Predicting Imperfect Echo Dynamics in Many-Body Quantum Systems

https://doi.org/10.1515/zna-2019-0383
Received December 31, 2019; accepted February 27, 2020

Abstract: Echo protocols provide a means to investigate the arrow of time in macroscopic processes. Starting from a nonequilibrium state, the many-body quantum system under study is evolved for a certain period of time \( t \). Thereafter, an (effective) time reversal is performed that would – if implemented perfectly – take the system back to the initial state after another time period \( t \). Typical examples are nuclear magnetic resonance imaging and polarisation echo experiments. The presence of small, uncontrolled inaccuracies during the backward propagation results in deviations of the “echo signal” from the original evolution and can be exploited to quantify the instability of nonequilibrium states and the irreversibility of the dynamics. We derive an analytic prediction for the typical dependence of this echo signal for macroscopic observables on the magnitude of the inaccuracies and on the duration \( t \) of the process, and verify it in numerical examples.

Keywords: Echo Dynamics; Many-Body Systems; Time Inversion.

1 Introduction

Explaining the irreversibility of processes in macroscopic systems based on the time-reversible laws governing their microscopic constituents is a major task of statistical mechanics, dating all the way back to Boltzmann’s \( H \)-theorem [1] and Loschmidt’s paradox [2]. Besides its ontological dimension, this question is also intimately related to the special role of nonequilibrium states and their apparent instability in many-body systems, which generically tend toward equilibrium as time progresses. Characterising this instability within the realm of quantum mechanics is one goal of the present work. Whereas a direct investigation of the pertinent states (i.e. Hilbert space vectors or density operators) can, in principle, have academic value, similarly to an analysis of phase-space points in classical systems, we focus here on observable quantities that can be extracted from macroscopic measurements.

Recently, so-called out-of-time-order correlators have gained considerable attention as a suggestion to generalise concepts from classical chaos theory, notably Lyapunov exponents, to quantum systems [3, 4], but the analogy is far from complete [5, 6]. With this in mind, we follow an even simpler route here and consider so-called echo dynamics [7], where a quantum many-body system with Hamiltonian \( H \) starts from a (pure or mixed) “target state” \( \rho_T \) and is evolved forward in time for a certain period \( t \) to reach the “return state” \( \rho_R \). At this point, one switches to the inverted Hamiltonian \( -H \), so that the direction of time is effectively reversed, and the system evolves back toward the target state after another time period \( t \). By introducing inaccuracies (experimentally unavoidable imprecisions) during this backward evolution via a Hamiltonian of the form \( H' := -H + \epsilon V \), the system will not reach the original initial state \( \rho_T \) again, but instead approach a perturbed state \( \rho_T' \) that deviates from it to some extent. In summary,

\[
\rho_T \xrightarrow{\frac{r}{-H}} \rho_R \xrightarrow{\frac{r}{-H+\epsilon V}} \rho_T'.
\]

The deviations between the initial and final states and their dependence on the time span \( r \) and on the amplitude \( \epsilon \) of the considered imperfections then quantify the instability of the nonequilibrium state and the irreversibility of the dynamics.

In case of a pure state, a seemingly direct probe is the Loschmidt echo, that is, the overlap between the original state \( \rho_T \) and the distorted echo state \( \rho_T' \) [8, 9]. (In case of a mixed state, the corresponding probe is the quantum fidelity.) However, this quantity is practically inaccessible in a many-body system, and as emphasized above, we will instead concentrate on echoes of macroscopic observables in the following and compare their expectation values at the beginning and at the end of the proposed protocol [9–12]. As macroscopic observables cannot distinguish between equivalent microstates, one inevitably
has to operate in the nonequilibrium regime to be able to characterise the sensitivity of a many-body system toward imperfections.

Taken literally, the suggested protocol (1) can only have the status of a gedankenexperiment as we cannot practically revert the direction of time in a concrete dynamical setup, and also an exchange of the Hamiltonian \( H \) for \(-H\) is still unphysical in many situations. For example, for a gas of particles in a box, it would require negative particle masses. Nevertheless, it is well known that an effective sign change of the Hamiltonian can be achieved in spin systems, which provides the mechanism underlying spin echo and nuclear magnetic resonance (NMR) experiments [7]. In fact, the presence of imperfections, i.e. “nonreversed components” of the Hamiltonian, forms the basis of magnetic resonance imaging (MRI) by exploiting that different imperfections in different tissues lead to distinct imperfect echo signals [13]. By means of so-called magic- or polarisation-echo techniques, these ideas have also been extended to interacting spin systems [14–21], employing suitably adapted radiofrequency external fields during the “backward” phase of the evolution. More generally, pulse sequences and time-dependent forces have been used to scan quite notable parameter ranges of (effective) spin Hamiltonians in a variety of experimental setups [22–25]. Yet another experimental approach toward an effective time reversal consists in tuning a cold atomic gas across a Feshbach resonance [26–28].

Given the neglected unreversed corrections as well as the sophisticated experimental setups necessary, some sort of imperfections of the form considered here are clearly unavoidable and sometimes, like in MRI, even desired.

Furthermore, an alternative view on the suggested protocol may be as follows: For a many-body system with Hamiltonian \( \tilde{H} (= -H \) in the language from above), suppose that we are given an initial state \( \rho_0 \) (previously the return state), for which it is known that the state obtained after time \( \tau \), \( \rho_\tau = e^{-i\tilde{H}\tau} \rho_0 e^{i\tilde{H}\tau} \) \( (h = 1) \), is out of equilibrium. Comparing the time evolution from \( \rho_0 \) under the Hamiltonian \( \tilde{H} \) with the dynamics obtained from a perturbed Hamiltonian \( \tilde{H}' = \tilde{H} + \epsilon V \), we achieve the same effect as in the above echo gedankenexperiment (1). However, there is no need for a “backward Hamiltonian” or some other sort of (experimentally difficult) reversal procedure. From a physical point of view, it is thus irrelevant whether the return state \( \rho_\tau \) was obtained by an explicit unitary time evolution or some other preparation method. Its only relevant property is that it reaches a manifestly out-of-equilibrium state within an accessible time scale \( \tau \) in order for the effects of imperfections to become macroscopically visible. This setting is silently included in the following, even though we will employ the language of the echo protocol (1) in the remainder of this work.

In Section 2, we set the stage and introduce the suggested echo protocol (1) and the considered imperfections \( V \) in detail. Our main result, an analytical prediction characterising the decay of echo signals under generic time-reversal inaccuracies, is derived in Section 3. Thereafter, we verify this result numerically in an explicit spin chain model in Section 4. In Section 5, we conclude by summarising the ideas and relating them to numerical and experimental results from the literature.

2 Setup

To begin with, we represent the Hamiltonian \( H \) appearing in (1) in terms of its eigenvalues and eigenvectors as

\[
H = \sum_n E_n |n\rangle \langle n|.
\]

Given some initial state \( \rho(0) \) at time \( t = 0 \), the state at any later time \( t > 0 \) follows as \( \rho(t) := e^{-iHt} \rho(0) e^{iHt} \). Being interested in some macroscopic observable (see Section 1) in the form of a self-adjointed operator \( A \), and denoting its expectation value in an arbitrary state \( \rho \) by \( \langle A \rangle_\rho := \text{Tr}[\rho A] \), the actual time evolution can thus be written as

\[
\langle A \rangle_{\rho(t)} = \sum_{m,n} e^{i(E_m - E_n)t} \langle m|\rho(0)|n\rangle \langle n|A|m\rangle.
\]

Despite the quasiperiodic nature of the right-hand side, a many-body system will usually equilibrate [29–31] and spend most of the time close to the time-averaged state \( \rho_{eq} \) with

\[
\langle m|\rho_{eq}|n\rangle := \delta_{mn} \langle n|\rho(0)|n\rangle,
\]

which we refer to as the equilibrium state in the following. In order to study the effect of imperfections in terms of expectation values of the observable \( A \), the considerations from Section 1 imply that the system must spend some time away from equilibrium; i.e. there must be a reasonable time interval during which \( \langle A \rangle_{\rho(t)} \) differs distinctly from \( \langle A \rangle_{\rho_{eq}} \). Therefore, we focus on these deviations from equilibrium, denoted by the symbol

\[
\Delta(t) := \langle A \rangle_{\rho(t)} - \langle A \rangle_{\rho_{eq}}.
\]

Provided that the system is out of equilibrium at time \( t = 0 \), we then ask how special this situation is by investigating how hard it is to return to this state by an effective, but possibly imperfect reversal of time after the
system has relaxed for a certain period $\tau$ as detailed in the protocol (1).

In the absence of any imperfections ($\epsilon = 0$), the system traces out the same trajectory in the forward and backward stages, such that

$$A(\tau + t) = A(\tau - t) \quad (0 \leq t \leq \tau). \quad (7)$$

for $t \in [0, \tau]$, which constitutes our reference dynamics. It is reasonable to expect that uncontrolled inaccuracies in the time-reversed dynamics will generically push the system closer to equilibrium because they spoil the fine-tuned correlations between state and observable needed for nonequilibrium conditions. Hence, the backward dynamics will usually lie closer to the equilibrium state than the forward one,

$$|A(\tau + t)| \lesssim |A(\tau - t)| \quad (0 \leq t \leq \tau). \quad (7)$$

The sensitivity of the deviations between the perfect and perturbed dynamics with respect to the magnitude $\epsilon$ of the inaccuracies is thus an indicator for the chaoticity and irreversibility of the many-body dynamics. The faster $A(\tau + t)$ decays with $\epsilon$ compared to $A(\tau - t)$, the harder it is to design a reversible process and the more extraordinary or special are the nonequilibrium states. Consequently, the relative echo signal $A(\tau + t)/A(\tau - t)$ for times $t \in [0, \tau]$ will be our principal object of study in this work, most importantly in the region around the revival or echo peak at $t = \tau$, where deviations from equilibrium will be most pronounced.

We denote the time-dependent state of the system in the forward and backward phases by

$$\rho(t) := e^{-iHt} \rho_0 e^{iHt}, \quad (8a)$$

$$\rho_0(t) := e^{i(H - \epsilon V)t} \rho_0 e^{-i(H - \epsilon V)t}, \quad (8b)$$

respectively. We also write $\rho(t)$ to refer to the state during the entire process, that is, $\rho(t) := \rho_0(t)$ for $t \in [0, \tau]$ and $\rho(t) := \rho_0(t - \tau)$ for $t \in [\tau, 2\tau]$.

An implicit assumption in all that follows is that the considered many-body system is finite and exhibits a well-defined macroscopic energy $E$. Consequently, the state $\rho(t)$ at any time can only significantly populate energy levels within a macroscopically small energy window

$$I_E := [E - \Delta E, E] \quad (9)$$

and the imperfections are assumed to be sufficiently small so that they do not modify this window. In addition, it is taken for granted that the density of states (DOS) of $H$ is approximately constant throughout this energy window, $D_0 = \text{const}$ and that the same holds for the (negative) imperfect backward Hamiltonian $H - \epsilon V$ with eigenvalues $E^\epsilon_l$ and eigenstates $|\psi^\epsilon_l\rangle$.

Focusing on the dynamics during the backward phase from (8b), we can use the transformation matrix $U_{kl} := \langle \mu|k \rangle$ between the eigenbases of the forward and backward Hamiltonians to write the time-dependent expectation values of the observable $A$ — similarly as in (3) — as

$$\langle A \rangle_{\rho_0(t)} = \sum_{\mu, \nu} \langle \mu|\rho_0(t)|\nu \rangle^* \langle \nu|A|\mu \rangle^*$$

$$= \sum_{\mu, \nu, \kappa, \lambda, m, n} e^{-i(E_\kappa - E_\lambda)t} e^{i(E_\kappa - E_\lambda)t} \times \langle k|\rho_0(t)|l \rangle \langle m|A|n \rangle U_{\mu k} U_{\nu l}^\dagger U_{\mu m} U_{\nu n}^\dagger. \quad (11)$$

Employing the assumed constant DOS for $H$ and $H - \epsilon V$, we can approximately identify energy differences $E_\kappa - E_\lambda \approx E_\nu - E_\mu$ of the two Hamiltonians within in the relevant time scales [32, 33], so that

$$\langle A \rangle_{\rho_0(t)} = \sum_{\mu, \nu} \sum_{\kappa, \lambda, m, n} e^{-i(E_\kappa - E_\lambda)t} e^{i(E_\kappa - E_\lambda)t} \times \langle k|\rho_0(t)|l \rangle \langle m|A|n \rangle U_{\mu k} U_{\nu l}^\dagger U_{\mu m} U_{\nu n}^\dagger. \quad (12)$$

We recall that the Hamiltonian $H$ corresponds to a given many-body quantum system, whereas the perturbation $V$ describes uncontrolled and/or unknown inaccuracies in the time-reversal procedure. In this spirit, we thus model our ignorance about these imperfections by an ensemble of random operators $V$, such that the matrix elements $\langle m|V|n \rangle$ of $V$ in the eigenbasis of $H$ become random variables. The actually considered $V$ ensembles are inspired by the structure of typical perturbations, featuring possible sparsity as well as an interaction strength depending on the energy difference between the coupled states (“bandedness”) [34–38]. Requiring hermiticity, $\langle m|V|n \rangle = \langle n|V|m \rangle^*$, and assuming independence of the $\langle m|V|n \rangle$ for $m \leq n$, this suggests the general form

$$dP_{mn}(v) := d\mu_{E_m - E_n}(v) \quad (13)$$

for the probability measures of the $\langle m|V|n \rangle$’s with $m < n$. Here, $\{d\mu_{E}\}_{E > 0}$ denotes a family of probability measures on $\mathbb{R}$ or $\mathbb{C}$ with mean zero and variance $\sigma^2(M)$, so that the smooth function $\sigma^2(M)$ captures the announced bandedness of the interaction matrix. Likewise, for $m = n$, the probability measure $dP_{nn}(v) := d\mu_{E}(v)$ of the (real-valued) diagonal elements $\langle n|V|n \rangle$ is assumed to have vanishing mean (otherwise, the perturbation would induce an energy shift) and finite variance.
To obtain a useful prediction regarding the behaviour of an actual system, we first compute the average effect of such a perturbation. In a second step, we establish that the resulting prediction satisfies a concentration of measure property, meaning that in a sufficiently high-dimensional Hilbert space a particular realisation of the ensemble becomes practically indistinguishable from the average behaviour. More precisely, deviations from the average will turn out to be suppressed in the number \( N_v \) of eigenstates of \( H \) that get mixed up by the perturbation \( eV \), to be defined explicitly in (19) below. Because of the extremely high-level density in generic many-body systems, this number \( N_v \) is typically exponentially large in the system’s degrees of freedom \( f \) if the perturbation has any appreciable effect at all \([39]\).

\[
N_v = 10^{\Omega(f)} \gg 1. \tag{14}
\]

### 3 Results

According to (12), averaging the echo signal over all possible realisations of the V ensemble requires an average over four transformation matrices \( U_{pk} \), the overlap of the eigenvectors \( |k\rangle \) of \( H \) and \(|\mu\rangle' \) of \( H - eV \). These overlaps inherit their distribution from the distribution of the \( V \) matrix elements. Writing \( \mathbb{E}[\cdots] \) for the average over all \( V \)’s, one finds

\[
\mathbb{E}[U_{\mu,k} U_{\mu,k}^* U_{\mu,k}^* U_{\mu,k}^*] = \delta_{k,l} \delta_{k,l} d_{k,k}^{\mu,\mu} + \delta_{k,l} \delta_{k,l} \left( d_{k,k}^{\mu,\mu} + d_{k,k}^{\mu,\mu} \right) \tag{15}
\]

in the limit of sufficiently weak \( e \) \([39]\). Here

\[
d_{k,k}^{\mu,\mu} := u(\alpha e^2, E_{\mu} - E_k) u(\alpha e^2, E_v - E_l), \tag{16}
\]

\[
f_{k,l}^{\mu,\mu} := -\left( \alpha e^2 / 2\pi D_0 \right) u(\alpha e^2, E_{\mu} - E_k) u(\alpha e^2, E_v - E_l) \times \frac{4\alpha^2 e^4 + (E_{\mu} - E_k)^2 + (E_{\mu} - E_v)^2 - (E_k + E_l - E_{\mu} - E_v)^2 + \alpha^2 e^4}{(E_{\mu} - E_k)^2 + \alpha^2 e^4} \tag{17}
\]

and \( \alpha := \pi \tilde{\sigma}_t^2 D_0 \), where \( \tilde{\sigma}_t^2 \) denotes the mean value of \( \sigma_t^2(\Delta) \), introduced below (13), for small argument. Furthermore, the function \( u(\alpha e^2, E_{\mu} - E_k) := \mathbb{E}[\mid U_{pk} \mid^2] \) represents the second moment of the transformation matrices \( U_{pk} \) and is given by the Breit–Wigner distribution

\[
u(\gamma, E) = \frac{\gamma}{\pi D_0 (\gamma^2 + E^2)}. \tag{18}
\]

Hence, we can identify

\[
N_v := 2\alpha D_0 e^2 = 2\pi \tilde{\sigma}_t^2 D_0 e^2 \tag{19}
\]

as the full width at half maximum of the average overlap \( \mathbb{E}[\mid U_{pk} \mid^2] \) between eigenvectors of \( H \) and \( H - eV \), quantifying the number of energy eigenstates mixed by the perturbation as introduced above (14).

Exploiting (15) in the average of (12), we obtain

\[
\mathbb{E}[(A)_{\rho_v(t)}] = \sum_{\mu} d_{k,l}^{\mu,\mu} \{ (E_{\mu} - E_k) \} |A| |l \} + \sum_{\mu,v} e^{-i(E_k - E_{\mu})t} \times \sum_{k,l} e^{i(E_k - E_{\mu})t} d_{k,l}^{\mu,\mu} \{ (E_{\mu} - E_k) \} |l \} |A| k \}

+ f_{k,l}^{\mu,\mu} \{ (E_{\mu} - E_k) \} |l \} |A| l \} \tag{20}
\]

If we make use of the constant DOS once again (see below (9)), which allows us to shift summation indices, we find that

\[
\sum_{\mu} d_{k,l}^{\mu,\mu} = u(2\alpha e^2, \omega_{k,l}), \tag{21}
\]

\[
\sum_{\mu,v} e^{-i(E_k - E_{\mu})t} d_{k,l}^{\mu,\mu} = u(2\alpha e^2, \omega_{k,l}) e^{-2\alpha t|e|^2}, \tag{22}
\]

\[
\sum_{\mu,v} e^{-i(E_k - E_{\mu})t} f_{k,l}^{\mu,\mu} = -u(2\alpha e^2, \omega_{k,l}) e^{-2\alpha t|e|^2} \times \left[ \right. \cos(\omega_{k,l}t) + \frac{2ae^2}{\omega_{k,l}} \sin(\omega_{k,l}t) \left. \right] \tag{23}
\]

with \( \omega_{k,l} := E_k - E_l \). Substituting into (20) yields

\[
\mathbb{E}[(A)_{\rho_v(t)}] - (A)_{\bar{\rho}} = e^{-2\alpha t|e|^2} \left[(A)_{\rho_v(t-\tau)} - (A)_{\bar{\rho}} \right]

+ R(t) \tag{24}
\]

with the locally averaged equilibrium state \( \bar{\rho} \) given by

\[
(m|\tilde{\rho}|n) := \delta_{mn} \sum_k u(2\alpha e^2, E_n - E_k) \langle k|\rho_T|k \rangle \tag{25}
\]

and

\[
R(t) := e^{-2\alpha t|e|^2} \sum_{k,l} \langle k|\rho_T|l \rangle \langle l|A|l \rangle u(2\alpha e^2, \omega_{k,l}) \times \left\{ 1 - \cos(\omega_{k,l}t) - \frac{2ae^2}{\omega_{k,l}} \sin(\omega_{k,l}t) \right\}. \tag{26}
\]

Note that \( \bar{\rho} \) is the state approached for large times and can thus be identified with the equilibrium state \( \rho_{eq} \) from (5). It usually corresponds to the pertinent thermal state \([40–43]\). We also observe that \( R(t) \) vanishes at \( t = 0 \) and for \( t \to \infty \). Furthermore, as shown in the Appendix its
magnitude can be bounded from above for arbitrary \( t \geq 0 \) according to

\[
R^2(t) \leq \frac{\delta^2 A}{50 N_v},
\]

where \( N_v \) is the width of the eigenvector overlaps from (19), and

\[
\delta^2 A := \sum_{n: E_n \in I_E} \left( A_{nn} - \langle A \rangle_{\rho_{\text{ave}}} \right)^2,
\]

where \( \rho_{\text{ave}} \) denotes the microcanonical density operator corresponding to the energy window from (9). For generic (nonintegrable) Hamiltonians \( H \), essentially all observables \( A \) of actual interest are expected to satisfy the so-called eigenstate thermalisation hypothesis (ETH) [44]. Hence, the right-hand side of (27) can be roughly estimated as \( ||A||^2 \) (with \( ||A|| \) denoting the operator norm of \( A \), i.e. the largest eigenvalue in modulus), and \( R(t) \) in (24) can be neglected according to (14) and (26).

For integrable systems, the relevant observables are still expected to satisfy the so-called weak ETH [45–47], and thus the right-hand side of (27) can be roughly estimated as \( ||A||^2 N/f \), where \( N \) is the number of energy levels \( E_n \) contained in \( I_E \), whereas \( f \) counts the degrees of freedom of the considered system and therefore scales as \( \ln(N) \) (see also (14)). Again, one can conclude from (26) that \( R(t) \) in (24) amounts in many cases to a small correction.

Finally, we point out that the bound (26) is still rather loose as the oscillating character of the summands in (25) with respect to both \( \omega_{kl} \) and \( t \) will usually result in very strong “accidental cancellation” effects, which are entirely disregarded in our derivation of the “worst case” bound (26) in the Appendix.

Indeed, we have not been able to identify any specific example of practical interest where the last term in (24) plays a significant role. Accordingly, this term is henceforth considered as negligible. With (5), (8), and (14), we thus arrive at the first key result of this section,

\[
\frac{\mathbb{E}[A(\tau + t)]}{\mathbb{E}[A(\tau - t)]} = e^{-2\alpha t e^2} \quad (0 \leq t \leq \tau),
\]

which quantifies the average effect of imprecisions during the backward evolution within the considered ensembles of \( V \)'s and for small enough \( \epsilon \). Analogously to [39], one can then proceed to derive a bound for the variance of \( A(\tau + t) \). This leads to

\[
\mathbb{E}[A(\tau + t)^2] - \mathbb{E}[A(\tau + t)]^2 \leq C_v ||A||^2 N_v,
\]

where \( C_v \) is a constant of order \( 10^3 \) or less. In view of (14), the variance (29) of \( A(\tau + t) \) with \( V \) is thus exponentially small in the number of degrees of freedom, establishing a so-called concentration of measure property of the considered ensembles of \( V \) operators. For instance, invoking Chebyshev’s inequality from probability theory, the estimate (29) implies that the probability for \( A(\tau + t) \) to differ by more than \( ||A|| N_v^{1/3} \) from the average \( \mathbb{E}[A(\tau + t)] \) at a certain instance in time \( t \) is less than \( C_v / N_v^{1/3} \). This is our second key result of this section, promoting (28) from a mere statement about the ensemble average to a prediction for individual realisations. As deviations from the average are extremely rare for reasonably large many-body systems, we can conclude that

\[
\frac{A(\tau + t)}{A(\tau - t)} = e^{-2\alpha t e^2} \quad (0 \leq t \leq \tau)
\]

is an excellent approximation for the vast majority of time-reversal inaccuracies \( V \) captured by the considered ensembles. This relation for the echo dynamics (1) under an imperfect backward Hamiltonian constitutes our main result. It asserts that the echo signal is exponentially suppressed in the propagation time \( t \) and the intensity \( e^2 \) of the imperfections.

## 4 Example

We consider a spin-\( \frac{1}{2} \) XXX chain model with Hamiltonian

\[
H = -\sum_{i=1}^{L-1} \sigma_i \cdot \sigma_{i+1},
\]

where \( \sigma_i = (\sigma_i^x, \sigma_i^y, \sigma_i^z) \) is a vector of Pauli matrices acting on site \( i \). For the perturbation \( V \), we choose

\[
V = \sum_{i<j}^3 \sum_{\alpha, \beta=1}^3 f_{ij}^{\alpha \beta} \sigma_i^\alpha \sigma_j^\beta,
\]

where the couplings \( f_{ij}^{\alpha \beta} \) are drawn independently from a normal distribution (unbiased Gaussian with unit variance). As the observable, we take the staggered magnetisation

\[
A = \sum_{i=1}^L (-1)^i \sigma_i^z.
\]

Turning to the initial (target) state \( \rho_{\text{t}} = |\psi\rangle \langle \psi| \), let us first consider a Néel state \( |\psi\rangle := |\uparrow \uparrow \downarrow \uparrow \cdots \rangle \). In order to account for the requirement that the DOS should be approximately constant (see below (9)), we
rescale the probability amplitudes $\langle n|\psi\rangle$ according to the corresponding energy eigenvalues $E_n$ with a Gaussian weight of zero mean and standard deviation $\sigma_\psi$, resulting in
\[
|\psi\rangle := C \sum_n e^{-E_n^2/2\sigma_\psi^2} \langle n|\psi\rangle |n\rangle ,
\] (34)
where the normalisation constant $C$ is chosen such that $\langle \psi|\psi\rangle = 1$. As discussed around (9), the large isolated systems we have in mind (e.g. an MRI sample) are expected to exhibit a macroscopically well-defined energy, so that $\sigma_\psi$ should lie below the measurement resolution. In particular, while it is possible to prepare a clean Néel state in few-body experiments with cold atoms, such attempts will most likely result in a filtered or coarse-grained variant as the degrees of freedom increase.

Quantitatively, for the example in Figure 1, we chose a chain length of $L = 14$ and a standard deviation of $\sigma_\psi = 1.3$, so that the state (34) is focused around energy $E = 0$ with approximately 15% of the total $2^L = 16,384$ levels $E_n$ within $\pm \sigma_\psi$. This procedure reduces the staggered magnetisation $A$ of $|\psi\rangle$ compared to $|\tilde{\psi}\rangle$, but still gives an appreciably out-of-equilibrium expectation value (see also Fig. 1).

After diagonalising $H$ numerically, we estimated the DOS $D_0$ by averaging over all states with energies $E_n \in [-2\sigma_\psi, 2\sigma_\psi]$ (receiving approximately 95% of the weight), resulting in $D_0 = 962$. Furthermore, we extracted $\tilde{\sigma}_D^2$ [see below (17)] from the squared matrix elements $|\langle m|V|n\rangle|^2$ within the relevant energy window in (9) (determined again by the $2\sigma_\psi$ criterion) by way of averaging around the diagonal within a band of 1000 states, yielding $\tilde{\sigma}_D^2 = 0.0729$. According to the definition below (17), this yields
\[
\alpha = \pi \tilde{\sigma}_D^2 D_0 \approx 220 .
\] (35)

All parameters entering our analytical prediction (30) are thus explicitly available; that is, there is no free fit parameter.

In Figure 1, we compare the numerical results obtained by exact diagonalisation with our prediction (30) for different propagation times $\tau$ and perturbation strengths $\epsilon$, showing good agreement. The largest deviations become apparent for small $\tau$ and large $\epsilon$. By generalising the analysis of [39], we expect that the band profile $\sigma^2_d(\Delta)$ of the perturbation $V$ becomes important in this regime. The exponential form (30) for the suppression of the echo signal is then anticipated to show a transition to a Bessel-like decay of the form $\sigma_f(x) x^2/\lambda^2$, where $x$ depends linearly on the noise strength $\epsilon$, the reversal time $\tau$, and the square root of the band width. More generally, within the considered ensemble of inaccuracies, the echo-signal attenuation is essentially given by the Fourier transform of $u(\gamma, E)$ introduced above (18), which can be viewed as the ensemble-averaged fidelity or survival probability [9, 48] of an eigenstate $|n\rangle$ of the clean Hamiltonian $H$ under the imprecise backward Hamiltonian $H'$. When the influence of the random inaccuracies in $H'$ increases, the echo signal may therefore be expected to approach the known decay of

\[\text{Figure 1: Time-dependent expectation values of the staggered magnetisation (33) for the spin-} \frac{3}{2} \text{ XXX chain (31) with } L = 14 \text{ under the “imperfect reversal” protocol (1) with various perturbation strengths } \epsilon \text{ and reversal times } \tau. \text{ The initial condition is chosen as a filtered Néel target state } \rho_f = |\psi\rangle \langle \psi| \text{ according to (34) with } \sigma_\psi = 1.3. \text{ The imperfection Hamiltonian } V \text{ in (1) is of the “spin-glass” form (32). Solid lines correspond to the numerical results using exact diagonalisation. Dashed lines show the prediction for the backward (echo) dynamics according to (30) and (35). fidelity in pure random matrix models [48]. Unfortunately, we are not aware of an exact analytic solution of the pertinent equations in the intermediate regime between the exponential and Bessel-type behaviours [39].

5 Conclusions

We investigated the stability of observable echo signals in many-body quantum systems under the influence of uncontrolled imperfections in the pertinent effective time reversal. The considered protocol starts from a nonequilibrium initial state and lets the system evolve under the time-independent Hamiltonian $H$ for some time $\tau$, at which an (effective) time reversal is performed that directs the system back toward the initial nonequilibrium state. By introducing small inaccuracies in the time-reversed Hamiltonian, we obtained a measure for the instability of nonequilibrium states and the irreversibility of the dynamics in terms of directly observable quantities.

Our prediction for the relative echo signal under such a distorted backward Hamiltonian, (30), includes an exponential dependence on both the squared perturbation strength $\epsilon^2$ and the propagation time $t$. In particular, the height of the echo peak at $t = \tau$ is thus expected to decay exponentially in $\tau$. Systems with this property were labelled “irreversible” in [11], as opposed to “reversible” ones where the decay is (at most) algebraic. In this sense, one may interpret the present result as a prediction that many-body quantum systems are typically irreversible. However, it should be pointed out that the functional dependence of the echo peak on $\tau$ rather appears to be a property of the inaccuracies $V$ than of the system itself, even though the structure of $V$ is (in a real system) of course influenced by the properties of the system. In any case, this functional dependence could also be confirmed for an exemplary spin-$\frac{1}{2}$ XXX model, whose dynamics shows good agreement with our analytical prediction without any remaining fit parameter.

The paradigmatic examples of macroscopic echo experiments are spin echoes and NMR [7], where nuclear spins precess in a strong magnetic field at different frequencies due to local inhomogeneities, leading to dephasing of the initially aligned magnetic moments. Applying a $\pi$ pulse at time $\tau$ reverses the relative orientation between the spins and the external field and thus effectively changes the sign of the corresponding term in the pertinent model Hamiltonian. However, interactions among the spins and with the environment are not reversed and amount to a “perturbation” that causes deviations of the echo signal at time $2\tau$, which – in line with our general echo analysis here – typically decays exponentially with $\tau$. It should be noted that the “imperfections” in this context are usually vital in applications such as MRI, precisely because different imperfections lead to slightly different decay rates and therefore allow one to distinguish different materials.

Experimental implementations of echo protocols are also available in a variety of interacting spin systems, see, for example, [15–17, 20, 21]. In these experiments, an effective sign flip of the dominant part of the Hamiltonian (including dipole–dipole or even quadrupole interactions) is achieved by means of an elaborate application of radiofrequency magnetic fields. The prevailing inaccuracies leading to deviations from the perfectly reversed signal are again due to nonreversible correction terms in the Hamiltonian, as well as possible experimental imprecisions in carrying out the required protocol. Their major contribution is thus expected to be of the type studied here, too.

Specifically, the experimental study [20] indeed reports an exponential decay of the peak height with the reversal time $\tau$ in a polarisation echo experiment involving the nuclear spins of a camptothecin polycrystalline sample. In the same study, data obtained from a ferrocene sample suggest an approximately Gaussian-shaped dependence; see also [21]. The authors explain this with the much larger relative strength of the nonreversible component in the Hamiltonian, compatible with our prediction that a crossover from an exponential to a Bessel-like decay is expected as the relative strength of $V$ increases; see the discussion at the end of Section 4.

From a conceptual point of view, the approach of our present work, where the Hamiltonians of the forward and backward phases differ slightly, assesses (via observable quantities) the stability of many-body trajectories with respect to variations of the dynamical laws. Therefore, it should be no surprise that deviations grow with the propagation time $\tau$, and the exponential dependence might have been anticipated from perturbation-theoretic considerations, even though the applicability of standard perturbation theory is rather limited for typical many-body systems with their extremely dense energy spectra. In that sense, the present derivation by nonperturbative methods is reassuring and also indicates how deviations from the exponential behaviour will manifest themselves if the influence of imperfections increases. For

---

1 Within the experimental error bars, the Bessel-like shape $4/\sqrt{(2\pi)^3}/(2x)^3$ is indistinguishable from a Gaussian shape $\exp(-x^2)$. Note that the two functions agree to third order in $x$, and the relative difference of the fourth-order Taylor coefficients is only $1/6$. 
future work, it will be interesting to investigate a complementary approach that studies the sensitivity toward variations of the initial conditions in macroscopic quantum system.

Appendix A: Derivation of (26)

Exploiting (18), we rewrite \( R(t) \) from (25) as

\[
R(t) = \tilde{R}(2ae^2 t) ,
\]

\[
\tilde{R}(t) := \sum_{m,n} \langle m|\rho_T|m\rangle \langle n|A|n\rangle h(m-n,t) ,
\]

\[
h(n,t) := e^{-t} \left\{ 1 - \cos(m/t)N_v - \frac{\sin(m/t)N_v}{N_v} \right\} ,
\]

where \( N_v \) is defined in (19), and where \( \omega_{kl} := E_k - E_l \) (see below (21)) has been approximated by \( (k - l)/D_0 \), as justified below (9).

According to (14), we can and will take for granted that

\[
N_v \gg 1 .
\]

In view of (38), it follows that the sum \( \sum_n h(n,t) \) can be very well approximated by the integral \( \int dx \ h(x,t) \). Moreover, a straightforward but somewhat tedious calculation yields \( \int dx \ h(x,t) = 0 \). Therefore, we can subtract a constant value from the observable \( A \) without changing the value of \( \tilde{R}(t) \) in (37). By means of the definition

\[
\tilde{A}_{nn} := \langle n|A|n\rangle - \langle A \rangle_{\rho_{nc}}
\]

we thus can rewrite (37) as

\[
\tilde{R}(t) = \sum_m \langle m|\rho_T|m\rangle \ \tilde{Q}(m,t) ,
\]

\[
\tilde{Q}(m,t) := \sum_n \tilde{A}_{nn} h(m-n,t) .
\]

Exploiting the Cauchy–Schwarz inequality yields

\[
\tilde{Q}^2(m,t) \leq \left[ \sum_n (\tilde{A}_{nn})^2 \right] \left[ \sum_n h^2(m-n,t) \right] .
\]

As the last sum over \( n \) is independent of \( m \), it follows that

\[
|\tilde{Q}(m,t)| \leq \sqrt{Q(t)} ,
\]

\[
Q(t) := q(t) \sum_n (\tilde{A}_{nn})^2 ,
\]

\[
q(t) := \sum_n h^2(n,t) .
\]

Accordingly, \( \tilde{R}(t) \) from (41) can be upper bounded as

\[
|\tilde{R}(t)| \leq \sqrt{Q(t)} \sum_m \langle m|\rho_T|m\rangle = \sqrt{Q(t)} ,
\]

where we exploited that \( \rho_T \) is a positive semidefinite operator of unit trace.

Because of (38) and (39), one can conclude similarly as below (39) – that the sum on the right-hand side of (46) is very well approximated by the integral \( \int dy \ h^2(y,t) \). After going over from the integration variable \( y \) to \( x := y/N_v \), one thus obtains in very good approximation

\[
q(t) = N_v^{-1} f(t) ,
\]

\[
f(t) := e^{-2t} \int dx \left[ \frac{1 - \cos(xt) - \sin(xt)x^2}{\pi(1 + x^2)} \right]^2 .
\]

An analytical evaluation of \( f(t) \) from (49) is possible but quite arduous, whereas a numerical evaluation is straightforward; see Figure 2. In either case, one finds that

\[
0 \leq f(t) \leq 1/50 =: c
\]

for all \( t \geq 0 \). Taking into account (36), (45), (47), and (48), we thus arrive at

\[
R^2(t) \leq \frac{c}{N_v} \sum_n (\tilde{A}_{nn})^2 .
\]
As discussed above (9), the diagonal matrix elements \( \langle n | \rho(0) | n \rangle \) appearing in (3) vanish whenever \( E_n \notin I_E \). Accordingly, we can arbitrarily modify the corresponding \( \langle n | A | n \rangle \)'s without any further consequences in (3). Specifically, we can modify them so that all \( \tilde{A}_{nn} \) in (40) are zero if \( E_n \notin I_E \). Therefore, the summation on the right-hand side of (51) can be restricted to those \( n \) with \( E_n \in I_E \). Altogether, we thus recover (26) and (27) from the main text.
