2005), although this correlation is valid for giant planet hosts only (Sousa et al. 2008, 2011b; Buchhave et al. 2012).

Interestingly, recent studies suggest that specific element abundances may have a particularly relevant role in the planet formation process (Adibekyan et al. 2014, 2015) or in its composition (Santos et al. 2015). The abundances of volatiles (such as C, N, and O) may be particularly relevant in this respect. This consideration prompted the study of specific chemical abundances in the planet-host stars. There are very few studies of nitrogen in solar-type stars owing to the lack of strong atomic lines. Ecuvillon et al. (2004) studied the abundance of nitrogen of 91 solar type stars. Using both the NH molecular band at 3360 Å and the NI atomic line at 7468 Å, they rejected the self-enrichment scenario as a formation source on the grounds that they could find no underabundances of volatiles compared to refractory elements. They showed that the observed abundances are representative of the primordial cloud where the star was formed. This idea is supported by models of planet formation and evolution based on the core-accretion process (e.g. Ida & Lin 2004; Mordasini et al. 2012).

More recently, Da Silva et al. (2015), using the CN band at 4215 Å, have studied the abundance of nitrogen in 140 dwarf stars. They found a steeper slope for the [N/Fe] versus [Fe/H] abundance ratios than Ecuvillon et al. (2004).

The main problem in studying nitrogen abundances is the lack of strong nitrogen lines in the red part of the spectrum so that near-UV measurements are required. We are forced to study the very crowded molecular band at 3360 Å, where continuum determination is not straightforward.

The purpose of this study is to extend the sample of Ecuvillon et al. (2004) and investigate in detail nitrogen abundances using the 3360 Å NH molecular band. We have performed a systematic study of nitrogen abundances in dwarf stars with a wide range of stellar parameters. The strategy and methodology followed in this study is the same as that stated in Ecuvillon et al. (2004), but with a larger sample and high-quality spectra.

We have also determined the kinematic properties of our sample. Then using the kinematic and chemical properties of the stars, we separated them into different stellar populations to investigate the N abundances within a Galactic context.

Table 1. Observing logs for the campaigns.

| Campaign       | Observing dates       |
|----------------|-----------------------|
| 074.C-0134(A)  | 21–22 Dec. 2004       |
| 075.D-0453(A)  | First semester 2005   |
| 086.D-0082(A)  | Oct. 2010–Nov. 2011   |
| 093.D-0328(A)  | Mar.–Jul. 2014        |

This work is the first step in comparing CNO abundances of planet-host stars with the CNO abundances of their planets (through transmission spectroscopy or direct spectroscopy, as in the case of Spitzer). Testing and improving planetary formation models will play a key role in future studies of habitability, CNO being key elements for life.

2. Sample description

The high-resolution spectra analysed in this study were obtained with the UVES spectrograph installed at the VLT/UT2 Kueyen telescope (Paranal Observatory, ESO, Chile) during several campaigns (see Table 1) and have previously been used in the analysis of stellar parameters, together with the derivation of precise chemical abundances (see e.g. Santos et al. 2004; Sousa et al. 2011a,b; Delgado Mena et al. 2012).

High spectral resolving power ($R = 80 000$) and a relatively high signal-to-noise ratio ($S/N$) are optimal for properly analysing the NH band at 3360 Å. The average $S/N$ of our sample in the studied regions is 150.

The sample consists of 74 dwarf stars (42 stars with planets1 and 32 comparison stars without detected planets) with effective temperatures between 4583 K and 6431 K, metallicities from $-0.45$ to 0.55 dex, and surface gravities from 3.69 to 4.82 dex. Comparison sample stars were taken from HARPS and CORALIE samples.

3. Analysis

3.1. Stellar parameters and chemical abundances

The stellar parameters used in this study were taken from Sousa et al. (2008, 2011a,b), Tsantaki et al. (2013) and González Hernández et al. (2010, 2013). All stellar parameters used were derived by measuring equivalent widths of Fe I and Fe II lines using the code ARES (Sousa et al. 2007). Also, chemical abundances of elements other than N were adopted in targets with more recent stellar parameters (derived by our group with the same technique). To do this, the uncertainties presented in their original source were followed so systematic effects in the chemical abundances or the stellar parameters are negligible, not affecting the consistency of our results.

Chemical abundances of the elements with spectral lines present in the NH band were obtained from Adibekyan et al. (2012b) and González Hernández et al. (2010, 2013). These elements are Ca, Ti, Mn, and Si (note that the abundances of these elements were simply scaled with iron in Ecuvillon et al. (2004)). The N abundance is also affected by C and O molecular equilibrium. The C and O abundances were obtained from Suárez-Andrés et al. (in prep.) and Bertran de Lis et al. (2015), respectively. However, there are 26 stars with no previous measurements of O. We have decided to use the aforementioned results to interpolate for a given set of stellar parameters and use

\[1\] Data from: www.exoplanet.eu
The NH band is the strongest feature observed in the $\lambda\lambda3345-3375$ Å spectral region. We determined N abundances by fitting synthetic spectra to the data in this wavelength range. The dissociation potential used for NH spectra is $D_e = 3.37$ eV, as recommended in Grevesse et al. (1990). The complete line list used in this study was obtained from Ecuvillon et al. (2004), which was calibrated with the KURUCZ ATLAS spectrum (Kurucz et al. 1984) using the abundance log($N/\text{H}$)$_0 = 8.05$ dex.

The number and the strength of the atomic lines of different elements in the spectral region of the NH band increase with metallicity. The presence of many blended lines and numerous strong molecular bands make the placement of the continuum level very difficult. The high-resolution solar atlas (Kurucz et al. 1984) can help to achieve a reliable continuum placement for solar-type stars (e.g. Ecuvillon et al. 2004). However, large variations of metallicity and effective temperature among the stars in our sample do not allow us to use the solar spectrum as a reference. To account for this effect, we have generated a grid of synthetic spectra for all the stars in our sample. Synthetic spectra are calculated for a given set of stellar parameters and variations of nitrogen abundances [N/H] between $-0.7$ and $0.5$. Our reference points for the continuum placement are those for which the flux variation (for a given T$_{\text{eff}}$) due to the N abundance changes from [N/Fe] = $-0.7$ to $+0.5$, is less than 1%. This strategy is demonstrated in Fig. 1 for two stars with different atmospheric parameters. Rotational broadening was set as a free parameter (it was fixed in Ecuvillon et al. 2004) with $v\sin i$ varying between 0.0 and 14.0 with a step of 1 km s$^{-1}$. Macroturbulence was not taken into account. In order to find the best fit abundance value for each star, we used the FITTING program (González Hernández et al. 2011) and the MOOG synthesis code in its 2013 version. The best fit was obtained using a $\chi^2$ minimization procedure by comparing each synthetic spectrum with the observed one in the following spectral regions: $\lambda\lambda3344.0-3344.3$ Å, $\lambda\lambda3346.2-3346.7$ Å, $\lambda\lambda3347.0-3347.8$ Å, $\lambda\lambda3353.8-3354.4$ Å, $\lambda\lambda3357.4-3358.0$ Å, $\lambda\lambda3358.5-3359.7$ Å, $\lambda\lambda3360.3-3362.0$ Å, $\lambda\lambda3364.1-3364.8$ Å, $\lambda\lambda3370.8-3371.8$ Å, $\lambda\lambda3374.9-3375.4$ Å. These spectral regions were chosen because of the presence of relatively strong NH features that allow reliable abundance measurements. We use a $\chi^2$ comparison for the observed and synthetic spectra, and we define $\chi^2 = \sum_{i=1}^{N} (F_i - S_i)^2/N$, where $F_i$ and $S_i$ are the observed and synthetic fluxes respectively at wavelength point $i$. The $\chi^2$ for each spectral region was normalised with the number of points, $N$. Best-fit nitrogen abundances are extracted from each spectral range and the final nitrogen abundance for each star is then computed as the average of these values.

The FITTING program creates the following input data, required by MOOG: the atmospheric model, the line list, the range of nitrogen abundance of the grid of synthetic spectra, and the wavelength at which we want to analyse these abundances. To obtain the final abundance value, we analysed ten different ranges but use only those that have abundance values within 1$\sigma$.

In Fig. 1 we show the observed and synthetic spectra for the Sun and two stars that are depicted for different temperatures and metallicities within our sample. For these two stars, these different nitrogen abundances are also shown.

To examine how variations in the atmospheric parameters affect the NH abundances, we test [N/H] sensitivity in stars with very different parameter values, given the wide range of stellar parameters. For each set of stars we tested the nitrogen-abundance sensitivity to changes in the atmospheric parameter.
Fig. 2. [N/Fe] abundance ratio of the stars in this study plotted against effective temperature, \( T_{\text{eff}} \). Filled green circles represent planet hosts and open red circles the comparison sample. Filled blue squares represent cool planet hosts while open blue squares represent single stars. The vertical dashed line at 5000 K separates the cool stars from the studied sample.

(±100 K for \( T_{\text{eff}} \), ±0.2 dex in log \( g \), ±0.2 in metallicity). The results are shown in Table 2. The effect of microturbulence was not taken into account because an increase of 0.3 km s\(^{-1}\) produced an average decrease of 0.002 dex in nitrogen abundance, which is negligible in comparison with the effects of other parameters. The error due to continuum placement of 0.1 dex was considered for all stars. All effects were added quadratically to obtain the final uncertainties in nitrogen abundances using the following relation:

\[
\Delta[N/H] = (\Delta^2 + \Delta_{t,\text{eff}}^2 + \Delta_{\log g}^2 + \Delta_{\text{met}}^2 + \Delta_{\text{cont}}^2)^{1/2}.
\]

4. Results

We analysed near-UV high-resolution spectra of 42 planet host stars and 32 comparison stars, as mentioned in Sect. 2. We aim to explore possible differences in nitrogen abundances between the two samples. Our results for planet-host are presented stars in Table A.1 and for the comparison sample in Table A.2.

In Fig. 2 we show the [N/Fe] abundance ratio as a function of \( T_{\text{eff}} \). Stars with effective temperatures below 5000 K were excluded from the analysis because of uncertainties in the behaviour of those cool stars: we find no explanation for the decrease in nitrogen abundance as we move to lower temperatures. The vertical dashed line at 5000 K separates the cool stars from the sample studied. From now on in this paper, all results and conclusions will refer to stars with \( T_{\text{eff}} > 5000 \) K (65 stars). Because of the high dispersion, we did not find any clear trend of [N/Fe] with \( T_{\text{eff}} \). However, it can be seen that most of the planet-host stars have [N/Fe] > 0.

We have also looked for distinguishable trends between these samples by representing [N/Fe] and [N/H] abundance ratios as functions of [Fe/H] for both samples (see Fig. 3). These plots indicate that both samples behave approximately similarly. However, there seems to be a steeper trend in [N/H] vs. [Fe/H] for stars with planets, whereas stars without planets almost maintain the 1:1 relation. We note the same behaviour in the bottom panel of Fig. 3 ([N/Fe] vs. [Fe/H]), where the stars with planets below and above solar metallicity have values of [N/Fe] lower and higher than zero respectively. Unfortunately, owing to the metal-rich nature of giant-planet hosts, the number of stars with giant planets at metallicities below solar is too small for us to be able to confirm this behaviour. The observed trend may simply be related to Galactic chemical evolution.

In the top panel of Fig. 4 we show the [N/Fe] abundance distributions for both samples. As can be seen, there is an offset between the samples, which is expected because planet-host stars are metal rich as compared with single stars. We expect this result because, if nitrogen scales with iron, then we can expect higher [N/H] because giant-planet host stars are enhanced in Fe. In the bottom panel of Fig. 4 we show the [N/Fe] abundance distribution. We see that most of the stars with planets have [N/Fe] ≥ 0 (~90 per cent), as opposed to the single-star sample, more spread than the stars with planets sample. In this case, only ~60 per cent of the stars have [N/Fe] ≥ 0. A Kolmogorov-Smirnov (K-S) test predicts the ~0.06 probability (\( P_{\text{KS}} \)) that stars with and without planets come from the same distribution. The distribution of abundance ratios [N/Fe] vs. [Fe/H] of stars without planets shows a weak linear increasing trend (see Fig. 3), although the slope is consistent with zero. The number of points may not be sufficient to really confirm this increasing trend. Thus, we may conclude that stars with planets are, on average, nitrogen rich when compared to single stars, but it may be due to the metal-rich nature of the planet host stars.

If we extend the study of nitrogen abundance to metal-poor stars (Israelian et al. 2004), we will ensure that the behaviour seen in Fig. 3 is part of the same trend observed in these metal-poor stars down to metallicites ~2 dex. In Fig. 5 we can see
Fig. 4. [N/H] and [N/Fe] abundance distributions.

Fig. 5. N/H plotted against Fe/H for metal-poor stars from Israelian et al. (2004) indicated by red squares and stars from this study indicated by green circles.

Fig. 6. Abundance ratio of [N/Fe] as a function of stellar age for the stars belonging to the thin disk. Linear fit is provided for the whole sample (black line) and each sub-sample (red and green lines).

Stellar ages for our sample were estimated applying stellar evolutional models from the Padova group (Bressan et al. 2012), using the web interface [2] (see Sousa et al. 2011a, for more details).

Nissen 2015 performed a detailed study of abundance ratios of several elements, such as C, O and Si, as a function of the stellar age. They conclude that each element behaves in a different way regarding the stellar age, suggesting that more variables such as an evolving initial mass function and asymptotic giant branch stars should also be considered. Although that work is only for solar twin stars, we try to extend this result to solar type stars and for nitrogen, an element not studied in that work.

In the top panel of Fig. 6 we show [N/Fe] abundances as a function of stellar age for the thin disk stars. There seem to be a weak trend in the behaviour of nitrogen, as its abundance decreases with age. Although single stars appear to show a steeper decreasing trend towards older stars than planet hosts stars, probably due to the low number of points and the high dispersion of the abundance measurements, the slopes of these two trends are consistent within their error bars.

6. Kinematic properties

To study the kinematic properties of the sample stars and which stellar populations they belong to, we applied both purely chemical (e.g. Adibekyan et al. 2011; Recio-Blanco et al. 2014) and kinematic approaches (e.g. Bensby et al. 2003; Reddy et al. 2006). The Galactic space velocity components of the stars were calculated as in Adibekyan et al. (2012b) using the astrometric [3] and radial velocity data of the stars. The average errors in the U, V, and W velocities are approximately 2–3 km s$^{-1}$.

To assess the likelihood of the stars being members of different stellar populations we followed Reddy et al. (2006), and adopted the results of Bensby et al. (2003) for the population fractions. According to this separation, among the 65 stars, we have 58 (89 per cent) stars from the thin disc, four from the thick disc, and three transition stars that do not belong to any group.

The separation of the Galactic stellar components based only on stellar abundances is probably superior to that based on kinematic properties.
Table 2. Sensitivity of the nitrogen abundance derived from the NH band at 3360 Å.

| Star     | (T$_{\text{eff}}$; log g; [Fe/H]) | ΔT$_{\text{eff}} = \pm 100$ K | Δ log g = ±0.2 dex | Δ([Fe/H]) = ±0.2 dex |
|----------|----------------------------------|-------------------------------|-------------------|----------------------|
| HD 93083 | (5048; 4.32; 0.04)               | ±0.05                         | ±0.01             | ±0.16               |
| HD 222582| (5779; 4.32; –0.01)             | ±0.08                         | ±0.05             | ±0.01               |
| HD 39091 | (6003; 4.42; 0.09)              | ±0.10                         | ±0.03             | ±0.08               |

**Notes.** Changes of 100 K in T$_{\text{eff}}$, 0.2 dex in gravity, and 0.2 in [Fe/H] were applied.

7. The star–planet connection

The increasing number of exoplanets discovered via different methods has led to a wide diversity of parameters (masses, radii, eccentricity, orbital period, etc.) being known for these planets. Many studies have suggested that the formation of giant planets correlates with the metallicities of stellar hosts, (see Santos et al. 2001, 2004; Fischer & Valenti 2005; Sousa et al. 2011a; Mortier et al. 2013). Moreover, it has been shown that the formation of planets (of both high and low masses) at low metallicities is favoured by enhanced α-elements (Adibekyan et al. 2012a,c).

Models of planet formation require precise stellar abundances. Chemical abundances of planet hosts are useful when studying the properties of the planetary companion (Sousa et al. 2015). The relationship between [N/Fe] and the mass of the planet is shown in Fig. 8. In those stars which host many planets, the most massive planet was considered in the plot. As we can see, the masses of the planets are between 0.015 and 10.3 $M_J$, but most stars have planets with less than 4 $M_J$ orbiting around them. To remove this bias, which is due to the lack of data in the highest-mass part, we created bins with increasing steps, with sizes of 0.5, 1, 1.5 $M_J$ and two bins of 4 $M_J$. Error bars indicate the standard deviation of each bin. Although the results are biased because of the lack of data in the highest-mass part, we cannot obtain a clear relationship between [N/Fe] and the planetary mass (covariance $s_{x,y} = 0.031$; where $x = M_p$ and $y = [N/Fe]$). We see an increase of the [N/Fe] ratio in the first mass bins followed by constant [N/Fe] value for the more massive planets.

8. The star–planet connection

The increasing number of exoplanets discovered via different methods has led to a wide diversity of parameters (masses, radii, eccentricity, orbital period, etc.) being known for these planets. Many studies have suggested that the formation of giant planets correlates with the metallicities of stellar hosts, (see Santos et al. 2001, 2004; Fischer & Valenti 2005; Sousa et al. 2011a; Mortier et al. 2013). Moreover, it has been shown that the formation of planets (of both high and low masses) at low metallicities is favoured by enhanced α-elements (Adibekyan et al. 2012a,c).

Models of planet formation require precise stellar abundances. Chemical abundances of planet hosts are useful when studying the properties of the planetary companion (Sousa et al. 2015). The relationship between [N/Fe] and the mass of the planet is shown in Fig. 8. In those stars which host many planets, the most massive planet was considered in the plot. As we can see, the masses of the planets are between 0.015 and 10.3 $M_J$, but most stars have planets with less than 4 $M_J$ orbiting around them. To remove this bias, which is due to the lack of data in the highest-mass part, we cannot obtain a clear relationship between [N/Fe] and the planetary mass (covariance $s_{x,y} = 0.031$; where $x = M_p$ and $y = [N/Fe]$). We see an increase of the [N/Fe] ratio in the first mass bins followed by constant [N/Fe] value for the more massive planets.
Even so, the number of stars is not statistically significant to confirm this.

8. Discussion and conclusions

We present nitrogen abundances for 74 solar-type stars observed with the UVEs spectrograph at the VLTI/UT2 Kueyen telescope (Paranal Observatory, ESO, Chile). In our sample, 42 of the 74 are planet-hosts and 32 stars do not have any known planetary companion. All targets have been studied using spectral synthesis in the NH band at 3360 Å. The stars in our sample have effective temperatures between 4583 K and 6431 K, metallicities from −0.45 to 0.55 dex, and surface gravities from 3.69 to 4.82 dex. We performed a detailed analysis of this sample to obtain precise nitrogen abundances and investigate possible differences between the stars with planets and the single stars. Nitrogen abundances of both samples behave in a similar way regarding $T_{\text{eff}}$, log $g$, and [Fe/H].

We extended our results to the metal-poor regime, comparing our results with previous work by Israeli et al. (2004). Both results can be accommodated under a common fit in an [N/H] versus [Fe/H] plot until metallicities down to −2.0 dex (where the production of nitrogen has a secondary origin), suggesting that both metal-poor stars and solar-like stars follow the same behaviour.

The correlation between the presence of planets and nitrogen abundances is expected: The large amount of nitrogen in a protoplanetary disc would favour the formation of massive giant planets through the core accretion scenario.

We searched for correlations between planet mass and [N/Fe] abundance ratio, but did not find any significant correlation.
