ABSTRACT

Aims. We present the results of the X-ray spectral analysis of an XMM-Newton-selected type II QSO sample with z ≥ 0.5 and 0.5–10 keV flux of 0.3–33 × 10⁻¹⁴ erg/s/cm². The distribution of absorbing column densities in type II QSOs is investigated and the dependence of absorption on X-ray luminosity and redshift is studied.

Methods. We inspected 51 spectroscopically classified type II QSO candidates from the XMM-Newton Marano field survey, the XMM-Newton-2dF wide angle survey (XWAS), and the AXIS survey to set-up a well-defined sample with secure optical type II identifications. Fourteen type II QSOs were classified and an X-ray spectral analysis performed. Since most of our sources have only ~40 X-ray counts (PN-detector), we carefully studied the fit results of the simulated X-ray spectra as a function of fit statistic and binning method. We determined that fitting the spectra with the Cash-statistic and a binning of minimum one count per bin recovers the input values of the simulated X-ray spectra best. Above 100 PN counts, the free fits of the spectrum’s slope and absorbing hydrogen column density are reliable.

Results. We find only moderate absorption (N_H = (2–10) × 10²² cm⁻²) and no obvious trends with redshift and intrinsic X-ray luminosity. In a few cases a Compton-thick absorber cannot be excluded. Two type II objects with no X-ray absorption were discovered. We find no evidence for an intrinsic separation between type II AGN and high X-ray luminosity type II QSO in terms of absorption. The stacked X-ray spectrum of our 14 type II QSOs shows no iron Kα line. In contrast, the stack of the 8 type II AGN reveals a very prominent iron Kα line at an energy of ~6.6 keV and an EW ~ 2 keV.

1. Introduction

The unification model for active galaxy nuclei (AGN) is based on the assumption that the Seyfert type I/type II dichotomy in AGN is a result of varying orientation relative to the line of sight of similar objects (Antonucci 1993). All AGN consist of a super-massive black hole with an accretion disk. This central engine is surrounded by optically thick, toroidally concentrated dust material. An observer can either view the central engine directly (type I AGN) or through the optically thick torus (type II AGN). Direct observation of the broad line region reveals a strong UV continuum and broad permitted emission lines. Hao et al. (2005) provided a formal separation criterion by finding a bimodal distribution in the Hα-FWHM with a significant dip at FWHM(Hα) = 1200 km s⁻¹.

Kleinmann et al. (1988) discovered the first type II quasi stellar object (QSO). QSOs show higher intrinsic luminosity than AGN. In the optical the conventional dividing line between Seyfert galaxies and QSOs is MB = −23. Despite their high intrinsic luminosities, type II QSOs are very hard to identify.

** Based on observations obtained with XMM-Newton, an ESA science mission with instruments and contributions directly funded by ESA Member States and NASA.

** Appendix is only available in electronic form at http://www.aanda.org

A significant fraction of the emitted power is absorbed by the optically thick torus. Furthermore, their lack of emission lines in a wide optical wavelength range hampers their identification. About 150 optically selected type II QSOs from the Sloan Digital Sky Survey were studied in Zakamska et al. (2003). However, type II QSOs are more efficiently found in follow-up observations of X-ray surveys (Szokoly et al. 2004; Mainieri et al. 2002; Krumpe et al. 2007; Barcons et al. 2007; Tedds et al. 2008).

Type II QSOs play an important role in understanding the X-ray universe. Since they show significant absorption, type II QSOs/AGN are considered to be a main contributor to the hard X-ray background and their existence in considerable numbers is needed for the synthesis of the X-ray background (Gilli et al. 2007). Possible evolution of the absorption with intrinsic luminosity and/or redshift is a matter of intensive debate and would essentially influence the X-ray background synthesis models.

Many papers discuss the fraction of absorbed AGN as a function of luminosity and/or redshift, and this is a highly controversial subject (Dwelly & Page 2006; Tozzi et al. 2006; Akylas et al. 2006). However, there are only a few studies (e.g. La Franca et al. 2005) which investigate the evolution of absorbing column densities in type II AGN up to high redshift. Other studies focus on the local universe, where the existence of so-called Compton-thick absorbed objects is well known (Maiolino et al. 1998; Bassani et al. 1999; Risaliti et al. 2000). A Compton-thick
object is absorbed by column densities of \(N_{\text{H}} > 1.5 \times 10^{22} \text{ cm}^{-2}\), so that the cross section of Compton scattering overcomes the photo-electric absorption. Hence, the reflected X-ray component is observable.

There is evidence for a large fraction of Compton-thick absorbed quasars at high redshifts (Martinez-Sansigre et al. 2007), but only one candidate has been reported so far at high redshift (Norman et al. 2002), and even in this case the column density is quite uncertain. Most of the X-ray sources from deep Chandra and XMM-Newton surveys are absorbed by column densities \(10^{21} < N_{\text{H}}/\text{cm}^{-2} < 10^{25}\), with hard X-ray luminosities of \(10^{42} < L_{\text{X,abs}}/(\text{erg/s}) < 10^{44}\) (Comastri 2004; Szokoly et al. 2004; Mainieri et al. 2002; Mateos et al. 2005). These values are also found in Compton-thin absorbed \((10^{21} < N_{\text{H}}/\text{cm}^{-2} < 10^{25})\) Seyfert II galaxies at low redshifts.

The definition of type II QSOs is somewhat arbitrary. Zakamska et al. (2003) define a type II QSO only based on its optical properties. They select AGN with narrow permitted emission lines \((FWHM < 2000\,\text{km}\,\text{s}^{-1})\) and classify objects with \([O\text{ III}] \lambda 5008\) line luminosity of \(L \geq 3 \times 10^{48} \text{ L}_\odot\) as type II QSO. Mainieri et al. (2002) introduce the term “type II QSO region”. Although their type I/II classification is based on optical spectra, a type II QSO has to have an intrinsic X-ray luminosity of \(L_{\text{X,int}} > 10^{44} \text{ erg/s} (0.5-10\,\text{keV})\) and an absorbing hydrogen column density of \(N_{\text{H}} > 10^{22} \text{ cm}^{-2}\). Throughout the paper we use the definition of a type II QSO to be an object with narrow forbidden and narrow permitted emission lines in the optical spectrum, as well as a de-absorbed intrinsic X-ray luminosity \(L_{\text{X,abs}} > 10^{44} \text{ erg/s} (0.5-10\,\text{keV})\) band. However, the Seyfert type II classification of our sample objects is strictly based on the optical spectra.

The present work focuses on properties of the high X-ray luminosity type II QSOs found in medium deep surveys performed by us. The paper is organised as follows. In Sect. 2 we describe how we selected our type II QSO candidate sample and we study the properties in Sect. 3. The X-ray data and the extraction of the X-ray spectra are described in Sect. 4. Since X-ray spectra with small numbers of counts have to be fitted, we studied different fitting and binning methods in Sect. 5 and then describe the analysis of the X-ray spectra. The results are discussed in Sect. 6. Finally, our conclusions are outlined in Sect. 7.

Unless mentioned otherwise, all errors refer to a 68% confidence interval. We assume \(H_0 = 70\,\text{km}\,\text{s}^{-1}\,\text{Mpc}^{-1}\), \(\Omega_M = 0.3\), and \(\Omega_{\Lambda} = 0.7\).

2. Definition of the type II QSO sample

We began with a list of 51 spectroscopically classified type II QSO candidates which are associated with X-ray sources. All optical counterparts have \(z \geq 0.5\) and observed X-ray luminosities (not corrected for intrinsic absorption) of \(\log (L_{\text{X,abs}}) > 42.5\). The type II QSO candidates were taken from three different X-ray surveys, the XMM-Newton Marano field survey (Krumpe et al. 2007), the XMM-2df wide angle survey (XWAS, Tedds et al. 2008), and from “An XMM-Newton International Survey” (AXIS, Barcons et al. 2002, 2007; Carrera et al. 2007). To obtain a well-defined sample with secure optical type II identifications and X-ray counterparts we applied a two stage process. First, we visually inspected the optical spectra of all type II QSO candidates from all X-ray surveys and determined the \(FWHM\) of the emission lines. The type II QSO candidate classification was only based on the optical spectra. The spectral resolution of the optical setup was \(\sim 1050\,\text{km}\,\text{s}^{-1}\) for the Marano field survey, \(\sim 700\,\text{km}\,\text{s}^{-1}\) for XWAS, and \(\sim 300–600\,\text{km}\,\text{s}^{-1}\) for AXIS. Therefore, an intrinsic line of \(1200\,\text{km}\,\text{s}^{-1}\) was observed with \(\sim 1250–1600\,\text{km}\,\text{s}^{-1}\). We defined emission lines with a measured resolution (including instrumental resolution) of \(FWHM \leq 1500\,\text{km}\,\text{s}^{-1}\) as narrow.

The optical spectra were only used to determine a secure Seyfert type of the objects. They were not used to separate between AGN and QSOs. None of the 51 type II QSO candidates showed obvious broad emission lines in the optical spectra. However, since we aimed for a very strict type II QSO sample, we excluded many objects that showed only the low excitation \(O\text{II}\) line. The optical spectrum had to comprise several emission lines that allowed us to establish an optically secure classification of the Seyfert type. In addition the signal-to-noise ratio had to be appropriate in order to verify the non-existence of broad permitted emission line. We excluded all doubtful cases.

We introduced two different categories of type II QSO candidates based on the reliability of the type II classification. Objects that have optical spectra with high excitation lines and at least one permitted AGN emission line that is detected but narrow (e.g. \(Ly\alpha, C\ IV, H\beta\)) are marked with the optical flag “secure” (see Table 1) — signifying a secure optical identification. Their optical classification is very robust.

Objects with less secure type II identification belong to the tentative sample (optical flag “tentative”). The classification as tentative object can be due to the following reasons:

- The optical spectrum shows narrow emission lines, common AGN high excitation lines, but no Mg II emission. Only \([Ne\text{ v}]\) and \([O\text{ II}]\) are detected in the spectra. The presence of a common AGN high excitation line \([Ne\text{ v}]\) without a broad Mg II suggests the classification as a type II QSO candidate. However, since no other permitted emission line is accessible, a secure type II classification cannot be established.
- Common AGN high excitation lines are narrow but show indications of underlying broad components (optical spectra in Appendix A). These objects are likely to be transition objects between Seyfert type II/type I.
- The signal-to-noise ratio of the H$\beta$ line, or its coincidence with the atmospheric band prevents a robust determination of the \(FWHM\) and could hide a weak, but broad H$\beta$ component.

For all sources in the tentative sample we give an individual comment at the end of this section. After inspection of the optical spectra we were left with 14 secure objects and 12 type II objects that belong to the tentative sample.

As a second step to setting up a well-defined type II QSO sample, we verified that the spectroscopically identified counterpart is associated with the X-ray source. For a significant number of objects much deeper imaging data have become available subsequent to the epoch when the spectra were obtained. For example, the XWAS optical counterparts were originally selected from SuperCosmos optical imaging survey data (Hamblly et al. 2001). For the majority of the objects we now have additional, deeper imaging data in different bands. These imaging data were obtained with the Wide Field Imager (WFI, 2.2 m telescope at La Silla) or the Wide Field Camera (WFC, 2.5 m Isaac Newton telescope on La Palma). We visually investigated the best available imaging data (WFI, WFC, SuperCosmos) for additional optical counterparts and rejected doubtful counterpart identifications. Furthermore, we computed the probability that the optical object with the \(R\)-band magnitude \(m_R\) is associated with the X-ray source. This was based on

\[
L = \frac{Q \exp(-\text{dim}^2_{\text{conf}}/2)}{2\pi\sigma^2\chi N(<m_R)}
\]

...
bols illustrate tentative type II QSO candidates. Dashed lines indicate symbols represent secure type II QSO candidates while small symbols illustrate tentative type II QSO candidates. The majority of our sources have $21 < R < 24$. The $0.5–10\,\text{keV}$ flux in the sample ranges from $0.3–33 \times 10^{-14}\,\text{erg/s/cm}^2$.

To calculate $f_X/f_{\text{OPT}}$ values we derived the optical fluxes in a band centred at 7000 Å with a width of 1000 Å using the equation $f_{\text{OPT}} = 10^{-0.4R – 5.759}$ (Zombeck 1990). X-ray fluxes were calculated for the $0.5–10\,\text{keV}$ energy range. The $R$-band magnitude vs. X-ray flux plane (Fig. 2) clearly shows AGN activity in all selected sources, since they have X-ray-to-optical flux ratios of $f_X/f_{\text{OPT}} > 0.25$. In accordance with Mainieri et al. (2002) we consider objects with $f_X/f_{\text{OPT}} > 0.1$ as AGN. Almost half of the selected type II QSO candidates have noticeable high X-ray-to-optical flux ratios ($f_X/f_{\text{OPT}} > 10$). Szokoly et al. (2004) mentioned that type II AGN/QSOs cluster at higher X-ray-to-optical flux ratios than type I AGN. The majority of the spectroscopically classified type II AGN/QSOs in the Lockman Hole also show high $f_X/f_{\text{OPT}}$ values (Mainieri et al. 2002). The observed $0.5–10\,\text{keV}$ X-ray luminosities (not corrected for intrinsic absorption) of our objects range from $L_{\text{X,obs}} \sim 10^{43–45}\,\text{erg/s}$.

4. XMM-Newton observations and extraction of X-ray spectra

All data were processed with the SAS version 7.0 (Science Analysis Software, Gabriel et al. 2004) package and corresponding calibration files. The epchain and emchain tasks were used for generating linearized event lists from the raw PN and MOS data. For all sources the effects of photon pile-up were negligible.

The XMM-Newton data reduction for the Marano field survey is described in detail in Krumpe et al. (2007). For the XWAS and AXIS sources we downloaded all available X-ray data from the XMM-Newton archive up to and including July 2007. Periods of high background were excluded from the analysis of all relevant data sets in the standard way.

Circular or box-shaped source and background regions were manually determined for all contributing observations. Sources at large off-axis angles in the contributing observations were not considered as follows. The largest off-axis angles were 720 arcsec for the PN and 820 arcsec for the MOS detectors, respectively. The lower PN area was a result of the enhanced background contamination near the edges of the PN detector. Additional X-ray sources in the background regions were masked out. The auxiliary response file (arf) was computed for each source and observation individually. For the Marano field sources, we used appropriately “canned” response matrices from the XMM-Newton calibration homepage (XMM-revolution 110 and pattern 0–12). The PN $y$-coordinate of an X-ray source was determined to link the relevant PN response matrix file (rmf for single and double events, version 6.8) to the X-ray spectrum of the source. For the XWAS and AXIS sources the response matrix files were computed on a case-by-case basis. Where multiple X-ray spectra of a given source were added, the mean rmf was computed as a weighted mean. For details of the procedure see Page et al. (2003). The two MOS spectra were always added to form a single MOS spectrum.

The X-ray source of the secure type II object phl5200-001 is surrounded by diffuse X-ray emission. For the reduction of the X-ray spectrum we used a smaller extraction radius for the point source and the diffuse X-ray emission as the background region.

5. X-ray spectral analysis

The X-ray spectral analysis was performed with XSPEC (Arnaud 1996) version 12.3.0. Although we have a few objects with several hundreds of net PN source counts in the $0.2–8\,\text{keV}$ range, the distribution peaks at $\sim 40$ net PN source counts. An appropriate X-ray spectral analysis for the low count regime has to be found. Although we only refer to the net PN counts in our simulations and in Table 4, the fit uses both the PN and MOS data. Hence, the total number of counts used by the fit is typically twice that given in Table 4.

5.1. Defining the appropriate fit statistic and binning method

A problem notorious to X-ray astronomy is proper fitting of spectra with relatively few counts. Tozzi et al. (2006) approached this problem for the X-ray sources in the Chandra Deep Field South by running simulations for two different fitting procedures: Cash-statistics (unbinned) and classic $\chi^2$-statistics with a binning of 10 counts per bin (min 10). They concluded that the

---

1. http://xmm.esac.esa.int/xsa
2. http://xmm.esac.esa.int/external/xmm_sw_cal/calib
The data were grouped from a minimum PHA channel (corresponding to 0.2 keV) to the maximum PHA channel (corresponding to 8 keV), with at least \( n \) counts per bin (abbreviated as min \( n \)) or with a fixed number \( n \) of channels (channel \( n \)).

Unbinned Cash-statistic fits recovered the input values better for X-ray spectra with less than 50 counts.

We carried out a much more extensive study of the fit results as a function of fit statistic and binning method. This investigation can be used to study the error distribution of the intrinsic column density \( (N_H) \) and to determine how many PN net counts are required to perform free fits of \( N_H \) and photon index \( \Gamma \) with acceptable errors in both parameters.

We assumed emission from the AGN to be described as a power law with photon index \( \Gamma \), modulated by Galactic foreground absorption and further intrinsic cold absorption at the redshift of the AGN. Following Mainieri et al. (2002) and Mateos et al. (2005), we simulated X-ray spectra with an input parameter for net PN counts less than 100.

The X-ray spectra were normalised to reach the desired photon index \( \Gamma \) and Galactic foreground absorption of \( N_{\text{H.GAL}} = 2 \times 10^{21} \) cm\(^{-2}\) and considered all possible parameter combinations of Table 2.

The X-ray spectra were normalised to reach the desired 0.2–8 keV net counts with a deviation of up to 5%. We added Poisson noise to the X-ray spectra. We used a typical representative background file (Marano 9A). As for the real data we added MOS1 and MOS2 spectra to form a single MOS spectrum. The same source was simulated 1000 times for each set of specific parameters.

The simulated X-ray spectra were grouped by using different binning methods (Table 3). Cash and \( \chi^2 \)-statistic were applied to recover the \( N_H \) input value. The redshift and the Galactic absorption were set to the input value. The nominal initial guess for the intrinsic absorption was \( N_H = 0 \) cm\(^{-2}\), but other initial guesses up to \( N_H = 10^{24} \) cm\(^{-2}\) were tested as well.

We studied the recovered \( N_H \) distribution with different fit statistics and binning methods by analysing the number of mismatches, the peak, the shape and the significance of \( N_H \) detection. The best fit statistic and binning method was selected by these criteria in the given order. In summary, the most important results of our simulations are as follows.

- With only very few exceptions, the Cash-statistic with a binning of one count per bin (min 1) recovered the input values best.
- Even at a level of 40 net PN counts, the Cash-statistic with a binning of minimum one count per bin correctly recovers more than 90% of the objects with an intrinsic absorption of \( N_H \sim 10^{22} - 10^{24} \) cm\(^{-2}\) up to \( z = 3.5 \).
- Figure 3 shows the retrieved \( N_H \) distribution for an input value of \( N_H = 10^{23} \) cm\(^{-2}\) at \( z = 2 \). The variance of the recovered \( N_H \) distribution increases with redshift. However, individual peaks clearly separate in the studied redshift range, when the intrinsic \( N_H \) values differ by a factor of approximately 10 in hydrogen column density. The recovered \( N_H \) distribution for an intrinsically unabsorbed source at \( z = 1 \) is shown in Fig. 4. Between 50–60% of all objects are correctly recovered independent of redshift. Although not all fits converge at \( N_H = 0 \) cm\(^{-2}\), none of the resulting \( N_H \) values is significantly different from zero. The peak of the misclassified absorbed objects shifts from \( N_H \sim 10^{21} \) cm\(^{-2}\) for \( z = 1 \) to \( N_H \sim 7 \times 10^{21} \) cm\(^{-2}\) for \( z = 3 \).
- For 10 net PN counts the fit retrieves a very broad \( N_H \) distribution for objects with an intrinsic absorption of \( N_H \sim 10^{22} - 10^{24} \) cm\(^{-2}\). Independent of redshift the fit recovers roughly 30% of the intrinsically absorbed X-ray sources as unabsorbed sources (\( N_H = 0 \) cm\(^{-2}\)). However, the fit does not significantly overpredict the \( N_H \) values. Although no absorption is recovered with a significance above 2\( \sigma \) due to the large errors, the fitted \( N_H \) values can be used as an estimate for the intrinsic \( N_H \) values.

We studied the recovered \( N_H \) distribution with different fit statistics and binning methods by analysing the number of mismatches, the peak, the shape and the significance of \( N_H \) detection. The best fit statistic and binning method was selected by these criteria in the given order. In summary, the most important results of our simulations are as follows.

- For a binning of min 10 or min 15 we find no difference between the Cash and the \( \chi^2 \)-statistic even at a level of 40 net PN counts. Only the significance of the absorption is marginally higher for the Cash-statistic. There is also no difference between a binning of min 10 and min 15.

- Free fits in \( N_H \) and \( \Gamma \) are acceptable above 100 PN net counts. The recovered \( N_H \) values show a narrow distribution at the input \( N_H \) value (FWHM ~ 0.4 dex). For all combinations of fitting and binning methods we retrieve the peak of absorption.
**6. Discussion**

In Fig. 6 we show the fitted intrinsic $N_{\text{H}}$ distribution of the sources. A column density peak at $N_{\text{H}} = 4 \times 10^{22}$ cm$^{-2}$ is found. We find moderate absorption in the majority of our objects. The significance of the absorption exceeds $2\sigma$ in most of the cases (see the confidence contours in Appendix A). Two type II objects are consistent with being unabsorbed X-ray sources, one of which is from the secure type II sample.

The determination of the intrinsic $N_{\text{H}}$ also allows us to compute the de-absorbed intrinsic X-ray luminosity $L_{\text{XINT}}$ of our sources. As mentioned in Sect. 1, we define a type II object by the detection of narrow emission lines in the optical spectrum. Figure 7 shows the intrinsic column density vs. de-absorbed intrinsic X-ray luminosity plane. The dividing line of $L_{\text{XINT}} = 10^{44}$ erg/s is used to distinguish between type II AGN and QSOs. Ten type II objects from the secure sample and four tentative objects are identified as QSOs. We detected one unabsorbed type II QSO but the object belongs to the tentative sample. No obvious trend of absorption in type II QSOs with intrinsic X-ray luminosity is found.

Most of the type II QSOs fall into the same region of the $N_{\text{H}} - L_{\text{XINT}}$ diagram where previous studies have also found type II QSOs (Mainieri et al. 2002; Szokoly et al. 2004; La Franca et al. 2005; Ptak et al. 2006). The additional criterion ($N_{\text{H}} > 10^{23}$ cm$^{-2}$, Mainieri et al. 2002) makes only a small difference to our sample selection (two more secure objects).

The $N_{\text{H}}$-redshift plane for type II QSOs and type II AGN is shown in Fig. 8. We found no obvious differences between the

* A two component fit was used, an absorbed power law (\( N_{\text{H}} \) is given here) and an unabsorbed power law to model the soft excess.

Fig. 6. Intrinsic \( N_{\text{H}} \) distribution of all 22 type II objects (black) and of the 14 type II QSOs (grey filled histogram).

\( N_{\text{H}} \) distribution of AGN and QSOs. Although a tentative anticorrelation of \( N_{\text{H}} \) vs. redshift below \( z < 1 \) and a direct correlation above \( z = 1 \) is indicated, when all data is taken together there is no significant trend in \( N_{\text{H}} \) with redshift. Considering the typical flux and column densities found for our sources we expected all \( z > 1 \) type II objects to be classified as QSOs. At lower redshifts \( \sim 40\% \) of the type II QSO candidates are actually type II QSOs.

Statistical fluctuations in the X-ray spectrum can lead to high values of spuriously measured \( N_{\text{H}} \) values at high redshifts (e.g. Akylas et al. 2006). However, Fig. 5 show that objects with intrinsic \( N_{\text{H}} \) of several \( 10^{22} \) \( \text{cm}^{-2} \) are not significantly influenced by systemic trends in redshift. The fit method is also able to pick up much higher absorptions than found in our sources. The scatter in the mentioned \( N_{\text{H}} \) range at \( z > 2.5 \) is consistent with an intrinsic absorption of \( N_{\text{H}} = 10^{23} \text{cm}^{-2} \) for all sources.

As a further test of the impact of statistical fluctuations, we plot in Fig. 8 the amount of \( N_{\text{H}} \) that is needed to reduce the 0.5 keV flux by 30% and 50%. The 30%-line agrees well with the 90% contours of unabsorbed sources in Fig. 5. Consequently, even for the sources at \( z > 2.5 \) the fitted \( N_{\text{H}} \) values are unlikely to be caused by statistical fluctuations.

The previous conclusions depend on not having misinterpreted Compton-thick absorbed objects (\( N_{\text{H}} > 1.5 \times 10^{23} \text{cm}^{-2} \)) as moderately absorbed objects. Increasing column densities
cause a hardening of the X-ray spectrum. This trend stops when the material becomes optically thick to electron scattering. The X-ray spectrum of a Compton-thick absorbed source is completely dominated by the reflection component. Their X-ray spectra show soft X-ray radiation but with a much lower photon index ($\Gamma \sim -0.4$ to $1.3$, Maiolino et al. 1998; Bassani et al. 1999; Risaliti et al. 2000; Iwasawa et al. 2001; Comastri 2004).

We simulated an X-ray spectrum with $\Gamma = 1$ as observed in the 3–12 keV band for NGC 1068. When we fit the spectrum with a fixed $\Gamma = 2.0$, we recover values for absorption of $N_H = 0.7 \times 10^{22}$ cm$^{-2}$, $N_H = 1.9 \times 10^{22}$ cm$^{-2}$ and $N_H = 3.8 \times 10^{22}$ cm$^{-2}$ for redshifts of $z = 1, 2, 3$ respectively. Hence, moderately absorbed sources are found if intrinsically Compton-thick absorbed sources are studied. However, we are able to exclude a general misinterpretation of the spectra based on the following arguments.

First we tested if the X-ray spectra are better modelled with a purely reflection-dominated model ($pexrav$). We used solar abundances and a cutoff energy of 100 keV. The ratio between the reflected and direct component (fit parameter: scaling factor) was set to 100 in order to obtain pure reflection. The cosine of the inclination was left as a free parameter. Again, we fitted the photon index as a free parameter only in the case the X-ray source had more than 100 PN net counts.

Only the data of X-ray source X00851_154 has a low count numbers in our X-ray spectra do not allow the analysis of the iron line which is normally outshone by the direct component. Due to the reflection of the X-ray radiation from cold material in the torus, an iron Kα fluorescence line with an equivalent width $EW \gtrsim 1$ keV is expected (Turner et al. 1997; Risaliti 2002).

The low count numbers in our X-ray spectra do not allow the study of individual spectral features such as an iron line. Based on the assumption that the intrinsic X-ray properties in the sample are similar, a stack of the individual spectra can reveal the intrinsic X-ray absorption which is inconsistent with Compton-thick absorbed objects. Only X00851_154 has a lower low $fx/f_{opt}$ ratio, but the best X-ray spectral fit is a moderately absorbed power law with $\Gamma = 1.6$. Under the assumption of Compton-thick absorption, all studied objects would be classified as QSOs and our sample would contain the most X-ray luminous QSOs ever studied ($L_X \sim 10^{47}$ erg/s).

6.1. Stacking of X-ray spectra

Another indication for Compton-thick absorption is the detection of the iron line which is normally outshone by the direct component. Due to the reflection of the X-ray radiation from cold material in the torus, an iron Kα fluorescence line with an equivalent width $EW \gtrsim 1$ keV is expected (Turner et al. 1997; Risaliti 2002).

The low count numbers in our X-ray spectra do not allow the study of individual spectral features such as an iron line. Based on the assumption that the intrinsic X-ray properties in the sample are similar, a stack of the individual spectra can reveal the presence of an iron line. Since the number of individual X-ray spectra increases the SNR in the stacked spectrum, we decided to include all 14 type II QSOs regardless of the optical flag. The assumption is justified because the secure and tentative sample do not show differences in $fx/f_{opt}$ (Fig. 2) and absorption values (Fig. 6).

Corral et al. (2008) explain the stacking process in detail. Here we outline the essential components of the process. Using the best-fit parameters, unfolded spectra (euSpec in XSPEC) from the ungrouped observed X-ray spectra (MOS and PN data) are extracted. The unfolded spectra are corrected for Galactic foreground absorption, shifted to the rest-frame and normalised to the same rest-frame flux in the 2–5 keV band. The flux is
show in Fig. 9, upper panel. The stacked type II QSO spectrum of the observed spectrum to the average simulated continuum is though in none of the individual AGN X-ray spectra a significant number of objects that we classified as AGN could be Compton-thick absorbed. Interestingly, except for one object, all X-ray sources, that can be better or equally well fitted by a reflection line from the accretion disk, which can be significantly broadened due to relativistic effects; a blend of narrow lines that is observed as a single unresolved broad line due to the low signal-to-noise ratio of our observations.

The typical equivalent widths of the disk iron lines are usually significantly lower than the EW of the iron line found in our AGN stack. The energy and width of the line is more consistent with a blend of narrow lines. Depending on the properties of the reflecting material different ionisation stages of iron are excited as observed in the the Compton-thick absorbed object NGC 1068 (Ogle et al. 2003). If the signal-to-noise ratio is lowered the three resolved lines will be observed as an unresolved broad (EW \geq 1 keV) line with a peak above 6.4 keV. In this case a significant number of objects that we classified as AGN could be Compton-thick absorbed. Interestingly, except for one object, all X-ray sources, that can be better or equally well fitted by a purely reflection-dominated model in comparison to the power law plus intrinsic absorption model, are AGN.

7. Conclusions

We selected 51 spectroscopically classified type II objects from the XMM-Newton Marano field survey, XWAS, and AXIS. We re-investigate the optical spectra for narrow and common AGN high excitation lines, as well as verifying the X-ray counterpart determination. 22 sources meet our selection criteria (13 secure identification, 9 tentative). All sources have \( z \geq 0.5 \) and observed 0.5–10 keV X-ray luminosities (not corrected for intrinsic absorption) of \( L_{\text{X,obs}} \sim 10^{43–44} \text{erg/s} \). The sample is not flux limited.

The selection of both optical, narrow high excitation emission lines and intrinsic X-ray luminosities \( L_{\text{X,obs}} \geq 10^{42} \text{erg/s} \) yielded 14 type II QSOs.

Since the distribution of net PN counts peaks at \( \sim 40 \), the X-ray spectral analysis has to account for this very low numbers of counts. We extensively simulated and studied such low count number X-ray spectra. A binning with at least one count per bin combined with the Cash-statistic recovered the input values best. We proved that the method is able to find absorption up to \( N_{\text{HI}} = 10^{23} \text{cm}^{-2} \).

However, we discover only moderately absorbed type II QSOs. One QSO is consistent with being unabsorbed but it belongs to the tentative sample. Compton-thick absorbed sources may be detected as moderately absorbed but we can exclude this scenario for the majority of our sources. The X-ray data are not well fitted by reflection models. The \( f_k/f_{\text{OPT}} \) values of the objects and the non-detection of a broad iron line in the stacked type II QSOs spectrum give evidence that we have not misclassified Compton-thick absorbed sources. In contrary to the QSO stack, the stack of 8 type II AGN revealed a very prominent iron line with an \( EW \sim 2 \text{keV} \). However, the shape of the single X-ray spectra and the modelling of the X-ray data showed that the majority of our AGN are most probably moderately absorbed X-ray sources.

The column density distribution found by us agrees well with those in deep Chandra and XMM-Newton surveys (Mainieri et al. 2002; Szokoly et al. 2004; Mateos et al. 2005; Ptak et al. 2006). These authors also reported a few cases of unabsorbed type II AGNs, as well as evidence for some heavily absorbed sources (\( N_{\text{HI}} \sim 10^{24} \text{cm}^{-2} \)). La Franca et al. (2005) studied column density trends with X-ray luminosity in different redshift bins. They classified type II AGN as all sources that do not show any emission lines with \( FWHM > 2000 \text{km s}^{-1} \). Independent of X-ray luminosity and redshift bins, they discovered type II AGN with an average absorption of \( N_{\text{HI}} \sim 10^{23} \text{cm}^{-2} \), slightly above the column density peak of our survey (\( N_{\text{HI}} = 4 \times 10^{22} \text{cm}^{-2} \)).

The present study of strictly classified type II AGN/QSOs, based on the optical spectra, verified that there is no obvious trend of absorbing column density with redshift or X-ray luminosity.

Our results apparently contradict studies of the local universe. Bassani et al. (1999) and Risaliti et al. (2000) found 75% of their sources with high absorption (\( N_{\text{HI}} > 10^{23} \text{cm}^{-2} \)) and 25–45% with \( N_{\text{HI}} > 10^{24} \text{cm}^{-2} \). Either the column density properties change dramatically from the local to distant universe or the majority of the heavily absorbed distant sources are missed in our surveys. Indeed even the most luminous Compton-thick absorbed sources in the local universe, e.g. NGC 6240, could not have been detected by our survey if they were at \( z \geq 0.4 \).

In summary, the column densities in our survey show no trend in X-ray luminosity and no clear trend in redshift. If we compare our results with samples of AGN in the local universe, our sample does not contain a significant fraction of heavily absorbed sources (\( N_{\text{HI}} > 10^{23} \text{cm}^{-2} \)). Of our survey with \( z \geq 0.5 \) is limited to observed X-ray luminosities in excess of \( L_{\text{X,obs}} > 10^{43} \text{erg/s} \). We can only expect to find QSOs intrinsically more luminous than \( L_{\text{X,obs}} > 10^{45} \text{erg/s} \) if they are Compton-thick absorbed. Norman et al. (2002) claim that for the most distant type II QSO ever detected (\( z = 3.7 \)), there is strong evidence for heavy or even Compton-thick absorption.
However, our survey rules out large numbers of Compton-thick absorbed sources with X-ray luminosities of \( L_{\text{XINT}} > 10^{45} \) erg/s. Hence, potential Compton-thick absorbed objects at high redshifts are likely to have similar X-ray luminosities to Compton-thick absorbed objects in the local universe. In order to find a supposed, rare population of very luminous, Compton-thick absorbed QSOs a larger survey area is needed. The 2XMM catalogue (Watson et al. 2008) with a survey area of \( \sim 360 \text{ deg}^2 \) could provide a valuable source to reveal such a population.

Appendix A: Optical and X-ray spectra, confidence contours

In this section we show the optical and X-ray spectra, as well as the confidence contours of X-ray spectral fits for the parameters $N_H$ and $\Gamma$.

**Optical spectra:** Optical atmospheric absorption corrected, wavelength and flux calibrated spectrum for the optical X-ray counterpart is shown. All spectra are in flux units of $10^{-18}$ erg cm$^{-2}$ s$^{-1}$ Å$^{-1}$. The black solid line represents the spectrum, the green solid line the error spectrum (not available in all spectra). Red markers indicate possible emission lines, blue markers absorption lines. There are exceptions in a few spectra. Spectral features at 5580 Å are spurious due to incomplete subtraction of a night sky line.

**X-ray spectra:**

The X-ray spectra show the PN (black) and combined MOS (red) data, as well as the best fit model (foreground Galactic absorption, power law with intrinsic absorption at the object’s redshift). In the case of Marano 51A and Marano 610A the shown best fit model consists of foreground Galactic absorption, an unabsorbed power law, and an power law with intrinsic absorption at the object’s redshift to account for the soft excess in the X-ray data.

For objects that have less than 100 PN source counts in the 0.2–8 keV band we fixed the photon index ($\Gamma = 2$). Otherwise, free fits in $N_H$ and $\Gamma$ are shown. The fit parameters are given in Table 4. For illustration purposes the X-ray data have been rebinned to different signal-to-noise ratio, after grouping to a minimum of one count per bin (min 1).

**Confidence contours:** Confidence contours of the absorbing column density in units of $N_H = 10^{22}$ cm$^{-2}$ vs. photon index $\Gamma$ of the X-ray spectral fits. Confidence contours are plotted for 68% (black), 90% (red) and 99% (green). The contours are based on free $N_H$ and $\Gamma$ X-ray spectral fits for all objects independent of PN net counts.

**Comments:** Below every set of optical & X-ray spectra and X-ray contour a comment for the objects shown is given. This comment includes the classification number of the optical counterpart and the corresponding redshift. Furthermore, a short fit description is given. For more details on the properties of the sources and the X-ray spectral fits see Tables 1, 4.

object Marano 9A, $z = 1.427$, free X-ray spectrum fit.
object Marano 20A, $z = 2.207$, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object Marano 32A, $z = 2.727$, free X-ray spectrum fit.
object Marano 39A, $z = 0.862$, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object Marano 47A, $z = 0.900$, frozen $\Gamma = 2.0$ X-ray spectrum fit.
object Marano 50A, $z = 0.986$, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object Marano 51A, $z = 0.58$, two power laws, frozen $\Gamma = 2.0$ X-ray spectrum fit.
object Marano 63A, $z = 2.800$, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object Marano 66A, $z = 0.981$, frozen $\Gamma = 2.0$ X-ray spectrum fit.
object Marano 116A, $z = 0.581$, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object Marano 133A, $z = 2.321$, frozen $\Gamma = 2.0$ X-ray spectrum fit.
object Marano 171A, $z = 0.800$, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object Marano 224B, $z = 0.690$, frozen $\Gamma = 2.0$ X-ray spectrum fit.
object Marano 253A, $z = 0.517$, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object Marano 463A, $z = 2.531$, frozen $\Gamma = 2.0$ X-ray spectrum fit.
object Marano 610A, $z = 0.699$, two power laws, frozen $\Gamma = 2.0$ X-ray spectrum fit.

object X21516_135, $z = 3.278$, frozen $\Gamma = 2.0$ X-ray spectrum fit.
object X00851_154, \(z = 2.976\), free X-ray spectrum fit.

object X01135_126, \(z = 0.543\), free X-ray spectrum fit.
object X03246_092, $z = 0.500$, frozen $\Gamma = 2.0$ X-ray spectrum fit (0.3–8 keV).

object phl5200-001, $z = 0.711$, free X-ray spectrum fit.
object sds1b-014, $z = 0.962$, free X-ray spectrum fit.

(optical spectrum taken from Akiyama et al. 2008).
