(Dated: August 27, 2018)

We investigate the ground state properties of Na$_2$IrO$_3$ based on numerical calculations of the recently proposed \textit{ab initio} Hamiltonian represented by Kitaev and extended Heisenberg interactions. To overcome the limitation posed by small tractable system sizes in the exact diagonalization study employed in a previous study (Yamaji et al., Phys. Rev. Lett. 113, 107201 (2014)), we apply two-dimensional density matrix renomalization group, and infinite-size tensor-network method. By calculating at much larger system sizes, we critically test the validity of the exact diagonalization results. The results consistently indicate that the ground state of Na$_2$IrO$_3$ is a magnetically ordered state with zigzag configuration in agreement with experimental observations and the previous diagonalization study. Applications of the two independent methods in addition to the exact diagonalization study further uncover a consistent and rich phase diagram near the zigzag phase beyond the accessibility of the exact diagonalization. For example, in the parameter space away from the \textit{ab initio} value of Na$_2$IrO$_3$ controlled by the trigonal distortion, we find three phases: (i) an ordered phase with the magnetic moment aligned mutually in 120 degrees orientation on every third hexagon, (ii) a magnetically ordered phase with a 16-site unit-cell, and (iii) an ordered phase with presumably incommensurate periodicity of the moment. It suggests that potentially rich magnetic structures may appear in A$_2$IrO$_3$ compounds for A other than Na. The present results also serve to establish the accuracy of the first-principles approach in reproducing the available experimental results thereby further contribute to find a route to realize the Kitaev spin liquid.

I. INTRODUCTION

Novel quantum phenomena induced by strong spin-orbit interaction have recently attracted much interest in condensed matter physics. Iridium oxides offer a typical example that shows rich and interesting phenomena. Among them, A$_2$IrO$_3$ (A = Na or Li) have most intensively been investigated since the theoretical proposal that the Kitaev spin liquid would be realized. The Kitaev interaction is an anisotropic Ising-like interaction, $S^3 S^7$, with the easy axes $\gamma$ depending on the direction of the interacting bonds. For the model represented only by the Kitaev interaction called Kitaev model, the ground state is proved to be a quantum spin-liquid. As a more realistic model representing Na$_2$IrO$_3$, the so-called Kitaev-Heisenberg model with both the Heisenberg and Kitaev interactions has been proposed. However, it has turned out that this model does not either properly account for the experimental observation of the zigzag magnetic order stabilized at low temperatures or ad-ditional anisotropic interactions caused by the trigonal distortion.

In this paper, in order to further clarify the nature of Na$_2$IrO$_3$, we investigate the ground state of the \textit{ab initio} Hamiltonian for Na$_2$IrO$_3$ proposed by Yamaji \textit{et al.} and summarized in Appendix A. In the \textit{ab initio} Hamiltonian, where off-diagonal anisotropic interactions due to the trigonal distortion as well as weak second-nearest neighbor and third-nearest neighbor interactions are nonzero beyond the simple Kitaev-Heisenberg Hamiltonian, the experimentally observed zigzag order was reproduced by exact diagonalizations (ED) of clusters of 24 and 32 sites. However, more thorough studies are desired beyond small clusters to understand intrinsic properties in the thermodynamic limit.

In the present article, we carry out larger size calculations using sophisticated numerical methods; density matrix renormalization group (DMRG) and tensor network (TN). Applicability of the newly developed TN method to \textit{ab initio} Hamiltonians containing complex interactions beyond simple model Hamiltonians, is examined by carefully comparing with the ED and DMRG. If the trigonal distortion is close to that of the \textit{ab initio} Hamiltonian for Na$_2$IrO$_3$, the two methods show the zigzag...
FIG. 1. (a) Two-dimensional honeycomb lattice where \( J_2 \) and \( J_3 \) represent the second- and the third-neighbor interaction pairs. In numerical calculations, we mainly use \( L_x \times L_y \) lattices or unit cells with periodic boundary condition for both of \( L_x \) and \( L_y \) directions. (b) Three directions of the nearest-neighbor interactions. (c) Definition of the unit used in the classical analysis.

order consistently with the exact diagonalization results in Ref. 18.

Another purpose of this study is to clarify the role of the trigonal distortion and search phases competing with the zigzag order when the trigonal distortion is deviated from that of \( \text{Na}_2\text{IrO}_3 \). Richer phase diagram beyond the exact diagonalization is determined, where several distinct symmetry broken magnetic orders emerge, when the trigonal distortion is monitored away from \( \text{Na}_2\text{IrO}_3 \) (as introduced in Eqs. (8) and (9), later). This study may have relevance to other materials \( A_2\text{IrO}_3 \) for \( A \) other than \( \text{Na} \) because the trigonal distortion depends on \( A \).

The rest of the paper is organized as follows. In Sec. II, we describe our model. In Sec. III, we present results of classical approximations. Our main results for the \textit{ab initio} Hamiltonian and its derivatives are presented in Sec. IV. Finally, we summarize our results in Sec. V.

II. MODEL

The Hamiltonian of the model we investigate is given by

\[
\mathcal{H} \equiv \mathcal{H}_{1st} + \mathcal{H}_{2nd} + \mathcal{H}_{3rd},
\]

where \( \mathcal{H}_{1st}, \mathcal{H}_{2nd}, \) and \( \mathcal{H}_{3rd} \) express the nearest neighbor, the second neighbor, and the third neighbor interactions on the honeycomb lattice, respectively (see Fig. 1). For the nearest neighbor interaction, we consider distorted Kitaev-Heisenberg interaction with off-diagonal terms as

\[
\mathcal{H}_{1st} \equiv \sum_{\Gamma=X,Y,Z} \sum_{(i,j)\in\Gamma} \bar{S}_i^T \bar{J}^*_\Gamma \bar{S}_j,
\]

where \( \Gamma \) means the directions of the interactions and real symmetric matrices \( J^{(3rd)}_\Gamma \) (\( \Gamma = X, Y, Z \)) are given by

\[
J^{(3rd)}_X = \begin{pmatrix} K' & I''_1 & I''_2 \\ I''_1 & I' & I''_2 \\ I''_2 & I''_1 & I' \end{pmatrix}, \quad J^{(3rd)}_Y = \begin{pmatrix} I''' & I''_1 & I''_2 \\ I''' & I' & I''_2 \\ I''' & I''_1 & I' \end{pmatrix}, \quad J^{(3rd)}_Z = \begin{pmatrix} J & I_1 & I_2 \\ I_1 & J & I_2 \\ I_2 & I_2 & K' \end{pmatrix}.
\]

For the second neighbor interactions, we consider only the interaction perpendicular to the \( Z \) bond:

\[
\mathcal{H}_{2nd} \equiv \sum_{\langle\langle(i,j)\rangle\rangle\in\mathbb{Z}'} \bar{S}_i^T \bar{J}^{(2nd)}_Z \bar{S}_j,
\]

where \( \sum_{\langle\langle(i,j)\rangle\rangle\in\mathbb{Z}'} \) represents the sum over second neighbor pairs parallel to the \( Z \) bond, and \( J^{(2nd)}_Z \) is give by

\[
J^{(2nd)}_Z = J^{(2nd)} = \begin{pmatrix} I_1^{(2nd)} & I_2^{(2nd)} \\ I_2^{(2nd)} & I_1^{(2nd)} \end{pmatrix}.
\]

Finally, for the third neighbor interaction the Hamiltonian is given by

\[
\mathcal{H}_{3rd} \equiv \sum_{\Gamma=X,Y,Z} \sum_{\langle\langle\langle(i,j)\rangle\rangle\rangle\in\Gamma} \bar{S}_i^T \bar{J}^{(3rd)}_\Gamma \bar{S}_j,
\]

where \( \sum_{\langle\langle\langle(i,j)\rangle\rangle\rangle\in\Gamma} \) represents the sum over the third neighbor pairs parallel to the \( \Gamma \) direction (\( \Gamma = X, Y, Z \)). We consider only the isotropic Heisenberg interaction for the third neighbor interaction:

\[
J^{(3rd)}_\Gamma = J^{(3rd)} = \begin{pmatrix} 0 & J^{(3rd)} & 0 \\ J^{(3rd)} & 0 & J^{(3rd)} \\ 0 & J^{(3rd)} & 0 \end{pmatrix}.
\]

The above spin Hamiltonian has been derived from the \textit{ab initio} Hamiltonian for \( t_{2g} \) electrons of iridium atoms in \( \text{Na}_2\text{IrO}_3 \):

\[
\hat{H}_{t_{2g}} = \hat{H}_0 + \hat{H}_{\text{tri}} + \hat{H}_{\text{SOC}} + \hat{H}_U,
\]

where \( \hat{H}_0, \hat{H}_{\text{tri}}, \hat{H}_{\text{SOC}} \) and \( \hat{H}_U \) represent the hopping term, the trigonal distortion with orbital-dependent chemical potentials, the spin-orbit coupling and the Coulomb term, respectively. Due to the trigonal distortion term, the spin Hamiltonian does not possess the symmetry among spin components \( S_x, S_y, S_z \); only \( S_x \) and \( S_y \) remain symmetric. Thus, the global symmetries of the Hamiltonian are the \( Z_2 \) time-reversal symmetry, the \( Z_2 \) symmetry against exchange of \( S_x \) and \( S_y \), and the lattice translational symmetry. By using a vector representation of the electron creation operators at site...
The trigonal distortion term is expressed as

\[ \hat{H}_{\text{tr}} = \sum_i \begin{pmatrix} -\mu_{yz} & \Delta & \Delta \\ \Delta & -\mu_{xx} & \Delta \\ \Delta & \Delta & -\mu_{xy} \end{pmatrix} \hat{\sigma}_0 \hat{c}_i, \]

where \( \hat{\sigma}_0 \) is the 2 \times 2 identity matrix. The \textit{ab initio} values of \( \mu_{yz}, \mu_{xx}, \mu_{xy} \) and \( \Delta \) for Na\( \text{IIrO}_3 \) were estimated as \( \mu_{xy} - \mu_{xx} = 35 \text{ meV}, \mu_{yz} \geq \mu_{xx} \) and \( \Delta = -28 \text{ meV} \).

All interactions for Na\( \text{IIrO}_3 \) have been determined based on the second-order perturbation theory by using the strong-coupling expansion applied to the first principles Hamiltonian (see Appendix A). Based on the exact diagonalization for small clusters, Yamaji et al. have shown that the ground state of the Hamiltonian for Na\( \text{IIrO}_3 \) is expected to be a magnetically ordered state with the zigzag configuration consistently with the experimental observations. Within the diagonalization of small clusters, they have also determined the phase diagram in the parameter space of the trigonal distortion monitored around the \textit{ab initio} value of Na\( \text{IIrO}_3 \), and have shown that several distinct magnetically ordered states emerge depending on the amplitude of the trigonal distortion. However, the system size in the previous exact diagonalization is only up to 24 sites, and is too small for establishing properties in the thermodynamic limit. Thus, in order to verify the conclusion of the previous work and further clarify the nature of the \textit{ab initio} Hamiltonian that contains anisotropic Kitaev-Heisenberg interaction, we clearly need to investigate larger system sizes. In the following sections, we clarify the ground state properties in the thermodynamic limit derived from results of much larger system sizes including the infinite-size calculations. We focus on the two problems; properties of the \textit{ab initio} Hamiltonian for Na\( \text{IIrO}_3 \) in comparison with the experimental results and the phase diagram of the Hamiltonian obtained by monitoring the trigonal distortion \( \Delta \) away from the \textit{ab initio} value, because \( \Delta \) is an experimentally tunable control parameter by pressure or elemental substitutions.

### III. Classical Approximation

We first consider the classical ground state, motivated by the fact that the system has a magnetic order in the experimentally observed ground state. In particular, the classical analysis provides us with insight complementary to the quantum analysis, because it enables studies on incommensurate order, whereas it is hard to capture within the framework of the TN or DMRG in which commensurability is assumed.

In the case of the classical Heisenberg spins, where \( \hat{S}_i \) is a unit vector with three components, the candidates of the ground state is obtained from the Fourier transform of exchange interactions. Suppose two spins connected by the \( z \)-bond on the honeycomb lattice as a unit (see Fig. 1(c)). Because the Hamiltonian retains the translational symmetry based on such units constituting the triangular lattice, the Hamiltonian is diagonalized by the Fourier transform as

\[ \mathcal{H}_c = \frac{1}{2} \sum_q \hat{S}_q^T \mathcal{J}_q \hat{S}_q, \]

where \( \sum_q \) is the summation over the wavevectors in the Brillouin zone. \( \mathcal{J}_q \) is the 6 \times 6 Hermitian matrix representing the Fourier transform of the exchange interaction and it is given by

\[ \mathcal{J}_q = \begin{pmatrix} A & B \\ B^\dagger & A \end{pmatrix}, \]

\[ A = 2J^{(2nd)} \cos q \cdot (a - b) \]

\[ B = J_x e^{-iq \cdot a} + J_y e^{-iq \cdot b} + J_z \]

\[ + J^{(3rd)} \left[ 2 \cos q \cdot (a - b) + e^{-iq \cdot (a + b)} \right], \]

where \( \hat{S}_q \) is the Fourier transform of spins in a unit

\[ \hat{S}_q = \begin{pmatrix} \hat{S}_q^{(1)} \\ \hat{S}_q^{(2)} \end{pmatrix}. \]

By diagonalizing the exchange matrix \( \mathcal{J}_q \) numerically, we obtain candidates of the classical ground states as the lowest eigen mode. However, note that the obtained eigenvector is not necessarily the ground state because it may not satisfy the fixed length condition of classical spins; \( |\hat{S}_q^{(1)}|^2 = 1 \) and \( |\hat{S}_q^{(2)}|^2 = 1 \) for each site on the lattice. Instead, the lowest eigen mode can be regarded as the ground state in the spherical approximation \( \sum_q |\hat{S}_q|^2 = 2N \). When the wavevector of the lowest eigen mode is incommensurate to the lattice, the eigenvector generally does not satisfy the fixed length condition. In such cases, a commensurate order, which usually satisfies the fixed length condition, close to the incommensurate wavevector often appears as the true ground state by recovering the fixed length condition.

In Fig. 2(a), we plotted the wavevector of the lowest energy mode as a function of the trigonal distortion \( \Delta \). We see that in the most part of the parameter \( \Delta \), the lowest eigen mode appears at wavevectors incommensurate to the lattice (see Fig. 2(b)). However, for \( -20 \text{ meV} \lesssim \Delta \lesssim -10 \text{ meV} \) we find that the commensurate zigzag(\( Z \)) order is the ground state, where the ferromagnetically-ordered chains consist of X and Y-bonds while these chains are anti-ferromagnetically coupled by the Z-bonds (see Fig. 3(a)). Note that the \textit{ab initio} value for the distortion of Na\( \text{IIrO}_3 \) is \( \Delta \approx -28 \text{ meV} \), which is in the vicinity of the zigzag(\( Z \)) phase boundary.

The obtained \( \Delta \) dependence of the wave vector clearly indicates that the incommensurate region consists of three distinct phases (see Fig. 2(a)). For large negative \( \Delta \), the lowest energy states are characterized by the
FIG. 2. (a) Classical phase diagram within the spherical approximation in the parameter space of the trigonal distortion around the \textit{ab initio} value. The symbols represent the amplitude of the wavevectors for the ground state. (b) The position of the ground-state wavevectors. The symbols (colors) follows the notation in (a). The dashed lines represent the boundaries of the first Brillouin zone and the circles indicate high symmetric points. (c) The Bragg peak positions of several magnetic orders that appear in the present \textit{ab initio} Hamiltonian (see also Fig. 3).
IV. GROUND STATE PROPERTIES

A. Methods

In order to investigate the ground state property of the Hamiltonian in the presence of strong quantum fluctuations, we conduct three types of numerical calculations based on the ED, two-dimensional DMRG and tensor network based methods.

Our ED calculations were done up to 32-site based on the Lanczos algorithm. A part of the results has already been reported in Ref. [18]. In order to investigate larger systems, we use a two-dimensional DMRG method where we represent the ground state wave function as a matrix product states (MPS) and variationally optimize the wave-function parameters so as to minimize the energy [23]. In the DMRG calculation, we investigate $L_x \times L_y$ lattice systems with periodic boundary conditions along both of $L_x$ and $L_y$ directions (see Fig. 1(a)). We keep 1000 states in DMRG processes and perform more than 10 sweeps, resulting in a typical truncation error $10^{-5}$ or smaller.

The ED and DMRG are quite accurate for finite systems. The maximum size they can treat is, however, restricted to about 100 sites, which are a little too small to clarify the thermodynamic properties beyond reasonable doubt. In order to investigate the property in the thermodynamic limit further, we also conduct recently developed tensor network methods which can treat infinite-size system directly. Here we use the tensor network ansatz for infinite-size systems so called infinite Projected Entangled Pair State (iPEPS) [24-26] or infinite Tensor Product State (iTPS) [27,28] as the ansatz of the ground state wave function. We assume infinitely repeated $L_x \times L_y$ unit-cell structure, i.e. $L_x \times L_y$ independent tensors with bond-dimensions $D$, which is the same shape with the lattice shape used in DMRG (Fig. 1). Note that the unit-cell structure used in iPEPS allows the ground state that spontaneously breaks the lattice translational symmetry in the thermodynamic limit with the periodicity taken into account up to the unit cell size. Thus, even if we assume a finite $L_x \times L_y$ unit-cell structure, a wave function represented by iPEPS is that of the infinite system without any finite size boundary effects. For the optimization of the tensors, we use the imaginary-time evolution with so called the simple update technique [29], which is extended to treat the second- and third-neighbor interactions (see Appendix A). Reliability of the simple update optimization is demonstrated by comparing with the full update [26,29] for the nearest-neighbor $ab$ initio Hamiltonian in Appendix B. After obtaining optimized tensors, we calculated physical quantities by using the corner transfer matrix method [30-36]. In the following calculations, we use the bond dimension $D \leq 9$ for the case of the $ab$ initio value of Na$_2$IrO$_3$ and $D \leq 6$ for the case of the trigonal distortion controlled away from the $ab$ initio value.

B. Ground state of Na$_2$IrO$_3$

First, we examine the ground state of the Hamiltonian at the $ab$ initio matrix elements in Eq. (2) for Na$_2$IrO$_3$ obtained by a first principles calculation [15]. Based on the second order perturbation theory, we can evaluate the exchange interactions as a function of $\Delta$ [15]. For Na$_2$IrO$_3$, the $ab$ initio value of the trigonal distortion was calculated as $\Delta = -28$ meV, and estimated interactions of the Hamiltonian are listed in Table I (see also Appendix A). At this value, 24-site ED calculation predicts that the ground state is the zigzag(Z) state where the ferromagnetically-ordered chains consist of X and Y-bonds while these chains are antiferromagnetically coupled by the Z-bonds (see Fig. 3(a)) [15].

\hline
\end{tabular}
\caption{Kitaev and extended Heisenberg exchange interactions derived from the second-order perturbation theory applied to the \textit{ab initio} Hamiltonian at $\Delta = -28$ meV.}
\end{table}

In Fig. 4(a), we show the energies calculated by ED, DMRG, and iPEPS as a function of the $1/\sqrt{N}$ (ED, DMRG) or $1/D$ (iPEPS). In the case of iPEPS, we used $L_x \times L_y = 4 \times 6$ unit cell. We see that the energies calculated by different methods are consistent with each other and they seem to reach a common value, $E \simeq -6.22$ meV in the limit of $D, N \to \infty$.

In order to further clarify the nature of the ground state, we plot in Fig. 4(b) the order parameter of the zigzag($Z$) state defined as

$$\tilde{M}_{zig(Z)} \equiv \frac{1}{2}(\sigma_1 - \sigma_2),$$

where $\sigma_\alpha$ ($\alpha = 1, 2$) represents the average of spins over the equivalent sites in zigzag($Z$) state (see Fig. 3(a)). In the cases of ED and DMRG we plot $M_{zig(Z)} = \sqrt{\langle \tilde{M}_{zig(Z)}^2 \rangle}$, while in the case of iPEPS we plotted $M_{zig(Z)} = \sqrt{\langle \tilde{M}_{zig(Z)}^2 \rangle}$. Note that these two definitions should reach the same thermodynamic limit. One can clearly see that $M_{zig(Z)}$ takes a large finite value and remains nonzero in the limit of $D, N \to \infty$, indicating that zigzag($Z$) state is stabilized as the ground state in the thermodynamic limit. Thus, the previous proposition that the ground state of the \textit{ab initio} Hamiltonian of Na$_2$IrO$_3$ is the zigzag($Z$) state has been established beyond reasonable doubt. In the inset of Fig. 4(b), we also plot the amplitude of $\langle \tilde{M}_{zig(Z)} \rangle$ projected onto $(x, y, z) = (1, 1, 0), (1, -1, 0)$ and $(0, 0, 1)$ directions obtained by iPEPS. We see that the $(1, 1, 0)$ component is dominant rather than $(1, -1, 0)$ and $(0, 0, 1)$ components. Similar results have been reported based on the pinning field analysis of ED in the previous studies.

Next, we discuss the ground-state phase diagram in the parameter space of the trigonal distortion monitored around the \textit{ab initio} value $\Delta = -28$ meV. Once we set $\Delta$, one can calculate the exchange couplings as a function of $\Delta$ through the second-order perturbation theory. As expected from the classical analysis, we need to keep in mind that magnetically ordered ground states stabilized by controlling the trigonal distortion are subject to have large unit cells including periodicity that is incommensurate to the lattice. In order to obtain the true ground state, we examine the dependence on the system size (DMRG) and on the assumed unit cell size and structure (iPEPS). We then take the lowest energy state among

\begin{figure}[h]

\includegraphics[width=\textwidth]{fig4.png}
\caption{Bond-dimension ($D$) or system size ($N$) dependences of the ground-state energy (a), and zigzag($Z$) order parameter (b) calculated by ED, DMRG and iPEPS for the \textit{ab initio} Hamiltonian of Na$_2$IrO$_3$, where the Kitaev and extended Heisenberg interactions are derived from the \textit{ab initio} value $\Delta = -28$ meV. The inset of (b) shows the amplitude of $\langle \tilde{M}_{zig(Z)} \rangle$ projected onto $(x, y, z) = (1, 1, 0), (1, -1, 0)$ and $(0, 0, 1)$ directions obtained by iPEPS ($D = 9$).}
\end{figure}

\section{Phase diagram for parameters away from the \textit{ab initio} trigonal distortion}

In Fig. 3(a), we show the energies calculated by ED, DMRG, and iPEPS as a function of the $1/\sqrt{N}$ (ED, DMRG) or $1/D$ (iPEPS). In the case of iPEPS, we used $L_x \times L_y = 4 \times 6$ unit cell. We see that the energies calculated by different methods are consistent with each other and they seem to reach a common value, $E \simeq -6.22$ meV in the limit of $D, N \to \infty$.

In order to further clarify the nature of the ground state, we plot in Fig. 3(b) the order parameter of the zigzag($Z$) state defined as

$$\tilde{M}_{zig(Z)} \equiv \frac{1}{2}(\sigma_1 - \sigma_2),$$

where $\sigma_\alpha$ ($\alpha = 1, 2$) represents the average of spins over the equivalent sites in zigzag($Z$) state (see Fig. 3(a)). In the cases of ED and DMRG we plot $M_{zig(Z)} = \sqrt{\langle \tilde{M}_{zig(Z)}^2 \rangle}$, while in the case of iPEPS we plotted $M_{zig(Z)} = \sqrt{\langle \tilde{M}_{zig(Z)}^2 \rangle}$. Note that these two definitions should reach the same thermodynamic limit. One can clearly see that $M_{zig(Z)}$ takes a large finite value and remains nonzero in the limit of $D, N \to \infty$, indicating that zigzag($Z$) state is stabilized as the ground state in the thermodynamic limit. Thus, the previous proposition that the ground state of the \textit{ab initio} Hamiltonian of Na$_2$IrO$_3$ is the zigzag($Z$) state has been established beyond reasonable doubt. In the inset of Fig. 4(b), we also plot the amplitude of $\langle \tilde{M}_{zig(Z)} \rangle$ projected onto $(x, y, z) = (1, 1, 0), (1, -1, 0)$ and $(0, 0, 1)$ directions obtained by iPEPS. We see that the $(1, 1, 0)$ component is dominant rather than $(1, -1, 0)$ and $(0, 0, 1)$ components. Similar results have been reported based on the pinning field analysis of ED in the previous study. Thus the ordered moment in this zigzag($Z$) state is nearly along $(1, 1, 0)$ direction in the effective spin basis, although it has also weak ($< 15\%$) $(0, 0, 1)$ component.

From x-ray resonant-magnetic-scattering experiments, the ordered moment in the low temperature phase of Na$_2$IrO$_3$ was estimated to be located in the $ac$ plane. Because $(1, 1, 0)$ direction in the effective spin model is converted to $(1, 1, 0)$ direction in the real space, which is on the ac plane of Na$_2$IrO$_3$, the predicted ordered spin direction is consistent with the experimental observation. On the other hand, further quantitative analysis of the experimental data suggested that the ordered moment was almost parallel to the $a$ axis, which was $(1, 1, -2)$ directions in the real space. Thus, ordered spin direction $(1, 1, 0)$ predicted from the \textit{ab initio} Hamiltonian does not completely match the experimental observation. In order to reproduce the ordered-moment direction more precisely, we might need to take into account the coupling between the honeycomb layers, which is ignored in the present \textit{ab initio} Hamiltonian.

Next, we discuss the ground-state phase diagram in the parameter space of the trigonal distortion monitored around the \textit{ab initio} value $\Delta = -28$ meV. Once we set $\Delta$, one can calculate the exchange couplings as a function of $\Delta$ through the second-order perturbation theory. As expected from the classical analysis, we need to keep in mind that magnetically ordered ground states stabilized by controlling the trigonal distortion are subject to have large unit cells including periodicity that is incommensurate to the lattice. In order to obtain the true ground state, we examine the dependence on the system size (DMRG) and on the assumed unit cell size and structure (iPEPS). We then take the lowest energy state among
the infinite system, we calculate Because the wave function obtained by iPEPS is that of \( \Delta \lesssim -3 \) meV, the zigzag phase is stabilized. The zigzag phase is separated in two types depending on the direction of ferromagnetically-ordered chains. For \( \Delta \lesssim -44 \) meV the ferromagnetically-ordered chains are perpendicular to the \( X\)-bond or to the \( Y\)-bond (zigzag(\( X\)) and zigzag(\( Y\)) states, respectively), while for \(-44 \) meV \( \lesssim \Delta \) \( \lesssim -3 \) meV they are perpendicular to the \( Z\)-bond (See Figs. 3 (a),(b)). This zigzag(\( Z\)) phase contains the \textit{ab initio} value of \( \text{Na}_2\text{IrO}_3\), \( \Delta = -28\text{meV} \). When we increase \( \Delta \), the 120 degree structure is stabilized for \(-3 \) meV \( \lesssim \Delta \) \( \lesssim -1 \) meV. Whereas the previous 24-site ED calculation suggested that the 120 degree structure survives for larger trigonal distortion \( \Delta < 40 \text{meV} \), the new results based on iPEPS and DMRG reliably show that the 16-site structure characterized by the wavevector \( \mathbf{q}/2\pi = (1/\sqrt{3}, 1/4) \) (see Fig. 2(c)) is stabilized for \(-1 \) meV \( \lesssim \Delta \) \( \lesssim 30 \) meV. Finally, for even larger \( \Delta \) values (\( \Delta \gtrsim 30 \) meV), large unit-cell magnetic structures appear as the ground state. As is indicated by the anomaly around \( 45 \) meV in the iPEPS result of \( \Delta \approx 30 \) meV. In the following, we investigate details of each phase transitions. In case of the DMRG, the finite-size effects smear the jump to some extent. The reason why only the two states are observed may be attributed to the limited sizes allowed for the iPEPS unit cell.

In order to see these magnetic orders clearly, we define the order parameter through the spin structure factor as

\[
M(\mathbf{q}) = \left( \frac{1}{N} \sum_{\gamma=x,y,z} \sum_{i=1}^{N} \langle \hat{S}_i^\gamma \hat{S}_i^\gamma \rangle \cos(\mathbf{q} \cdot \mathbf{r}_i) \right)^{1/2}.
\]

In the case of iPEPS, we use

\[
M(\mathbf{q}) = \sqrt{\frac{1}{N} \sum_{\gamma=x,y,z} \sum_{i=1}^{N} \langle \hat{S}_i^\gamma \rangle e^{i\mathbf{q} \cdot \mathbf{r}_i} \langle \hat{S}_i^\gamma \rangle \langle e^{i\mathbf{q} \cdot \mathbf{r}_i} \rangle^*}.
\]

Because the wave function obtained by iPEPS is that of the infinite system, we calculate \( M(\mathbf{q}) \) of iPEPS approximately by using the 96 \( \times \) 96 finite lattice. In Fig. 4 we plot \( M(\mathbf{q}) \)'s corresponding to zigzag(\( Z\)), zigzag(\( X\)) (and zigzag(\( Y\))), 120 degree structure and 16-site order together with the 48-site order representing the incommensurate region in the phase diagram. The Bragg wavevector for each state is given as

\[
\mathbf{q}/2\pi = \begin{cases} \left( \frac{1}{\sqrt{3}}, \frac{1}{2} \right), \left( -\frac{1}{2\sqrt{3}}, \frac{1}{4} \right) & \text{(zigzag}(X,Y)) \text{ (16-site)} \\ \left( \frac{1}{\sqrt{3}}, 0 \right) & \text{(zigzag}(Z)) \text{ (48-site)} \end{cases}\]

One can see that corresponding order parameters become finite in each phase, which ensures the stability of the identified phases. Note that the order parameters at the phase boundaries remain at large nonzero values before the transition to zero indicating the first order nature of the phase transitions. In case of the DMRG, the finite-size effects smear the jump to some extent.

In the following, we investigate details of each phase in the phase diagram.

1. zigzag phase

As we have shown in the phase diagram, two types of zigzag states are stabilized in the negatively large \( \Delta \) region. In the vicinity of the phase boundary, we can obtain both of the zigzag(\( X,Y\)) and the zigzag(\( Z\)) states depending on the unit-cell structures and/or the initial conditions of the tensors in the iPEPS, at least as a metastable states. Thus, we can locate the first-order
phase boundary at the point where the two energy curves cross each other. In Fig. 7(a), we plot the energies of the zigzag(X,Y) state and zigzag(Z) state obtained by the iPEPS. We see a clear energy crossing around $\Delta = -44$ meV indicating the first-order phase transition between the zigzag(X,Y) phase and the zigzag(Z) phase.

In the DMRG for 6\times8 cluster, there is no clear anomaly around $\Delta = -44$ meV in the energy and the order parameters (see Figs. 5 and 6). Because 6 cluster does not fit the zigzag(X,Y) structure, the zigzag(Z) state is probably stabilized in wider region than the iPEPS. Note that the degeneracy of the ground states is different between the zigzag(X,Y) and the zigzag(Z) phases; four-fold degeneracy for the zigzag(X,Y) state, while two-fold for the zigzag(Z) state. Thus we expect finite-temperature phase transitions with the $Z_4$ symmetry breaking for the zigzag(X,Y) phase, distinct from the $Z_2$ symmetry breaking for the zigzag(Z) state.

2. 120 degree phase

Next we focus on the phase with the 120 degree structure. In Fig. 7(b), we plot the energies of the zigzag(Z), the 120 degree, and the 16-site states as a function of $\Delta$. For $-3$ meV $\lesssim \Delta \lesssim -1$ meV, the 120 degree state has the lowest energy. Although, the range of the 120 degree structure is largely reduced from the previous estimate based on the 24-site ED calculation, the data show that the 120 degree structure phase survives.

Although the 120 degree structure does not fit 6\times8 cluster used in DMRG, we observed that in DMRG for 8\times6 cluster the 120 degree structure appears and around $\Delta = 0$ meV its energy is lower than that of 6\times8 cluster. This observation also indicates that around $\Delta = 0$ meV, the 120 degree structure is stabilized rather than the 16-site structure.

As we mentioned in Sec. III in the case of the simple Rau’s model, the classical 120 degree state is highly degenerated including 3-site and 6-site states in Fig. 4(c,d). In the case of the present ab initio Hamiltonian, the 120 degree state is expected to be slightly distorted from 120 degrees structure by varying the canting angle because of the anisotropy. Then the quantum fluctuation and the distortion would lift the degeneracy between 3-site and 6-site states, and one of them could be realized as the ground state. Although it is difficult to determine which structure is actually realized in the ground state from finite-size calculations that prohibit spontaneous symmetry breaking, we can investigate the structures of infinite system using iPEPS where we observe the spontaneous symmetry breaking measured by a nonezero local magnetization.

In order to investigate the magnetic structure, we study the relative angle $\phi$ between two spins connected by $z$ bond, which is defined as

$$\cos(\phi) \equiv \frac{(S^{(1)}) \cdot (S^{(2)})}{|S^{(1)}||S^{(2)}|}.$$  \hfill (17)

In the ideal 120 degree structure, $\cos(\phi)$ takes three values depending on the position. For the 3-site and the 6-site structures, they are

$$\cos(\phi) = \begin{cases} (1, -1/2, -1/2) & \text{3-site} \\ (-1, 1/2, 1/2) & \text{6-site}. \end{cases}$$  \hfill (18)

In the iPEPS, we obtained two sets of $\cos(\phi)$ depending on the initial conditions: They are $\cos \phi = (-0.98, 0.75, 0.58)$ and $\cos \phi = (1.00, -0.25, -0.26)$ at $\Delta = -2$ meV. Based on the comparison with the expected values of the 3-site and the 6-site structures, we interpret that the states obtained by iPEPS correspond to 3-site and 6-site states with distortion caused by the anisotropy. The energy of the expected 6-site state is slightly lower than that of the 3-site state. However, the energy difference is only $\Delta \approx 0.0003$ meV which seems to be smaller than the numerical errors that arise from the imaginary-time evolution with finite time steps and the approximate contraction of the infinite tensor network.\cite{14,15,16} Thus, based on the present numerical data, we only conclude that the 3-site state or the 6-site state are realized as the ground states in the 120 degree phase.

Both of the 3-site and 6-site 120 degree states are six-fold degenerate: $Z_4$ from the lattice translation and $Z_2$ from the time reversal symmetries. Thus, one can expect a finite-temperature phase transition with breaking of the $Z_6$ symmetry, which is usually a successive Berezinskii-Kosterlitz-Thouless (BKT) transitions. By decreasing the temperature from the high temperature paramagnetic phase, a BKT transition occurs at $T = T_{c1}$ and quasi long-range ordered phase of an emergent $U(1)$
symmetry appears in $T_{c2} < T < T_{c1}$. Below the second BKT transition temperature $T_{c2}$, the magnetic long-range order with breaking $Z_6$ symmetry is expected to be stabilized.

3. 16-site phase

Based on the DMRG and iPEPS, we found that the 16-site state, which has not been reported in the previous analyses, is stabilized in a wide region of the phase diagram. Here we investigate the magnetic structure of the 16-site state.

As we mentioned, the 16-site state is characterized by the wavevector $\mathbf{q}^*/2\pi = (1/\sqrt{3}, 1/4)$. Using the wavevector $\mathbf{q}^*$, the local magnetizations obtained from iPEPS are well reproduced by

$$
\langle \hat{S}^{(1)}(\mathbf{r}) \rangle = 
\begin{pmatrix}
 r_{xy} \cos(\mathbf{q} \cdot \mathbf{r} + \theta + \alpha) \\
 r_{xy} \cos(\mathbf{q} \cdot \mathbf{r} - \theta + \alpha) \\
 r_{z} \cos(\mathbf{q} \cdot \mathbf{r} + \alpha)
\end{pmatrix}
$$

and

$$
\langle \hat{S}^{(2)}(\mathbf{r}) \rangle = 
\begin{pmatrix}
 r_{xy} \cos(\mathbf{q} \cdot \mathbf{r} - \theta + \alpha) \\
 r_{xy} \cos(\mathbf{q} \cdot \mathbf{r} + \theta + \alpha) \\
 r_{z} \cos(\mathbf{q} \cdot \mathbf{r} + \alpha)
\end{pmatrix}
$$

where $\hat{S}^{(1)}(\mathbf{r})$ and $\hat{S}^{(2)}(\mathbf{r})$ are two spins in the unit defined in Fig. 1(c) located at $\mathbf{r}$. Note that the amplitudes and the phases $r_{xy}$, $r_{z}$, $\theta$, and $\alpha$ depend on $\Delta$. For a better understanding of the complex spin structure, we plot a schematic view of this 16-site structure in Figs. 3(c) and (f). We found that this spin structure is consistent with the eigenvectors obtained from the classical analysis described in Sec. 3.

Although the classical analysis totally ignores the quantum fluctuation effects, it still offers insight into the reason why the 16-site state has lower energy than the 120 degree state. In the region of $-1\text{meV} \lesssim \Delta \lesssim 20\text{meV}$, the lowest-energy mode (wavevector) in the classical analysis is closer to the $q_y/(2\pi) = 1/4$ (the 16-site) than the $q_y/(2\pi) = 2/3$ (the 120 degree) (see Fig. 2(a,b)). Thus, the 16-site state is more favorable than the 120 degree state. This simple interpretation also explains why the 120 degree structure is stabilized for $\Delta \lesssim -1\text{meV}$:

The lowest-energy mode of the classical analysis shows that the wavenumber approaches $q_y/(2\pi) = 2/3$ in this region.

Because the lowest modes are also close to $\mathbf{q}/(2\pi) = (1/\sqrt{3}, 1/5)$, one might speculate that a state characterized by this wavevector could be realized. However, that is not the case. Although we also calculated the energy using the iPEPS with $6 \times 10$ unit-cell, which is compatible with $\mathbf{q}/(2\pi) = (1/\sqrt{3}, 1/5)$, the energy was higher than that of the 16-site state. In this model, the state with $\mathbf{q}/(2\pi) = (1/\sqrt{3}, 1/5)$ does not appear as the ground state.

The 16-site state has eight-fold degeneracy: $Z_4$ from the lattice translation and $Z_2$ from the time reversal symmetries. In this case, we again expect a successive BKT transitions at nonzero temperatures with breaking of the $Z_8$ symmetry similar to the case of $Z_6$ symmetry.

4. Incommensurate phase

Finally, we investigate the incommensurate phase. In Fig. 7(c), we show the energies obtained by iPEPS around the incommensurate phase. In the incommensurate phase, we obtained two types of large unit-cell structure depending on the unit-cell shape used in the iPEPS. In addition to the phase transition between the 16-site phase and these large unit-cell states around $\Delta \approx 35$ meV, one can see the energy crossing between two distinct large unit-cell states around $\Delta \approx 45$ meV indicated by an arrow. Although the second energy crossing may represent a phase transition, it could instead be “finite size effects” due to finite unit-cells used in the iPEPS.
ously shift for $\Delta \gtrsim 35$ meV. It suggests the existence of the incommensurate phase in this region, the possibility of which in the quantum case is not excluded from the present analysis. Thus, we tentatively speculate that these two large unit-cell structures are a part of the incommensurate phase, where the Bragg wavenumber continuously moves with $\Delta$ in the thermodynamic limit.

V. CONCLUSIONS

In this paper, we have investigated the ground state properties of the realistic effective Hamiltonian for Na$_2$IrO$_3$. Based on the three numerical methods, ED, DMRG and iPEPS, we have firmly established that the ground state of the \textit{ab initio} Hamiltonian for Na$_2$IrO$_3$ is the zigzag(Z) state, in agreement with the experiment. In zigzag(Z) state, ferromagnetically-coupled chains are perpendicular to the $z$-bond and ordered spin moments are on the $ac$ plane of Na$_2$IrO$_3$. These features are also consistent with the experimental observation.

On the other hand, the direction of the ordered moment predicted from our \textit{ab initio} Hamiltonian, which is nearly parallel to t $(x, y, z) = (1, 1, 0)$ direction, does not match the analysis of experimental data implying the moment nearly parallel to the $a$ axis (the $(1, 1, -2)$ direction). In order to reproduce the precise direction, the weaker interactions ignored in the present \textit{ab initio} Hamiltonian, such as the couplings between honeycomb layers, could be important. However, the experimental data are not from the single crystal and more definite determination of the direction is also desired.

We have also determined the ground state phase diagram of the Hamiltonian when the trigonal distortion $\Delta$ is monitored as a control parameter away from the \textit{ab initio} value for Na$_2$IrO$_3$. We have found, at least, five distinct magnetically ordered phases: the zigzag($X, Y$), the zigzag($Z$), the 120 degree structure, the 16-site structure, and the presumably incommensurate phase that appears as 48-site states in the present calculation. For large negative $\Delta$ region, zigzag($X, Y$) states are stabilized. When we increase $\Delta$, the direction of the ferromagnetically-coupled chain in the zigzag state rotates 120 degree forming zigzag($Z$) state around $\Delta \simeq -44$ meV. In the middle of the phase diagram 120 degree structure appears in the narrow region. We have identified it as the 3-site and/or the 6-site order according to the result of the iPEPS calculations for infinite systems. When we increase $\Delta$ toward positive values, the 16-site phase is stabilized. Although the previous 24-site ED calculation has not identified this phase, we have found that it has a lower energy than that of the 120 degree structures in a wide region based on the DMRG and iPEPS calculations. For large positive $\Delta$, we have found a presumable incommensurate state. Although it is difficult to prove the "true" incommensurate nature because of the limitation of finite-size systems (ED, DMRG) or the number of the independent tensors (iPEPS), the results indicate that its magnetic unit cell is at least larger than that consisting of 48 spins. Since the trigonal distortion may be selectively controlled by substitution of elements in Na$_2$IrO$_3$, the present results give a useful guideline to understand possible rich phase diagram based on the combined effort of the reliable \textit{ab initio} approach and experimental progress.

The accuracy and reliability of the \textit{ab initio} Hamiltonian has been established in the present study through the detailed comparison with the experimental indications: The present study by combining three independent and accurate numerical algorithms has enabled a reliable approach to the thermodynamic limit by keeping high accuracy of the result.

An interesting question untouched in the present study on the \textit{ab initio} Hamiltonian and left for future studies is how we can approach the spin-liquid state starting from the magnetic Na$_2$IrO$_3$ under the normal pressure. Based on 24-site ED calculation, Yamaji \textit{et al} pointed out that a lattice expansion from Na$_2$IrO$_3$ may stabilize a Kitaev-type spin-liquid state. Since it was already shown that the iPEPS is able to describe the Kitaev spin liquid state reliably searching and designing the spin liquid state by using the combined DMRG or PEPS on the realistic and first-principles framework is an intriguing future subject.

Appendix A: the \textit{ab initio} Hamiltonian of Na$_2$IrO$_3$

In this appendix, we summarize the derivation of \textit{ab initio} Hamiltonian of Na$_2$IrO$_3$. In order to derive the effective spin Hamiltonian from the \textit{ab initio} Hamiltonian for $t_{2g}$ electrons, we employ the second order perturbation theory: Here we take the Hamiltonian of an isolated iridium atom $H_{\text{tri}} + H_{\text{SOC}} + H_U$ as an unperturbed Hamiltonian and the hopping

\textit{H}$_{\text{red}}^\text{\textit{ab initio}}$
is the largest exchange interaction of the model. In this Appendix, we describe methods used in iPEPS calculations. In our calculation, we first represent the ground-state wave-function \( |\Psi\rangle \) of the model as a tensor product state:

\[
|\Psi\rangle = \sum_{\{m_{r_1}, m_{r_2}, \ldots, m_{r_s}\}} \text{Tr} \left( A_1[m_{1,R}] A_2[m_{2,R}] \cdots A_s[m_{s,R}] \right) |m_{r_1}, m_{r_2}, \ldots, m_{r_s}\rangle,
\]

where \( A_i[m] \) is a 4-rank tensor located at the vertex \( i \) of the honeycomb lattice with three virtual indices and one physical index, \( m_i \) (see Fig. 8), and \( \text{Tr} \) means the contraction over virtual indices. In order to treat infinite system, we assume that the tensors are translationally invariant with a unit cell containing \( N = L_x \times L_y \) sites, and \( m_i = m_{i,R} \) means the \( i \)th spin on a unit cell located at \( R \) (see Fig. 8). Note that this iPEPS ansatz with a unit cell is totally different from a finite system with the periodic boundary condition. Although the same tensors repeatedly appear in the definition of the wave function, (namely, \( A_i \) does not depend on \( R \) in Eq. (B1)), the spins on equivalent but different unit-cell sites can take different values \( m_{i,R} \). Thus, the iPEPS is able to take into account infinitely large spin degrees of freedom in contrast to the finite-size algorithm.

Our iPEPS calculations are conducted in two steps. The first step is optimization of the tensors and the second step is calculation of physical quantities.

In the first step, we optimize tensors using the imaginary-time evolution by multiplying \( e^{-\tau \hat{H}} \) repeatedly. The imaginary-time evolution operator is decomposed into a product of \( e^{-\tau \hat{H}_{ij}} \) with two-body interactions \( \hat{H}_{ij} \) using Suzuki-Trotter decomposition\(^{39,40} \). Typically, we start from \( \tau = 0.1/|K| \) and gradually decrease \( \tau \) to \( \tau = 0.001/|K| \) to reach the ground state accurately, where \( K \) is the largest exchange interaction of the model. In this imaginary-time evolution, we need a truncation in order to keep the bond-dimensions of the tensor \( A_i[m] \) within a tractable size. For this truncation we use so called the simple-update method\(^{29} \). In this simple-update method we insert diagonal matrices \( \lambda_{i,j} \) on the bond connecting virtual indices and they are considered as mean-field like environments at the truncation (see Fig. 8a). For
the nearest-neighbor interactions, we use the singular value decomposition (SVD) and truncate smaller singular values\textsuperscript{25}.

In the presence of further neighbor interactions, we need to treat at least three tensors simultaneously because the tensors \( A_i \) and \( A_j \) interacting through a further-neighbor interaction are not directly connected in our tensor network. In order to treat further-neighbor interaction, we connect \( A_i \) and \( A_j \) through other intermediate tensor(s) and consider the imaginary-time evolution of the cluster as shown in Fig. 9(a). In order to construct the clusters, we use the smallest cluster (the shortest path). If there are more than one smallest clusters, we decompose the imaginary-time evolution. For instance, if two smallest clusters exist, we decompose it as \( e^{\tau \mathcal{H}_{i,j}} = e^{\tau \mathcal{H}_{i,j}/2} e^{\tau \mathcal{H}_{i,j}/2} \), and assign the different cluster to each of \( e^{\tau \mathcal{H}_{i,j}/2} \). In the case of the \textit{ab initio} Kitaev-Heisenberg Hamiltonian, the smallest cluster is unique for \( J_2 \) interaction (see Fig. 11(a)), while there are two types of the smallest cluster for \( J_3 \) interactions (see Figs. 11(b) and (c)).

In order to decompose the cluster, we use symmetric decomposition by constructing projectors, which is slightly different from the decomposition using successive SVDs\textsuperscript{29–36}.

In the case of a cluster consisting of three tensors, first we construct a cluster by combining three \( A \) tensors, mean-field like environments \( \sqrt{\lambda} \), and the imaginary-time evolution operator as shown in Fig. 9 (a). Note that we can see the cluster as a one-dimensional chain shown in the left part of Fig. 9(a), where for the sake of flowing calculations we introduce the matrix product operator (MPO) representation of the imaginary-time evolution operator.

Next, we perform two SVDs which decompose the cluster into 2 + 1 and 1 + 2 segments (see Fig. 9(b)). From these SVDs, we obtain two sets of tensors and singular values, \((U_r, \lambda_r, V_r^\dagger)\) and \((U_l, \lambda_l, V_l^\dagger)\).

Then, we construct two pairs of projectors \((P_r, \tilde{P}_r)\) and \((P_l, \tilde{P}_l)\) by using tensors obtained by the previous SVDs as shown in Fig. 9(c). Note that these projectors satisfy the relation \( \tilde{P}P = \text{identity} \).

Finally, we insert projectors into the cluster (Fig. 9(d)) and decompose it into three parts to obtain updated tensors. The updated tensors are defined as Fig. 9(e).

For larger clusters we can use the same method by considering several SVDs and creating projectors. In the actual calculation, we perform QR decomposition of tensors \( A_i \) and \( A_j \) before applying imaginary-time evolution operator in order to reduce the computational cost\textsuperscript{32–34}.

In the second step, we calculate expectation values from the obtained wave function. In this step, we use the approximate contraction based on the corner transfer matrix (CTM) method\textsuperscript{30–36}. In order to treat the several unit-cell shapes, we use the directional CTM renormalization group\textsuperscript{(30)}, with the generalization to arbitrary unit-cell sizes\textsuperscript{35–36}. As the bond dimension \( \chi \) of the CTMs, we typically use \( \chi = D^2 \) because further increase of \( \chi \) beyond \( D^2 \) did not change expectation values largely in the case of magnetically ordered phase we observed.
FIG. 10. (Color online) Schematic pictures representing the smallest clusters used in imaginary-time evolutions for further-neighbor interactions. Blue open circles represent tensors interacting through a further-neighbor interaction. Red open circles are intermediate tensors. The smallest clusters are indicated by red rectangles. (a) In the case of the second-neighbor interaction, the smallest cluster is uniquely determined. (b,c) In the case of the third-neighbor interactions, there are two types of the smallest cluster.

Appendix C: iPEPS calculation for the nearest-neighbor model

In this appendix, to compare with the full \textit{ab initio} studies and to gain further insights, we briefly show the analysis on a simplified nearest-neighbor \textit{ab initio} Hamiltonian for Na$_2$IrO$_3$ where we neglect the second and the third neighbor interactions and consider only the nearest-neighbor interactions. For this analysis, we use tensor network methods with the iPEPS ansatz. In the case of the nearest-neighbor interaction, we can easily apply the so-called “full update” method\textsuperscript{[26,30]}, which is expected to be more accurate than the simple update used in the analysis of the main part. By considering the nearest-neighbor interaction only, we can compare the results obtained by the simple update and the full update, and estimate the reliability of simple update method.

In Fig. 11(a), we show the energy of the nearest-neighbor \textit{ab initio} Hamiltonian as a function of the bond dimension $D$. Although the energies obtained by the full update method is slightly lower than those of the simple update at the same $D$, the difference is quite small compared with the decrease in the energy with increasing the bond dimension. Thus, the simple update seems to be sufficiently reliable for the present \textit{ab initio} Hamiltonian whose ground state is expected to be a magnetically ordered state.

In order to further investigate the nature of the ground state, we show the spin correlation along the $y$-direction (see Fig. 1 in Fig. 11(b). One can see that the spin correlation shows four-site periodicity, which is totally different from the zigzag$(Z)$ structure observed in the ground state of \textit{ab initio} Hamiltonian including the second and the further neighbor interactions. Indeed, the ground state of the nearest-neighbor \textit{ab initio} Hamiltonian is an 8-site state different from the zigzag$(Z)$ state. Thus, in order to obtain the experimentally observed zigzag$(Z)$ state, the further-neighbor interactions are crucially important.

Note that the iPEPS has been able to describe the Kitaev spin liquid state by using the full update optimization if it is applied to the Kitaev-Heisenberg model\textsuperscript{[22]}. Therefore, the method is capable of describing the Kitaev spin liquid in general. Nevertheless, we did not obtain the spin liquid state for a more realistic Hamiltonian with only the nearest-neighbor interaction truncated from the \textit{ab initio} Hamiltonian even if we used the full update. Furthermore, the further-neighbor interactions stabilize the magnetically ordered state rather than the Kitaev spin liquid, as we see in the ground state of the full \textit{ab initio} Hamiltonian, which includes the second and the third neighbor interactions. Therefore, our result shows that the magnetic order rather than the spin liquid is robust around the \textit{ab initio} parameter values, consistently with the experimental results.
