With the aim to loosen the entanglement requirements of quantum illumination, we study the performance of a family of Gaussian states at the transmitter, combined with an optimal and joint quantum measurement at the receiver. We find that maximal entanglement is not strictly necessary to achieve quantum advantage over the classical benchmark of a coherent-state transmitter, in both settings of symmetric and asymmetric hypothesis testing. While performing this quantum-classical comparison, we also investigate a suitable regime of parameters for potential short-range radar (or scanner) applications.

I. INTRODUCTION

Hypothesis testing (HT) [1] and quantum hypothesis testing (QHT) [2] play crucial roles in information [3] and quantum information theory [4], HT has fundamental links to both communication and estimation theory, ultimately underlying the task of radar detection [5] which has been extended to the quantum realm by the protocol of quantum illumination (QI) [6, 7] and, more precisely, by the model of microwave quantum illumination [8] (see Ref. 8 for a recent review on these topics). The simplest scenario of both HT and QHT is that of a binary decision, so that they are reduced to the statistical discrimination between just two hypotheses (null, $H_0$, and alternative, $H_1$).

At its most basic level a quantum radar is a task of binary QHT. The two alternate hypotheses are encoded in two quantum channels in through which a signal mode is sent. Depending on the presence or not of a target, the initial state of signal mode undergoes different transformations which result in two different quantum states at the output. Final detection is then reduced to distinguishing between these two possible quantum states. The ability to do this accurately, with a low probability of error, directly relates to an ability to determine the correct result. This fundamental mechanism can then be easily augmented with geometrical ranging arguments which account for the quantification of the round-trip time from the target, i.e., its distance.

While QI radars may potentially achieve the best performances [10], they require the generation of a large number of entangled states which may be a demanding task, especially if we consider the microwave regime. At the same time, the definition itself of quantum radar may be generalized beyond QI to any model that exploits a quantum part or device to beat the performance of a corresponding classical radar in the same conditions of energy, range etc. Driven by these ideas, we progressively relax the entanglement requirements of QI and we study the corresponding detection performances to the point where the source becomes just-separable, i.e., a maximally-correlated separable state. It is worth noting that, although Gaussian entanglement is the main resource of QI, previous literature has also considered the use of separable non-Gaussian sources with non-positive P-representations, finding an advantage over a restricted classical benchmark [11]. More generally, quantum correlations beyond entanglement have also been considered for a number of other quantum information and computation tasks [12,13]. However, our current study is specifically focused on Gaussian states because they are, so far, the only sources showing a quantum advantage over the best classical benchmark. The analysis is done in the setting of symmetric and asymmetric QHT. In particular we show how a quantum advantage can still be achieved with less entangled sources, especially in a scenario of very short-range target detection.

II. GENERAL QUANTUM-CORRELATED SOURCE

Following Gaussian QI, we consider a source modelled as a two-mode Gaussian state [16], comprising a signal (s) mode, sent out to some target region, and an idler (i) mode, retained at the source for later joint measurement. Each of these modes has $N_s$ mean number of photons. However, instead of using a two-mode squeezed vacuum (TMSV) state as in QI, we can employ a generic zero-mean Gaussian state whose covariance matrix (CM) takes the following block form

$$\mathbf{V}_{\text{gen}}^{ss} = \begin{pmatrix} \mathbf{S} & \mathbf{C} \\ \mathbf{C} & \mathbf{S} \end{pmatrix} \oplus \begin{pmatrix} \mathbf{S} & \mathbf{-C} \\ \mathbf{-C} & \mathbf{S} \end{pmatrix},$$

$$S := N_s + 1/2,$$

$$0 \leq C \leq \sqrt{S^2 - 1/4} = \sqrt{N_s(N_s + 1)},$$

where the direct sum operator $\oplus$ acts on two matrices $A$ and $B$ such that $A \oplus B = (A_{00} \ 0 \ B)$. The terms in the leading diagonal, $S := N_s + 1/2$, quantify the amount of thermal noise within each of the local modes, $S$ and $I$, while the covariance, $C$, quantifying the correlations
between these two modes, may take any value within the range given by Eq. 3. Mathematically, these are the second-order statistical moments of the quantum state (see Ref. 16 for more details).

At maximal quantum correlations we have $C = C_q := \sqrt{N_s(N_s + 1)}$, corresponding to the TMSV state, while the case $C = C_d := N_s$ renders the state just-separable [17]. At this border point, the state is not entangled but it still has quantum correlations [18]. In fact, its quantum discord is maximal among the states within the two-way quantum capacities of bosonic Gaussian channels [22]. In our work, we will then relax the QI model by studying the performance of the source in Eqs. (11)–(13), up to the border case of $C = C_d$.

Let us now look at the output state at the receiver. Two hypotheses exist for the experiment’s outcome:

$H_0$ :: Target is absent, so that the return signal is a noisy background modelled as a thermal state with mean number of photons per mode $N_b \gg 1$.

$H_1$ :: Target is present with reflectivity $\kappa \ll 1$, so that a proportion of signal modes is reflected back to the transmitter. In this high-loss regime, the return signal is combined with a very strong background with mean photons per mode $N_b/(1 - \kappa)$.

The joint state of our returning ($r$) mode and the retained idler is given by, under $H_0$ and $H_1$, respectively:

$$\Psi_{r_i}^{(0)} = \left( \begin{array}{cc} B & 0 \\ 0 & S \end{array} \right) \oplus \left( \begin{array}{cc} B & 0 \\ 0 & S \end{array} \right),$$

$$\Psi_{r_i}^{(1)} = \left( \begin{array}{cc} A & \sqrt{\kappa C} \\ \sqrt{\kappa C} & S \end{array} \right) \oplus \left( \begin{array}{cc} A & -\sqrt{\kappa C} \\ -\sqrt{\kappa C} & S \end{array} \right),$$

where $B := N_b + 1/2$ and $A := \kappa N_s + B$. For an arbitrary Gaussian state with leading diagonal entries $a$ and $b$, separability corresponds to the off-diagonal term $c \leq c_d := (a - 1/2)(b - 1/2)$ [22]. For each of these output quantum states, conditional on $H_0$ and $H_1$, we have that $0 \leq \sqrt{N_b N_s}$ and $\sqrt{\kappa C} \leq (\kappa N_s + N_b)N_s$, for small $\kappa$, respectively, thus the separability criterion is always satisfied and neither of these states are entangled.

In the absence of the idler, the best strategy is to use coherent states. This is a semi-classical design which is used as a classical benchmark in quantum information to evaluate the effective performance of quantum-correlated sources [3, 4]. Let us work within the formalism of creation, $\hat{a}^\dagger$, and annihilation, $\hat{a}$, operators for bosonic modes defined by

$$\hat{a}^\dagger |n\rangle = \sqrt{n + 1}|n + 1\rangle,$$

$$\hat{a}|n\rangle = \sqrt{n}|n - 1\rangle,$$

where $|n\rangle$ is a Fock state (an eigenstate of the photon-number operator $\hat{n} = \hat{a}^\dagger \hat{a}$). Letting $\hat{a}_r$ be the annihilation operator for the signal mode prepared in the coherent state $|\sqrt{N_s}\rangle$ (satisfying the eigenvalue equation $\hat{a}_r|\sqrt{N_s}\rangle = \sqrt{N_s}|\sqrt{N_s}\rangle$), we send such a mode to some target region. Under $H_0$ the return signal, with annihilation operator $\hat{a}_r$, is equal to that of the background which is in a thermal state with mean photons per mode $N_b$, i.e., $\hat{a}_r = \hat{a}_b$. The state has mean vector of zero and CM $(N_b + 1/2)1_2$, where $1_2$ is the $2 \times 2$ identity matrix. Under $H_1$ the target is present and reflects a small proportion of our signal back. This is mixed with with the background radiation such that our return takes the form $\hat{a}_r = \sqrt{\kappa} \hat{a}_b + \sqrt{1 - \kappa} \hat{a}_s$, where $\kappa \in (0, 1)$ and the background has mean photons per mode $N_b/(1 - \kappa)$. This corresponds to a displaced thermal state with mean vector $(\sqrt{2\kappa N_s}0)$ and CM $(N_b + 1/2)1_2$.

### III. Hypothesis Testing for Quantum Radar Detection

Radar detection requires successful distinguishing between the two alternatives $H_0$ and $H_1$, which happens with detection probability $P_{d1} := P(H_1|H_0)$. There are two types of error which may occur: type-I (false alarm) error $P_{a0} = P(H_1|H_0)$, where we incorrectly reject the null hypothesis, and type-II (missed detection) error $P_{md}(H_0|H_1)$, where we incorrectly reject the alternative hypothesis. The optimization of these probabilities can be carried out in a range of ways based on the potentially situation-dependent rules one wishes to follow for decision making. That is, one can associate with each error type a cost. For example, considering the result of a diagnostic test then it is clear that the risk associated with receiving a false negative (type-II) could far outweigh that associated with a false positive (type-I).

In such scenarios one may consider asymmetric testing in order to take in account these discrepancies. On the other hand, a symmetric approach may be used if one’s aim is to obtain a global minimization over all errors, irrespective of their origin. In this case, one considers the minimization of the average error probability

$$P_{err} := P(H_0)P(H_1|H_0) + P(H_1)P(H_0|H_1),$$

where $P(H_0)$ and $P(H_1)$ are the prior probabilities associated with the two hypotheses.

In the following subsections, we briefly review the main tools for symmetric and asymmetric QHT. We will use these tools for the results of the next sections.

#### A. Review of symmetric detection

In symmetric QHT, the average error probability $P_{err}$ of Eq. (3) is minimized. Consider $M$ identical copies...
\[ P_{\text{err}}^{\text{min}} \leq P_{\text{err}}^{\text{QCB}} := \frac{1}{2} \left( \inf_{0 \leq s \leq 1} C_s \right)^M, \quad C_s := \text{Tr} \left( \rho_0 \rho_1^{-1-s} \right). \] (9)

Minimization of the s-overlap \( C_s \) occurs over all \( 0 \leq s \leq 1 \). Forgoing minimization and setting \( s = 1/2 \) one defines a simpler, though weaker, upper bound, also known as the quantum Chernoff bound (QCB) \[24, 25, 26, 27\].

\[ P_{\text{err}}^{\text{QBB}} := \frac{1}{2} \text{Tr} \left( \sqrt{\rho_0 \rho_1} \right)^M. \] (10)

In the case of Gaussian states, we can compute these quantities by means of closed analytical formulas \[25\].

Consider \( N \) bosonic modes with quadratures \( \vec{x} = (q_1, \ldots, q_N, p_1, \ldots, p_N)^T \) and associated symplectic form

\[ \Omega = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \otimes 1_N, \] (11)

where \( 1_N \) is the \( N \times N \) identity matrix. Then consider two arbitrary \( N \)-mode Gaussian states, \( \hat{\rho}_0(x_0, V_0) \) and \( \hat{\rho}_1(x_1, V_1) \), with mean \( x_i \) and CM \( V_i \). We can write the following Gaussian formulas for the s-overlap of the quantum Chernoff bound \[25\].

\[ C_s = 2^N \sqrt{\det \Pi_s / \det \Sigma_s} \exp \left( -\frac{\text{d}^T \Sigma_s^{-1} \text{d}}{2} \right), \] (12)

where \( \text{d} = x_0 - x_1 \). Here \( \Pi_s \) and \( \Sigma_s \) are defined as

\[ \Pi_s := \Sigma_s \left( \text{V}^0_s \right) \Pi_1^- (\text{V}^1_s), \] (13)

\[ \Sigma_s := \Sigma_s \left[ \Lambda_s \left( \text{V}^0_s \right) \right] \Sigma_s^T + \Sigma_s \left[ \Lambda_1^- \left( \text{V}^1_s \right) \right] \Sigma_s^T, \] (14)

introducing the two real functions

\[ G_s(x) = \frac{1}{(x + 1/2)^s - (x - 1/2)^s}, \] (15)

\[ \Lambda_s(x) = \frac{(x + 1/2)^s + (x - 1/2)^s}{(x + 1/2)^s - (x - 1/2)^s}, \] (16)

calculated over the Williamson forms

\[ \text{V}_i^0 := \bigoplus_{n=1}^N \nu_{i}^{(n)} 1_2, \] where \( \text{V}_i^0 = \Sigma_s \text{V}_i^0 \Sigma_s^T \) for symplectic \( \Sigma_s \) and \( \nu_{i}^{(n)} \geq 1/2 \) are the symplectic spectra \[24, 27\].

**B. Review of asymmetric detection**

In asymmetric QHT, we wish to minimize one type of error as much as possible while allowing for some flexibility on the other. Consider again \( M \) identical copies of the state \( \hat{\rho}_i \) (\( \hat{\rho}_i^M \)), encoding the classical bit \( i \in \{0, 1\} \). As in the symmetric case, the optimal choice of measurement is a dichotomic POVM \( \{E_0, E_1\} \). From the binary outcome, we can define the two types of error, i.e., the type-I (false alarm) error

\[ P_{\text{fa}} := P(H_1|H_0) = \text{Tr} \left( E_1 \hat{\rho}_0^M \right), \] (17)

and the type-II (missed detection) error

\[ P_{\text{md}} := P(H_0|H_1) = \text{Tr} \left( E_0 \hat{\rho}_1^M \right). \] (18)

These probabilities are dependent on the number \( M \) of copies and, for \( M \gg 1 \), they both tend to zero, i.e.,

\[ P_{\text{fa}} \simeq e^{-\alpha R M}, \quad P_{\text{md}} \simeq e^{-\beta R M}, \] (19)

where we define the ‘error-exponents’ or ‘rate limits’ as

\[ \alpha_R = - \lim_{M \to +\infty} \frac{1}{M} \ln P_{\text{fa}}, \] (20)

\[ \beta_R = - \lim_{M \to +\infty} \frac{1}{M} \ln P_{\text{md}}. \] (21)

It is not possible to make both error probabilities arbitrarily small simultaneously. Instead we place a relatively loose constraint \( P_{\text{fa}} < \epsilon \) on the type-I error, allowing us more freedom to minimize \( P_{\text{md}} \). The quantum Stein’s lemma \[28, 29\] tells us that the quantum relative entropy \( D(\hat{\rho}_0||\hat{\rho}_1) = \text{Tr}[\hat{\rho}_0 (\ln \hat{\rho}_0 - \ln \hat{\rho}_1)] \) between two quantum states, \( \hat{\rho}_0 \) and \( \hat{\rho}_1 \), is the optimal decay rate for the type-II error probability, given some fixed constraint on the type-I error probability. Further, if the type-II error tends to 0 with an exponent larger than \( D(\hat{\rho}_0||\hat{\rho}_1) \), then the type-I error converges to 1 \[24\]. (Note that an alternative approach based on the quantum Hoeffding bound \[30\] is not considered here, but it could be explored using the Gaussian formulas developed in Ref. \[31\]).

Refinement of quantum Stein’s lemma has been provided by considering the second order (in \( M \)) asymptotics \[32\] to account for the discontinuity observed in the type-I error probability, jumping sharply from 0 to 1, when the type-II error probability increases past the value set by \( D(\hat{\rho}_0||\hat{\rho}_1) \). Tracking the type-II error exponent to second order depth, that is to order \( \sqrt{M} \), allows one to define the quantum relative entropy variance

\[ V(\hat{\rho}_0||\hat{\rho}_1) = \text{Tr}[\hat{\rho}_0 (\ln \hat{\rho}_0 - \ln \hat{\rho}_1)^2] - D(\hat{\rho}_0||\hat{\rho}_1)^2, \] (22)

and in turn establish that the optimal type-II (missed detection) error probability, for sample size \( M \), takes the exponential form \[32\]

\[ P_{\text{md}} = \exp \left\{ - \left[ M D(\hat{\rho}_0||\hat{\rho}_1) + \sqrt{MV(\hat{\rho}_0||\hat{\rho}_1)} \Phi^{-1}(\epsilon) \right] \right\} + O(\log M), \] (23)
where \( \epsilon \in (0, 1) \) bounds \( P_{\text{td}} \) and
\[
\Phi(y) := \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{y} dx \exp \left(-x^2/2\right)
\]  
(24)
is the cumulative of a normal distribution. More precisely, for finite third-order moment (as in the present case) and sufficiently large \( M \), we may write the upper bound \cite[Theorem 5]{32}:
\[
P_{\text{md}} \leq \hat{P}_{\text{md}} := \exp \left\{ -\left[ MD (\hat{\rho}_0||\hat{\rho}_1) + \sqrt{MV (\hat{\rho}_0||\hat{\rho}_1) \Phi^{-1}(\epsilon) + O(1)} \right] \right\}.
\]  
(25)
We can write explicit formulas for the relative entropy \( D (\hat{\rho}_0||\hat{\rho}_1) \) and the relative entropy variance \( V (\hat{\rho}_0||\hat{\rho}_1) \) of two arbitrary \( N \)-mode Gaussian states, \( \hat{\rho}_0(x_0, V_0) \) and \( \hat{\rho}_1(x_1, V_1) \). The first one is given by \cite{22}:
\[
D (\hat{\rho}_0||\hat{\rho}_1) = -\Sigma (V_0, V_0) + \Sigma (V_0, V_1),
\]  
(26)
where we have defined the function
\[
\Sigma (V_0, V_1) = \ln \det \left( V_1 + \frac{\delta}{2} \right) + \text{Tr} (V_0 G_1) + \delta^T G_1 \delta,
\]  
(27)
with \( \delta = x_0 - x_1 \) and \( G_1 = 2i \Omega \coth^{-1} (2i V_1 \Omega) \) being the Gibbs matrix \cite{33}. The second one is given by
\[
V (\hat{\rho}_0||\hat{\rho}_1) = \frac{\text{Tr} \left[ (\Gamma V_0)^2 \right]}{2} + \frac{\text{Tr} \left[ (\Gamma \Omega)^2 \right]}{8} + \delta^T G_1 V_0 G_1 \delta,
\]  
(28)
where \( \Gamma = G_0 - G_1 \) \cite{34} (see also Ref. \cite[App. A]{33}).

\section{IV. QUANTUM RADAR DETECTION WITH GENERAL SOURCE}

Using the generic quantum-correlated Gaussian source of Sec. \cite{11} and the tools for symmetric and asymmetric QHT of Sec. \cite{11} we study the performance of a relaxed QI protocol, clarifying how much entanglement is needed to beat the semi-classical benchmark of the coherent-state transmitter under symmetric testing. Then, in the setting of asymmetric testing, we repeat the study in terms of the receiver operating characteristic (ROC), where the mis-detection probability is plotted versus the false alarm probability.

\subsection{A. Symmetric detection with general source}

Let us assume the typical conditions of QI, which are low-reflectivity \( \kappa \ll 1 \), high thermal-noise \( N_b \gg 1 \), low photon number per mode \( N_s \ll 1 \). It is then known that, using a TMSV state, the minimum error probability satisfies \cite{11}:
\[
P_{\text{err}}^{\text{TMSV}} \leq e^{-M \kappa N_s / N_b} / 2.
\]  
(29)
This is computed using the quantum Bhattacharyya bound, it is exponentially tight in the limit of large \( M \), and it is also known to be achieved by the sum-frequency-generation receiver of Ref. \cite{10}. Its error-rate exponent has a factor of 4 advantage over the same bound computed over a coherent-state transmitter in the same conditions, for which we have \cite{11}:
\[
P_{\text{err}}^{\text{CS}} \leq e^{-M \kappa N_s / 4N_b} / 2.
\]  
(30)
In order to extend Eq. (29) to the error probability for a generic Gaussian source, let us start with single probing \( M = 1 \), assuming the usual limits \( \kappa \ll 1 \), \( N_b \gg 1 \) and \( N_s \ll 1 \). The quantum Bhattacharyya bound takes the form
\[
P_{\text{err}}^{\text{gen}} \leq e^{-\kappa N_s g_C(N_s) / N_s} / 2,
\]  
(31)
where the function \( g_C(N_s) \) is proportional to \( C^2 \) (see Appendix \cite{A} for details), i.e., the amount of correlations existing between the signal and idler modes. Demanding the equivalence of exponents in the TMSV limit \( C \rightarrow C_q \), we find that the quantum Bhattacharyya bound for \( M \) probings becomes
\[
P_{\text{err}}^{\text{gen}} \leq e^{-M \kappa N_s C^2 / N_s C_q^2} / 2.
\]  
(32)
By comparing Eqs. (32) and (30), we see that a quantum-correlated transmitter beats the coherent state transmitter if \( P_{\text{err}}^{\text{gen}} \leq P_{\text{err}}^{\text{CS}} \) which means
\[
\frac{C^2}{C_q^2} \geq \frac{1}{4} \Rightarrow C \geq \frac{1}{2} \sqrt{N_s (N_s + 1)}.
\]  
(33)
Thus, according to the quantum Bhattacharyya bound, the quadrature correlations required to outperform the semi-classical benchmark is half the value of those of a TMSV state. At the separable limit \( C = N_s \) the relation is only satisfied for \( N_s \geq 1/3 \) which contradicts the assumption \( N_s \ll 1 \) (a similar analysis holds if we relax the assumption of \( N_s \ll 1 \)). Therefore, according to the quantum Bhattacharyya bound, the employment of a source at the separable limit is not capable of beating coherent states under symmetric testing.

\subsection{B. Asymmetric detection with general source}

Let us compute the quantum relative entropy and the quantum relative entropy variance for the quantum-correlated transmitter of Eqs. (11)–(13). Though the full expressions for these quantities are far too long to display here, we evaluate them to first order in \( N_b \) by taking an asymptotic expansion for large \( N_b \) while keeping \( N_s \) fixed. We obtain
\[
D_{\text{gen}} := D \left( \rho_{RI}^{(0)} \| \rho_{RI}^{(1)} \right) = \kappa C^2 / N_b \ln \left( 1 + \frac{1}{N_s} \right) + O \left( N_b^{-2} \right),
\]  
(34)
\[ V_{\text{gen}} := V(\hat{\rho}_{\text{HI}} |\hat{\rho}_{\text{HI}}^{(1)}) = \frac{N_s}{N_b} \ln^2 \left( 1 + \frac{1}{N_b} \right) + O(N_b^{-2}). \]

For coherent states these quantities take the form

\[ D_{\text{CS}} := D(\hat{\rho}_{\text{CS}} |\hat{\rho}_{\text{CS}}^{(1)}) = \kappa N_s \ln \left( 1 + \frac{1}{N_b} \right), \]

\[ V_{\text{CS}} := V(\hat{\rho}_{\text{CS}} |\hat{\rho}_{\text{CS}}^{(1)}) = \kappa N_s (2N_b + 1) \ln^2 \left( 1 + \frac{1}{N_b} \right), \]

which hold for all values of \( N_s, N_b \) and \( \kappa \). For comparative purposes we evaluate again to first order in \( N \) which hold for all values of \( N, N_b \) and \( \kappa \). For comparative purposes we evaluate again to first order in \( N_b \) while keeping \( N_s \) fixed to obtain the simple expressions

\[ D_{\text{CS}} \simeq \gamma + O(N_b^{-2}), \quad V_{\text{CS}} \simeq 2\gamma + O(N_b^{-2}), \]

where

\[ \gamma := \frac{\kappa N_s}{N_b} \]

is the signal-to-noise ratio (SNR), usually expressed in decibels (dB) via \( \gamma_{\text{dB}} = 10 \log_{10} \gamma \).

In the limit of very large \( M \), we can approximately neglect the variance contribution and just consider the relative entropy in the type-II (missed detection) error probability of Eq. (23) which simply becomes \( P_{\text{md}} \simeq \exp \left[ -M D(\hat{\rho}_0, \hat{\rho}_1) \right] \). Then, we can deduce that, for large \( M \) and a very high background \( N_b \gg 1 \), the error exponent of a quantum-correlated source [Eq. (34)] has the following ratio with respect to a coherent state source [Eq. (35)]

\[ A(C, N_s) := \frac{D_{\text{gen}}}{D_{\text{CS}}} = \frac{C^2}{N_s} \ln \left( 1 + \frac{1}{N_s} \right). \]

In Fig. 1 we plot the ratio \( A \) for a just-separable discordant source \((C = N_s)\) and that for a TMSV state, for varying \( N_s \). We can see how the ultimate benefits of employing maximal entanglement for QI are exhibited only for very small energies, i.e., when \( N_s \) is of the order of units or less. For increasing \( N_s \), the ratio \( A \) tends to the same asymptotic value, irrespective of source specification. This also means that the just-separable source quickly approaches the performance of QI at as little as about 20 photons per mode. As we will see in Sec. IV C for a given range \( R \) the radar equation imposes a \( 1/R^4 \) loss factor in received signal power and necessitates high overall photon numbers, particularly at long range, regardless of the underlying detection protocol. Our results show that at long range there is little-to-no advantage in using a QI-based radar over a coherent state protocol due to the need of large signal power \((N_s)\). QI is thus limited to applications where losses are relatively small so \( N_s \) may in turn take small values, for example, at short ranges.

### Receivers operating characteristic

In the asymmetric setting, we now study the mis-detection probability versus the false alarm probability of the generic Gaussian source with respect to the classical benchmark of coherent states. For the latter, we consider the performance achievable by coherent states and homodyne detection at the output. This is the best-known measurement design which can be used when the phase of the optical field is perfectly maintained in the interaction with the target, so that one can adopt a coherent integration of the pulses (i.e., the quadrature outcomes can be added before making a classical binary test on the total value). If the phase of the field is deterministically changed to some unknown value but it is still coherently maintained among the pulses, then the typical choice is the heterodyne detection, followed by coherent integration of the outcomes from both the quadratures. If the coherence is lost among the pulses, then the classical strategy is to use heterodyne and perform a non-coherent integration of the pulses, which means to sum the recorded intensities (squared values of the quadratures). In this case, the performance (for non-fluctuating targets) is given by the Marcum’s Q-function, an approximation of which is known as Albersheim’s equation. An overestimation of the Marcum benchmark can be simply achieved by assuming a single coherent pulse with mean number of photons equal to \( MN_s \).

In mathematical terms, the ROC \( P_{\text{md}} = P_{\text{md}}(P_{\text{fa}}) \) of the generic Gaussian source can be upper bounded \( P_{\text{md}} \leq P_{\text{md}} \) by combining Eqs. (23), (34), and (55). For sufficiently large \( M \) (e.g., \( \gtrsim 10^5 \)), the second-order asymptotics is a good approximation, and for large \( N_b \) (e.g., \( \gtrsim 10^2 \)) the expansions in Eqs. (34) and (55) are
valid. Therefore, under these assumptions, we may write
\[ \bar{P}_{\text{md}}^{\text{gen}} = \exp \left\{ - \left[ \frac{M\gamma}{N_s} \Delta C \ln \left( 1 + \frac{1}{N_s} \right) + \mathcal{O}(N_s^{-1}, 1) \right] \right\}, \]
(41)
\[ \Lambda := \left( \frac{M\gamma}{N_s} C + \sqrt{2N_s + 1} \Phi^{-1} (P_{fa}) \right). \]
(42)

In the case of coherent states and homodyne detection (followed by coherent integration and binary testing), the ROC is given by combining the following expressions
\[ P_{fa}^{\text{hom}} (x) = \frac{1}{2} \text{erfc} \left[ \frac{x}{\sqrt{M(2N_s + 1)}} \right], \]
(43)
\[ P_{\text{md}}^{\text{hom}} (x) = \frac{1}{2} \text{erfc} \left[ \frac{M\sqrt{2N_s} - x}{\sqrt{M(2N_s + 1)}} \right], \]
(44)
where \( \text{erfc}(z) := 1 - 2\pi^{-1/2} \int_0^z \exp(-t^2) dt \) is the complementary error function. Therefore we can invert Eq. (43) and replace in Eq. (44) to derive the corresponding ROC.

Finally, as already mentioned, we can also write a lower bound to Marcum’s classical radar performance by assuming a single coherent state with mean number of photons \( M N_s \) so that the total SNR is given by \( M\gamma \). This can be expressed as follows
\[ P_{\text{md}}^{\text{Marcum}} = 1 - Q \left( \sqrt{2M\gamma}, \sqrt{2\ln P_{fa}} \right), \]
(45)
where the Marcum Q-function is defined as
\[ Q(x, y) := \int_y^\infty dt \, e^{-t^2 + x^2} I_0(t), \]
(46)
with \( I_0(.) \) being the modified Bessel function of the first kind of zero order [37].

Before comparing the ROCs of the various transmitters, let us choose a suitable regime of parameters for potential short-range applications (of the order of 1m, e.g., for security or biomedical applications), where \( N_s \) need not be too large and a quantum advantage may be observed. By fixing some specific radar frequency \( \nu \) and the temperature \( T \) of the environment, we automatically fix the mean number of photons \( N_b \) of the thermal background. Thus, for \( \nu = 1 \text{GHz} \) (L band) and \( T = 290 \text{K} \) (room temperature), we get \( N_b \approx 6 \times 10^3 \text{ photons} \) (bright noise). Assume broadband pulses, with 10% bandwidth (100MHz), so that their individual duration is about 10ns. If we use \( M = 10^8 \) pulses then we have an integration time of the order of 1s, which is acceptable for slowly-moving or still objects. Since we are interested in low-energy applications, assume \( N_s = 1 \) mean photon per pulse. What is left is an estimation of the SNR \( \gamma \) which comes from the overall transmissivity/reflectivity \( \kappa \).

This remaining quantity can be estimated using the radar equation. This equation expresses the power \( P_R \) of the return signal in terms of the signal power \( P_T \) at the transmitter, the cross section \( \sigma \) of the target, the range \( R \) of the target, and other parameters, such as the transmit antenna gain \( G \), the receive antenna collecting area \( A_R \) and the form factor \( F \) which describes the transmissivity of the space between the radar and the target. It takes the form

\[ P_R = \frac{GF^4 A_R \sigma}{(4\pi)^2 R^4} P_T. \]
(47)
Here the factor \( (4\pi)^{-2} R^{-4} \) accounts for the loss due to the pulse propagating as a spherical wave (back and forth). This is partly mitigated by the gain \( G \) which introduces anisotropies from the spherical wave description, accounting for the directivity of the actual outgoing beam. In fact \( G \) describes the ratio between the power irradiated in the direction of the target over the power that would have been irradiated by an isotropic antenna [36]. For a pencil beam, \( G \) can be much higher than 1 (which is the value of an isotropic antenna).

It is clear that \( \kappa \) also provides the ratio between received and transmitted power, so that Eq. (47) leads to
\[ \kappa = \frac{P_R}{P_T} = \frac{GF^4 A_R \sigma}{(4\pi)^2 R^4}, \]
(48)
which is also easy to invert, so as to express the range \( R \) in terms of \( \kappa \) and the other parameters. Assume \( F = 1 \) (no free-space loss) and an ideal pencil beam, such that its solid angle \( \delta \) is exactly subtended by the target’s cross section \( \sigma \) (valid assumption at short ranges). This means that gain is ideally given by
\[ G = \frac{4\pi}{\delta} = \frac{4\pi R^2}{\sigma}, \]
(49)
which fully compensates the loss in the forward propagation. Therefore, we find
\[ \kappa = \frac{A_R}{(4\pi R)^2}, \quad R = \frac{1}{4\pi} \sqrt{\frac{A_R}{\kappa}}. \]
(50)
By fixing the receive antenna collecting area \( A_R \), we have a one-to-one correspondence between range \( R \) and transmissivity \( \kappa \). Assuming \( A_R = 0.1 m^2 \) and short-range \( R \approx 1 m \), we get \( \kappa \approx 6 \times 10^{-4} \) which leads to \( \gamma_{dB} = -70 \text{dB} \) when we account for the values of \( N_b \) and \( N_s \).

Considering this regime of parameters, we find the ROCs plotted in Fig. 2. In particular, we show the performance of a generic Gaussian source with correlation parameter \( C(p) = p C_d + (1 - p) C_q \) between the extremal points given by the just-separable source \( C_d = N_s \) and the maximally-entangled source (at that energy) \( C_q = \sqrt{N_b(N_b + 1)} \) (another study of the ROC of the maximally-entangled case can be found in Ref. [32] but for the regime \( N_s \ll 1 \)). We perform the comparison for two scenarios while maintaining the same SNR, background characteristics and total number of uses: the first
with off-diagonal correlation parameter for quantum illumination based on a generic Gaussian state. In particular, we show the performance for an intermediate state (red dotted). Between these two extremal curves, there are all the Gaussian states with intermediate correlations. In this work, we have investigated how to loosen the transmitter requirements of QI, from the usual maximally-entangled TMSV source to a more general quantum-correlated Gaussian source, which may become just-separable. At the same time, we maintain the optimal quantum joint-measurement procedure at the receiver side. We perform this investigation in both scenarios of symmetric and asymmetric testing where we test the quantum performance with respect to suitable classical benchmarks. Our results show that we can still find quantum advantage by using Gaussian sources which are not necessarily maximally entangled. In particular, this is an advantage which appears at short ranges, so that the spherical beam spreading does not involve too many dBs of loss, a major killing factor for any quantum radar design based on the exploitation of quantum correlations.

A short-range low-power radar is potentially interesting not only as a non-invasive scanning tool for biomedical applications but also for security and safety purposes, e.g., as a scanner for metallic objects or as proximity sensor for obstacle detection. Once quantum advantage in detection is achieved at fixed target distance, it can be extended to variable distances to enable a measurement of the range. For instance, this could be done by sending signal-idler pulses at different carrier frequencies and interrogating their reflection at different round-trip times. For slowly moving objects at short ranges, the total interrogation time would be small and the effective distance of the object could be well-resolved by sweeping a reasonable number of frequencies. In a static setting, e.g., biomedical, detection is naturally associated with a fixed depth, which is then gradually increased so as to provide a progressive scan of the target region. This quantum scanner would investigate the presence of the target at different layers, e.g., of a tissue, while irradiating it with off-diagonal correlation parameter for quantum illumination based on a generic Gaussian state.

V. CONCLUSION

In this work, we have investigated how to loosen the transmitter requirements of QI, from the usual maximally-entangled TMSV source to a more general quantum-correlated Gaussian source, which may become just-separable. At the same time, we maintain the optimal quantum joint-measurement procedure at the receiver side. We perform this investigation in both scenarios of symmetric and asymmetric testing where we test the quantum performance with respect to suitable classical benchmarks. Our results show that we can still find quantum advantage by using Gaussian sources which are not necessarily maximally entangled. In particular, this is an advantage which appears at short ranges, so that the spherical beam spreading does not involve too many dBs of loss, a major killing factor for any quantum radar design based on the exploitation of quantum correlations.

A short-range low-power radar is potentially interesting not only as a non-invasive scanning tool for biomedical applications but also for security and safety purposes, e.g., as a scanner for metallic objects or as proximity sensor for obstacle detection. Once quantum advantage in detection is achieved at fixed target distance, it can be extended to variable distances to enable a measurement of the range. For instance, this could be done by sending signal-idler pulses at different carrier frequencies and interrogating their reflection at different round-trip times. For slowly moving objects at short ranges, the total interrogation time would be small and the effective distance of the object could be well-resolved by sweeping a reasonable number of frequencies. In a static setting, e.g., biomedical, detection is naturally associated with a fixed depth, which is then gradually increased so as to provide a progressive scan of the target region. This quantum scanner would investigate the presence of the target at different layers, e.g., of a tissue, while irradiating it with off-diagonal correlation parameter for quantum illumination based on a generic Gaussian state.
Such a quantum scanner would then realize an ideal non-local velocity of the target within a layer of the tissue. In conjunction with standard Doppler techniques it could also extract information about the local velocity of the target within a layer of the tissue. Such a quantum scanner would then realize an ideal non-invasive diagnostic tool.

 Appendix A: Quantum Bhattacharyya bound for generic Gaussian source

Using the generic quantum-correlated Gaussian source defined in Sec. III A along with formulae and tools for symmetric QHT described in Sec. III A of the main text, one can compute the exact form of the quantum Bhattacharyya bound (QBB) for QI. The complete formula is too long to be displayed however, imposing parameter constraints, one can achieve a closed-form for the asymptotic performance in specified limits.

We begin by assuming the typical conditions of QI, which are low-reflectivity $\kappa \ll 1$, high thermal-noise $N_b \gg 1$, low photon number per mode $N_s \ll 1$. Then, using numerical techniques, one can confirm that the a TMSV state, the minimum error probability satisfies

$$P_{\text{err}}^{\text{TMSV}} \leq e^{-MN_s/N_b}/2,$$  \hspace{1cm} (A1)

which is exponentially tight in the limit of large $M$ and is valid under the parameter constraints previously defined.

In order to extend Eq. (A1) to the error probability for a generic Gaussian source, we first note that as we only vary the value of cross-correlation parameter $C$ the variation in the bound will be entirely dependent on this parameter. We also note that the parameter $C$ is constrained by the terms on the leading diagonal such that

$$0 \leq C \leq \sqrt{N_s(N_s+1)} := C_q,$$  \hspace{1cm} (A2)

where the upper bound corresponds to the maximally-entangled TMSV state yielding Eq. (A1). Since the just-separable state corresponds to $C = C_d := N_s$, it is clear that $C = C(N_s)$.

The form of Eq. (A1) is not surprising; the error exponent is directly proportional to the SNR, $\gamma = \kappa N_s/N_b$, and one would expect the same for our generic source. Starting with single probing, $M = 1$, and subject to the limits $\kappa \ll 1$, $N_b \gg 1$ and $N_s \ll 1$, we can write the QBB for our generic source as

$$P_{\text{err}}^{\text{gen}} \leq e^{-\kappa N_b g_c(N_s)/N_b}/2,$$  \hspace{1cm} (A3)

where we define the function $g_c(N_s)$ as a constant of proportionality, entirely dependent on the parameter $C$ and thus $N_s$. In particular, we demand the equivalence of exponents in the TMSV limit $C \rightarrow C_0$ such that $g_c(N_s) = 1$, recovering the bound given by Eq. (A1).

To determine the form of $g_c(N_s)$ we use a numerical program to perform an asymptotic expansion of our generic source’s exact QBB for small $\kappa \ll 1$. Keeping terms to first order, we obtain an equation of the form

$$2P_{\text{err}}^{\text{gen}} \leq 1 - x\kappa + O(\kappa^2) \simeq e^{-x\kappa},$$  \hspace{1cm} (A4)

where the last equality holds when $x = \frac{N_b}{N_s} g_c(N_s)$, from Eq. (A3), is small, i.e., $N_s \ll 1$ and $N_b \gg 1$.

Numerical analysis shows that the coefficient $x$ is exactly proportional to $C^2$, independent of $N_s$ and $N_b$, thus...
we can write \( g_C(N_s) \propto C^2 \) and, imposing the condition that \( g_{C,q}(N_s) = 1 \) determine that

\[
g_C(N_s) = C^2/C_q^2. \tag{A5}
\]

Fig. 3 plots the function \( g_C(N_s) \) as a function of cross-correlation parameter \( C \) for two sets of parameter values: (a) \( N_s = 10^{-2}, N_b = 20 \) and (b) \( N_s = 10^{-4}, N_b = 200 \). It shows that in the regime of low brightness and high background the function \( \tilde{g}_C(N_s) \to g_C(N_s) \), given by Eq. (A5), and we can write that the QBB for a generic Gaussian source is given by

\[
P_{\text{err}}^{\text{gen}} \leq e^{-M\kappa N_s C^2/N_b C_q^2/2}, \tag{A6}
\]

as given in the main text. Note that the extension from \( M = 1 \) to generic \( M \) just follows from the structure of the QCB and QBB in Eqs. (9) and (10).
