Functional regeneration after axonal injury requires transected axons to regrow and reestablish connection with their original target tissue. The spontaneous regenerative mechanism known as axonal fusion provides a highly efficient means of achieving targeted reconnection, as a regrowing axon is able to recognize and fuse with its own detached axon segment, thereby rapidly reestablishing the original axonal tract. Here, we use behavioral assays and fluorescent reporters to show that axonal fusion enables full recovery of function after axotomy of Caenorhabditis elegans mechanosensory neurons. Furthermore, we reveal that the phospholipid phosphatidylserine, which becomes exposed on the damaged axon to function as a “save-me” signal, defines the level of axonal fusion. We also show that successful axonal fusion correlates with the regrowth potential and branching of the proximal fragment and with the retraction length and degeneration of the separated segment. Finally, we identify discrete axonal domains that vary in their propensity to regrow through fusion and show that the level of axonal fusion can be genetically modulated. Taken together, our results reveal that axonal fusion restores full function to injured neurons, is dependent on exposure of phospholipid signals, and is achieved through the balance between regenerative potential and level of degeneration.

Significance

Nervous system injury can cause lifelong disability, because repair rarely leads to reconnection with the target tissue. In the nematode Caenorhabditis elegans and in several other species, regeneration can proceed through a mechanism of axonal fusion, whereby regrowing axons reconnect and fuse with their own separated fragments, rapidly and efficiently restoring the original axonal tract. We have found that the process of axonal fusion restores full function to the C. elegans PLM neurons after laser-induced axotomy, reestablishing active transport within the axon. We show that the amount of PS

“save-me” signals exposed on the axonal membrane strongly correlates with the level of axonal fusion and increases with age. Thus, despite the decrease in regrowth that occurs in aged animals, a higher percentage of reconnection events is made possible because of enhanced levels of internalized PS, increasing the potential for complete repair of the transected PLM axon by fusion. Furthermore, we reveal that the length of retraction between the two axon segments after injury and the amount of regenerative branching also contribute to the percentage of axons regrowing through fusion. We also show that genetically enhancing the regrowth capacity of PLM increases the frequency of axonal fusion. Taken together, these findings define axonal fusion as a fully functional mechanism of repair.

Results

Axonal Fusion Fully Restores Function to Transected Neurons. To determine whether regenerative axonal fusion (Fig. L4 and Fig. S1A) conveys functional recovery, we focused on the bilateral pair of PLM neurons that mediate forward acceleration upon gentle mechanical stimulation applied to the posterior half of the animal’s body. We assayed PLM function using the light touch assay (22). To facilitate our analyses and to make them more precise, we focused on a single PLM neuron by killing one of two neurons and then performing axotomy on the remaining one. One of the PLM neurons was ablated 20 h posthatching, and the axon of the contralateral PLM neuron was transected 24 h later at the L4 stage (Fig. 1B). A light touch assay was performed on these animals at both 24 and 48 h postaxotomy followed by epifluorescence microscopy analysis to determine if the axon had regrown through axonal fusion. As shown in Fig. 1C, we found no functional recovery at 24 h postaxotomy, whereas at 48 h striking recovery was apparent in animals in which axonal fusion occurred (Fig. 1 D and F). Significant deterioration of function occurred in the absence of axonal fusion (Fig. 1 D and E). The functional recovery observed after axonal fusion was indistinguishable from the function of PLM neurons in control animals in which a mock axotomy was performed (Fig. 1 D, G, and H), showing that axonal fusion restores full neuronal function. Touch assays performed in animals with one PLM ablated and the axon of the second PLM severed 6 h before analysis revealed that neuronal function rapidly declines after axotomy (Fig. S1B). Interestingly, the reduction in function at this time point was almost identical to that found at 24 h postaxotomy in animals without fusion (Fig. S1C). This indicates that PLM function does not significantly worsen between the 6- and 24-h time points, which is likely a reflection of the slow rate of degeneration that occurs in the separated distal segment (23). We observed no change in the function of the anterior mechanosensory circuit [mediated by the anterior lateral microtubule (ALM) and anterior ventral microtubule (AVM) neurons] after axotomy or ablation of PLM (Fig. 1I and J and Fig. S1D), highlighting the specificity of these procedures.

We previously showed that diffusible fluorophores can traverse across the site of axonal fusion in both anterograde and retrograde directions (17). Because of the critical importance of intact transport mechanisms for neuronal function (24), we assessed whether active transport mechanisms are also restored by axonal fusion. To achieve this, we used a functional GFP-tagged version of UNC-104/kinesin-3 (25), a motor protein responsible for the movement of synaptic vesicles to presynaptic sites (26). Expression of this molecule in the PLM neurons produced a weak GFP signal

![Fig. 1. Axonal fusion restores complete function to transected PLM neurons.](image-url)
throughout the majority of the axon, with strong fluorescence (pooling) observed at the distal end of the axon and at presynaptic sites (25, 27) (Fig. S2A). We used this pooling of GFP fluorescence as a readout for axonal transport. As expected, axotomy induced pooling of GFP on the proximal side of the cut site, indicating that the axon had been transected and that transport had been blocked (Fig. 2 and Fig. S2B). As shown in Fig. 2 B–F, this blockage of axonal transport was released after axonal fusion, whereas GFP pooling remained in those animals in which axonal fusion did not occur (Fig. S2C). Thus, axonal fusion reestablishes movement of UNC-104/kinesin-3 and active anterograde transport.

To further investigate functional recovery, we asked if the regenerative capacity of PLM could be restored by axonal fusion. To address this, we performed experiments in which the PLM axon was transected at two different sites: first, at the typical site 50 μm anterior to the cell body and second, immediately afterward at a more anterior point (10 μm posterior to the synaptic branch, equating to ≈250 μm anterior to the cell body) (Fig. 3A). We compared the length of regrowth from the second axotomy site at 24 and 48 h postaxotomy in animals with no fusion at the first site as well as in those where axonal fusion occurred at the first site. Interestingly, the vast majority of animals (irrespective of fusion status at the first site of axotomy) displayed regrowth from the second cut within the first 24 h postaxotomy (33 of 34 animals with an average of 33.09 ± 3.84 μm of regrowth) (Fig. 3B, white bars), showing that the PLM axon is able to mount a regenerative response even when separated from its soma. This regrowth confirms previous reports of growth cone activity in severed PLM segments (28), as well as sustained functionality of sensory neurites when separated from their soma (29, 30). However, animals without fusion at the first cut site (Fig. 3C) displayed little to no additional regrowth from the second site after this time point, and in some cases displayed reduced regrowth, likely because of pruning or retraction of the new branches after the 24-h time point (0.69-fold change in average length of regrowth from 24 to 48 h postaxotomy) (Fig. 3B). Conversely, axonal fusion at the first cut site (Fig. 3D) greatly facilitated regeneration from the second site, with significant regrowth observed in these animals between the 24- and 48-h time points (1.36-fold change in regrowth) (Fig. 3B). Remarkably, in one of the animals analyzed, we found evidence of fusion occurring at both sites (Fig. 3E and F). Taken together, these data provide strong support to the notion that regenerative axonal fusion leads to restoration of neuronal structure and function.

The Level of Axonal Fusion Is Modulated by Age. To define how the level of axonal fusion changes with age, we performed PLM axotomies in animals at each of the four developmental larval stages and in four different adult stages. This revealed that larval-stage animals present a relatively low level of reconnection and successful fusion [defined as maintenance of the separated distal segment after reconnection had been made (17, 18)] compared with adult-stage animals that displayed a high capacity for using axonal fusion as a means of repair (Fig. 4A and B and Table S1). As it is well-established that the length of regrowth declines with advancing age, we next determined how the level of reconnection compared with the length of regrowth. To account for the dramatic increase in the length of the PLM axon that occurs during development (mean length 189.84 ± 7.94 μm at L1 compared with 571.71 ± 17.21 μm at the 5-d-old adult stage; n ≥ 14, P-value from t test: P < 0.001), we calculated the average length of regrowth relative to the total length of the PLM axon. Regrowth capacity was maximal in the early larval stages and significantly reduced in the adult stages (Fig. 4C and Table S1). Intriguingly, the extent of reconnection showed a strong inverse correlation with the average length of regrowth (r = −0.856) (Fig. S3A). We also found that the level of reconnection inversely correlated with the length of retraction after axotomy (r = −0.557) (Fig. 4D and Fig. S3B) and with the extent of axonal degeneration (r = 0.732) (Fig. 4E and Fig. S3C) and directly correlated with the amount of regenerative branching (r = 0.843) (Fig. 4F and Fig. S3D).

PS Exposure Modulates the Extent of Axonal Fusion. We recently reported that PS is exposed on the external surface of the PLM axon after injury and proposed that this acts as an essential save signal for recognition by the regrowing axon (18). To determine whether this PS signal is modulated by age and may, therefore, be responsible for mediating the different levels of axonal fusion across ages, we visualized PS with an inducible mRFP-tagged version of Annexin V (Phsp::sAnxV::mRFP) (31). sAnxV::mRFP expression was induced by heat shock 4 h before PLM axotomy, and PS exposure was quantified 1 h postaxotomy.

Fig. 2. Axonal transport is restored after axonal fusion. (A) Images and schematic 6 h after axotomy of PLM expressing diffusible tagRFP and UNC-104::GFP. Transection of the PLM axon prevents the normal anterograde transport, leading to pooling of UNC-104::GFP fluorescence on the proximal side of the cut site. Closed arrowheads designate cut sites. (Scale bars: 25 μm.) (B) By 24 h postaxotomy, axonal fusion has occurred in the same animal as shown in A, restoring axonal transport and releasing the pool of UNC-104::GFP. a time point at which we previously observed strong exposure of PS (18). As shown in Fig. 5 A and B, the relative levels of PS exposure closely mirrored the percentages of reconnection that we observed (Fig. 4C), with very low levels of ANXV binding detected in larval-stage animals compared with much stronger levels in adults. These different levels of PS exposure displayed a very strong correlation with the levels of reconnection \( r = 0.914 \) (Fig. 5C), indicating that the ability of PLM to undergo axonal fusion is strongly mediated by the amount of PS exposed after injury. Interestingly, we observed comparable levels of PS exposure on both the distal and proximal sides of the cut site across all ages analyzed (Fig. S4A). Similar observations have been made during apoptosis, in which PS exposure on the engulfing cell, in addition to the apoptotic cell, is essential for the efficient clearance of dying cells (31–33). Our data suggest the similar importance of PS exposure on both sides of the membrane, and indicate that the level of PS exposure on the transected axon defines whether regeneration can occur through axonal fusion.

We previously showed that proximal-distal reconnection during axonal fusion is mediated by components of the apoptotic recognition pathway (18). The secreted lipid binding protein TTR-52/transthyretin, the membrane-bound CED-7/ABC transporter, the PS receptor PSR-1, and the intracellular adapter CED-6/GULP function in a molecular cascade to allow the regrowing proximal axon to recognize its separated distal segment (18). To determine if these molecules affect PS exposure and to better define the

**Fig. 3.** Axonal fusion facilitates regrowth from a second site of axotomy. (A) Schematic representation of a lateral view of the PLM neuron showing where the two cuts were performed. (Upper) shows the first axotomy site = 50 μm from the PLM cell body, and (Lower) shows the second site = 10 μm from the PLM synaptic branch. The second axotomy was performed immediately after the first. (B) Average length of regrowth at 24 h (white bars) and 48 h (black bars) postaxotomy quantified for animals that displayed no fusion at the first fusion and those in which fusion was observed at the first axotomy site. Bars represent mean ± SE; \( n \) values are within each bar. \( P \) value is from Tukey’s multiple comparisons test. ** \( P < 0.01 \). Images and schematic of an animal 24 h postaxotomy (C) in which reconnection and fusion have failed to occur at either cut site and (D) in which fusion has occurred only at the first cut site. (E) Images and schematic of an animal 48 h postaxotomy with fusion occurring at both cut sites. Dashed boxes highlight regions magnified in Right, which shows the two fusion sites after transection 50 μm anterior from the cell body (i) and 10 μm posterior from the synaptic branch (ii). This was the only animal in which double fusion was observed; one other animal displayed reconnection at the second site but not successful fusion. No reconnection events were observed at the second site in animals without fusion at the first site. Closed arrowheads designate the cut sites, and open arrowheads designate the fusion sites. Autofluorescence from the intestinal cells is visible in some images. (Scale bars: C–E, 25 μm; E, i and ii, 10 μm.) pathway of regrowth, reconnection, and fusion, we quantified sAmV binding in animals carrying mutations in the encoding genes. As shown in Fig. S5D and Fig. S4B, mutations in any of the genes involved in reconnection failed to significantly alter the level of PS exposure on the PLM axon after axotomy. Next, we performed similar experiments in animals lacking the fusogen EFF-1, which is required for fusing the axonal membranes after reconnection occurs (5, 18). Similar to our findings for the genes involved in reconnection, loss of EFF-1 did not affect the level of PS exposed after axotomy compared with WT animals (Fig. S5D and Fig. S4B). Finally, we assessed PS exposure in animals defective for regrowth by targeting the MAPKK kinase DLK-1, a key intrinsin regulator of axonal regeneration (3, 4). Although loss of DLK-1 largely abolished PLM regrowth (Fig. 5E), the level of PS exposure was not significantly changed compared with WT animals (Fig. S5D and Fig. S4B). Overall, these results show that PS exposure is an early, initiating event for axonal fusion, which is not affected by disrupting downstream molecules involved in regrowth, reconnection, or fusion.

The Location of Axotomy and the Genetic Background Influence the Level of Axonal Fusion. To determine whether axonal fusion is affected by different genetic backgrounds as previously suggested (5), we compared the regrowth of PLM in four different transgenic strains: zdIs4(Pmec-4::GFP), which we routinely use for analysis; zdIs4(Pmec-4::GFP), which is an independent but similar transgene integrated in a different region of the genome; jsIs973(Pmec-7::mRFP), in which PLM is labeled with the red fluorescent protein mRFP; and uIs115(Pmec-17::tagRFP), in which a different red fluorescent protein (tagRFP) labels PLM. Interestingly, we found differences in many aspects of regeneration between the four transgenes, including in the percentages of reconnection and successful fusion (Fig. 6A), the length of regrowth, the extent of degeneration in the separated distal fragment, and the level of regenerative branching (Fig. 5S). PLM neurons in the jsIs973 background displayed a large increase in the percentage of reconnection, increasing from $\approx40\%$ in zdIs5 and zdIs4 to more than $70\%$ (Fig. 6A), which corresponded to a large increase in the level of regenerative branching (Fig. 5S). Animals analyzed in the zdIs4 background displayed an $\approx50\%$ reduction in the level of successful fusion compared with the other three transgenes (Fig. 6A) as well as a similar reduction in regrowth potential (Fig. 5S). To assess whether these differences were associated with variation in mechanosensory function between the strains, we performed two-trial touch assays in the absence of any manipulations. The responses of animals carrying the zdIs5, jsIs973, and uIs115 transgenes were indistinguishable from one another; however, those with the zdIs4 transgene displayed significantly reduced responses to both anterior and posterior stimulations (Fig. 6B and C). To determine if these differences would affect recovery of function after axotomy, we repeated the assays shown in Fig. 1 in animals carrying the zdIs4 transgene. As shown in Fig. 6D and E, animals displaying axonal fusion again displayed a strong recovery of function $48\,h$ postaxotomy that was not significantly different from the mock axotomy condition. Disruption of the posterior mechanosensory neurons again had no effect on the function of the anterior mechanosensory neurons (Fig. 6F and G). Thus, despite the differences in penetrance between the genetic backgrounds, a substantial number of animals displayed regenerative...
axon fusion in all four, and this was again concomitant with full recovery of function.

To assess whether the dynamics of axonal fusion vary along the length of the PLM axon, we performed axotomies at increasing distances from the cell body and assessed regrowth. Axotomies were performed at 50-μm intervals beginning 50 μm from the cell body and extending as far as possible toward the synaptic branch (250 μm), after which the PLM axon does not regrow (1). As shown in Fig. 7A, we found a significant reduction in the percentage of reconnection when we performed axotomies farther from the cell body, with a more than fourfold reduction observed when the axon was severed 200 μm or more from the soma. The level of successful fusion after reconnection was also reduced, with a success rate of 50% or less when the axon was cut beyond the typical 50-μm distance, at which we find an 83% success rate (Fig. 7B and Table S1).

Severing the PLM axon at the farther distances led to modest but significant differences in the average length of regrowth and retraction, in the degeneration of the separated fragment, and in the level of branching observed after axotomy (Fig. S6A-D). Analysis of externalized PS using the sAnxV::mRFP marker revealed a 35% reduction in exposure on the distal axon segment when axotomy was performed 200 μm from the PLM cell body compared with when it was cut at 50 μm (Fig. 7C). Although this reduction did not reach statistical significance (P = 0.1003 from t test), the large decrease adds support to the notion that PS exposure is a critical factor in determining the level of axonal fusion.

We next assessed whether sex differences affected regeneration of the PLM neurons. As shown in Fig. 7D, PLM displayed almost identical percentages of reconnection and successful fusion in males and in hermaphrodites. Males were also similar in their average length of regrowth, branching, and extent of degeneration in the separated axon segment (Fig. S6E, G, and H), although they did show significant differences in the length of retraction (Fig. S6F). Taken together, these results suggest that sex does not have a strong effect on the dynamics of axonal regeneration in C. elegans.

The Level of Axonal Fusion Can Be Enhanced by Increasing Regrowth Potential. The DLK-1 mitogen-activated kinase pathway is a major conserved regulator of axonal regeneration (34). The ubiquitin ligase RPM-1 negatively regulates DLK-1; loss of RPM-1 stabilizes DLK-1, a condition that has previously been shown to increase axonal regeneration of the C. elegans GABAergic motor and
Fig. 6. Axonal fusion is modulated by genetic background. (A) Quantification of reconnection and successful axonal fusion in different genetic backgrounds: zdIs5(Pmec-4::GFP), zdIs4(Pmec-4::GFP), jstIs73(Pmec-7::mRFP), and uIs115(Pmec-17::tagRFP). Bars represent mean ± SE of proportion; n values are within each bar. P values are from t tests. *P < 0.05. (B and C) Behavioral response of four different transgenic backgrounds to mechanical stimulation (two-trial light touch assays) performed either on the anterior (B) or posterior (C) section of the animals. (D and E) A light touch assay was performed on zdIs4 animals with one PLM neuron ablated and the second transected as per Fig. 1. Responses were recorded at 24 h (D) and 48 h (E) postaxotomy. Animals with one PLM ablated and no axotomy performed on the second PLM neuron were used as controls (mock axotomy). Bars represent mean ± SE; symbols represent individual animals. P values are from Tukey's multiple comparisons test. ns, not significant. *P < 0.05; **P < 0.01. (F and G) Backward response to anterior light touch at 24 h (F) and 48 h (G) postaxotomy for animals in which one PLM neuron was ablated and the axon of the second PLM was either transected or left intact (mock axotomy); disruption of the posterior mechanosensory neurons did not affect the function of the anterior mechanosensory neurons.

Discussion
Complete regeneration of neuronal circuits is essential for full recovery of function after injury to the nervous system. Here, we show that regenerative axonal fusion achieves this goal through restoration of the damaged neuron and complete functional recovery. Axonal fusion prevents degeneration of the detached axon segment, restores membrane and cytoplasmic continuity (17), reinstates axonal transport and the regrowth capacity of the axon, and as a consequence, restores full functionality within 48 h of injury. Previous research in other species is also supportive of axonal fusion as an efficient means of restoring function after injury. Bedi and Glanzman (12) reported that an axonal fusion-like mechanism in cultured mechanosensory neurons of *Aplysia californica* restored cytoplasmic continuity and suppressed the hyperexcitability and morphological changes normally associated with damaged axons. Furthermore, axonal fusion in the regenerating axons of crayfish, earthworms, and leeches allows action potentials generated proximal to the lesion to pass through the fusion site and into the distal axon segments (13–15). Thus, axonal fusion seems to provide an efficient means of achieving functional recovery in every species in which it has been observed.

The observed decline in regrowth capacity of the PLM neurons with increasing age accords with previous data obtained in this species (34), and also parallels observations made in mammalian species (35–37). However, somewhat counterintuitively, we observed a large increase in the level of axonal fusion with advancing age and found that higher percentages of reconnection strongly correlate with reduced regrowth capacity. Perhaps more predictably, we also observed that the reconnection percentage strongly correlated with reduced retraction, reduced degeneration in the distal segment, and increased number of branches extending from the regrowing axon. These factors facilitate fusion by providing a reduction in the distance between the proximal and distal ends of the axon, a more intact distal segment, and a greater probability of contact between the two segments. Moreover, the increased frequency of axonal fusion observed in the regrowth-promoting *rpm-1* mutant background shows that declining regrowth potential can be uncoupled from the increased level of fusion. Thus, although older animals lack the regrowth capacity of their younger counterparts, they maintain sufficient levels of regrowth to permit axonal extension across the cut site.

We observed a very strong correlation between the relative level of PS exposure and the reconnection percentage. We also showed that PS exposure is unchanged by mutations in pathways that disrupt regrowth, reconnection, or fusion. These data together with our previous research showing PS exposure on the PLM axon within 15 min of axotomy (18) strongly support the notion that PS exposure is a crucial early event that is required for proximal–distal reconnection to occur. PS is normally restricted to the inner leaflet of plasma membranes through the activity of flippase proteins that translocate it in an ATP-dependent manner from the outer to the anterior ventral mechanosensory neurons (4, 21). To determine if the level of axonal fusion could be enhanced by simply increasing the length of regrowth, we analyzed regeneration in animals carrying a loss-of-function allele in *rpm-1*. As shown in Fig. 7E, we found that animals carrying the *rpm-1(ju41)* mutant allele displayed a 39% increase in the length of PLM regrowth 24 h postaxotomy, whereas there was no effect on the length of retraction, level of degeneration in the separated distal segment, or the average number of regenerative branches (Fig. S6 I–K). This increase in length of regrowth was sufficient to significantly increase the percentage of reconnection from 43% in WT animals to 71% in *rpm-1(ju41)* animals (Fig. 7F), and resulted in a 30% increase in the total number of animals regrowing through axonal fusion (35.7% in the WT compared with 65.7% in *rpm-1* mutants) (Table S1). Thus, these data indicate that genetic enhancement of regrowth capacity can be used to facilitate axonal fusion.
inner leaflet of the membrane (38). Initiation of cellular events, such as apoptosis or platelet activation, disrupts this polarized distribution of PS through the caspase-mediated inactivation of flipases (39) and activation of scramblase proteins through caspase- and/or Ca\textsuperscript{2+}-dependent mechanisms (40–43). Consequently, PS is aberrantly exposed on the external leaflet of the membrane, where it serves as a recognition signal to trigger the phagocytic engulfment of apoptotic cells (44) or act as a scaffold for coagulation factors (45). In the case of axonal fusion, exposed PS serves as a save-me signal that mediates the recognition between the regrowing axon and its detached segment (18). Given that the loss of either the executioner caspase CED-3 or its activator CED-4/APAF-1 does not significantly affect the level of axonal fusion in the PLM neurons (18), it is likely that the exposure of PS after axonal injury is not caspase-dependent. Although C. elegans possesses three other caspase-like molecules (46) that are yet to be studied in the context of axonal fusion, we speculate that Ca\textsuperscript{2+}-dependent scramblases are likely to mediate PS exposure after axotomy in the PLM neurons. Indeed, axotomy of these neurons induces rapid calcium transients that correlate with the length of regrowth (5) and also correspond with the rapid exposure of PS that occurs after axotomy (18). Our data showing no change in PS exposure after axotomy in the WT and rpm-1(ju41) mutants suggests that they do not perform the same function during axonal fusion as they do during apoptosis. Alternatively, they might mediate the transfer of PS at later time points during the regenerative process (i.e., beyond the 1-h time point analyzed in this study) or possess redundant roles. Although the role of PS exposure in mediating axonal fusion is clear, its function on the proximal side of the cut site and exactly how it is regulated remain to be determined.

PS has previously been shown to carry out important roles in diverse membrane fusion events. During the process of exocytosis, SNARE proteins mediate the docking of synaptic vesicles with their presynaptic target membranes (47). Temporal control for this process is provided by synaptotagmin-1 in the membrane of the vesicles. Binding of Ca\textsuperscript{2+} to synaptotagmin-1 allows it to insert into the target membrane and permits interactions with SNARE proteins and membrane phospholipids to induce fusion between the two membranes (48). PS is essential for efficient binding of synaptotagmin-1 to the membrane, increasing the depth of its membrane penetration and reducing its dissociation rate from the membrane (49). PS is also vital for the normal function of α-synuclein, a Parkinson’s disease-associated protein, in promoting SNARE complex assembly and vesicle docking (50). In addition, PS exposure is a key event for fusion events outside of the nervous system, including during homotypic fusion essential for correct morphogenesis and function of the endoplasmic reticulum (51) and for myotube formation (52), macrophage polykaryon formation (53), fertilization of eggs (54), and development of the placental...
synaptotrophoblast (55). Thus, nonapoptotic exposure of PS seems to be play a common role in various types of membrane fusion events through interactions with a variety of different proteins. Exposed PS also serves as a co-factor for viral infection. Binding of HIV-1 to receptors on its target cell surface induces PS exposure, which plays an important role in mediating membrane fusion and viral infection (56). Furthermore, a number of other viruses require PS for efficient host-cell infection, including vaccinia, dengue, and Ebola (57–59). Intriguingly, the E glycoprotein of dengue virus and EFT-1 are structurally and functionally related class II fusion proteins (60). As both proteins require PS for membrane fusion, it is possible that PS has similar functions during the various cell-cell, virus-cell, and axon-axon fusion events. It is also conceivable, therefore, that, under specific circumstances, structurally similar fusion proteins in other species might also be capable of mediating axonal fusion-like regenerative paradigms.

An important finding from this study is that the level of axonal fusion can be endogenously modulated by age, injury site, and the level of PS exposure, and can be ectopically increased by enhancing regrowth capacity. This knowledge combined with the identification of the molecular pathways that mediate the process (18) significantly build on our understanding of this efficient and functional mechanism. Extensive recent reports have established genetic targets that could be used to significantly promote regeneration in mammalian systems (61) and establish viable strategies with which to induce axonal fusion-like mechanisms to repair peripheral nervous system injuries (62). A complete understanding of the axonal fusion process in *C. elegans* may, therefore, aid in the development of paradigms to induce axonal fusion mechanisms for therapeutic purposes.

**Methods**

*C. elegans* Strains and Genetics. Maintenance, crosses, and other genetic manipulations were all performed via standard procedures (63). Hermaphrodites were used for all experiments unless otherwise specified and were grown at 20 °C on nematode growth medium (NGM) plates seeded with OP50 *Escherichia coli*. The *ced-6*(t1813), *ced-7*(n2690), *dlk-1*(u476), *eff-1*(ok1021), *par-1* (ok714), *rpm-1*(u411), and *trl-52*(sm211) mutant strains were used together with the following transgenes: *jdIs1111(Prmec-4::UNC-104::GFP)* (25), *jsl5375(Pmec-7::mRFP)* (64), *smIs12(Pmec17::tagRFP)* (31), *jsdIs115(Pmec-17::tagRFP)* (65), *zdIs4(Pmec-4::GFP)*, and *zdIs5(Pmec-4::GFP)*. A full list of strains is provided in Table S2.

**Laser Axotomy and Microscopy.** Axotomies were performed as previously described (17, 18) at the L1 (7 h posthatching), L2 (16 h posthatching), and L3 (26 h posthatching) stages. Animals with only a primary regrowth branch from these analyses. Retraction length was recorded by measuring the distance from the PLM cell body to the end of the original axon 24 h postaxotomy. Animals in which the separated distal axon had been completely cleared were excluded. Instead, the laser was fired at a point 10 μm away from the soma. Mock cell ablations were performed similarly, with laser pulses directed to the tail with an eyebrow hair, and their responses were recorded. Full responses were defined as movement backward (after head touch) or forward (tail touch) more than a body length; partial responses were when the animal responded but moved less than a body length. No responses were when no change in behavior occurred. The individual responses of all of the animals for a given population were combined to represent the percentage of response for a specific strain.

**Quantification of UNC-104::GFP.** The maximum intensity of tagRFP and UNC-104::GFP was calculated 6 h postaxotomy from a region at the end of both the proximal and distal sides of the cut site using ImageJ 1.47v software. GFP intensity was normalized to tagRFP, and these values were used to compare the relative GFP intensity on the proximal and distal cut sites. GFP intensity from the posthatching was quantified from measurements taken at the fusion site or at the end of the longest regrowing branch before being compared with the distal side of the cut site. “No cut” control animals were imaged without axotomy, and measurements were calculated as 50 μm anterior to the PLM cell body.

**Quantification of Annexin V.** To induce sAnx::mRFP expression, *smIs52* (Phsp16-2::sAnxV::mRFP) animals were imaged at 55°C for 30 min 4 h before analysis. PS exposure was visualized with a Leica SP8 confocal microscope equipped with LAS X software. Green fluorescence was visualized with a 488-nm laser (2.4% power; 600 gain; 8x averaging), and red fluorescence was visualized with a 543-nm laser (100% power; 1,000 gain; 8x averaging). Fluorescence intensities were calculated from line scans recorded in 15-μm measurements along both the proximal and distal axon segments using ImageJ 1.47v software. To avoid fluorescence caused by colateral damage, line scans were taken 5 μm away from the cut site. mRFP expression 1 h postaxotomy was calculated relative to expression levels immediately preceding axotomy.

**Statistical Analysis.** Statistical analysis was performed using GraphPad Prism 7 and Primer of Biostatistics. The error of proportions was used to assess variation across a single population, two-way comparison was performed using the t test, and ANOVA was used for comparing groups with more than two samples followed by Tukey’s multiple comparisons or Kruskal–Wallis (for comparisons of axonal integrity scores, which did not follow a normal distribution) post hoc tests.

**ACKNOWLEDGMENTS.** We thank Ding Xue, Sandhya Koushika, Martin Chalfie, and Michael Neton for helpful discussions. Rob Coakley, and Ming Soh for manuscript comments, and members of the laboratory of B.N. and Roger Pocock’s laboratory for valuable input. Some strains were
