We use a double quantum dot as a frequency-tunable on-chip microwave detector to investigate the radiation from electron shot-noise in a near-by quantum point contact. The device is realized by monitoring the inelastic tunneling of electrons between the quantum dots due to photon absorption. The frequency of the absorbed radiation is set by the energy separation between the dots, which is easily tuned with gate voltages. Using time-resolved charge detection techniques, we can directly relate the detection of a tunneling electron to the absorption of a single photon.

The interplay between quantum optics and mesoscopic physics opens up new horizons for investigating radiation produced in nanoscale conductors [1, 2]. Microwave photons emitted from quantum conductors are predicted to show non-classical behavior such as anti-bunching [3] and entanglement [4]. Experimental investigations of such systems require sensitive, high-bandwidth detectors operating at microwave-frequency [5]. On-chip detection schemes, with the device and detector being strongly capacitively coupled, offer advantages in terms of sensitivity and large bandwidths. In previous work, the detection mechanism was implemented utilizing photon-assisted tunneling in a superconductor-insulator-superconductor junction [6, 7] or in a single quantum dot (QD) [8].

Aguado and Kouwenhoven proposed to use a double quantum dot (DQD) as a frequency-tunable quantum noise detector [9]. The idea is sketched in Fig. 1(a), showing the energy levels of the DQD together with a quantum point contact (QPC) acting as a noise source. The DQD is operated with a fixed detuning $\delta$ between the electrochemical potentials of the left and right QD. If the system absorbs an energy $E = \delta$ from the environment, the electron in QD1 is excited to QD2. This electron may leave to the drain lead, a new electron enters from the source contact and the cycle can be repeated. The process induces a current flow through the system. Since the detuning $\delta$ may be varied continuously by applying appropriate gate voltages, the absorption energy is fully tunable.

The scheme is experimentally challenging, due to low current levels and fast relaxation processes between the QDs [10]. Here, we show that these problems can be overcome by using time-resolved charge-detection techniques to detect single electrons tunneling into and out of the DQD. Apart from giving higher sensitivity than conventional current measurement techniques, the method also allows us to directly relate a single-electron tunneling event to the absorption of a single photon. The system can thus be viewed as a frequency-selective single-photon detector for microwave energies. This, together with the fact that the charge-detection methods allow precise determination of the device parameters, provide major advantages compared to other setups [2, 3, 5, 6, 7, 8].

The sample [Fig. 1(b)] was fabricated by local oxidation [11] of a GaAs/Al$_{0.3}$Ga$_{0.7}$As heterostructure, containing a two-dimensional electron gas (2DEG) 34 nm below the surface (mobility $3.5 \times 10^5$ cm$^2$/Vs, density $4.6 \times 10^{11}$ cm$^{-2}$). The sample also has a backgate 1400 nm below the 2DEG, isolated by a layer of low-temperature-grown (LT)-GaAs. The structure consists of two QDs in series (marked by 1 and 2 in the figure) with a nearby QPC used as a charge detector (lower-right corner of the figure). The dots are coupled via two separate tunneling barriers, formed in the upper and lower arms between the QDs. For this experiment, only the upper arm was kept open, the lower one was pinched off. The gates T, B, L and R are used to tune the height of the tunneling barriers, while gates G1 and G2 control the

FIG. 1: (a) Schematic for operating a double quantum dot (DQD) as a high-frequency noise detector. The tunable level separation $\delta$ of the DQD allows frequency-selective detection. (b) Sample used in the measurement, with two QDs (marked by 1 and 2) and a near-by QPC. (c) Charge stability diagram of the DQD, measured by counting electrons entering the DQD. The numbers in brackets denote the charge population of the two QDs. (d) Typical traces of the detector signal, taken at point I (red) and II (black) in (c).
electrochemical potentials of the two QDs.

Due to electrostatic coupling between the QDs and the QPC, the conductance of the QPC is strongly influenced by the electron population of the QDs [12]. By voltage biasing the QPC and continuously monitoring its conductance, electrons entering or leaving the QDs can be detected in real-time [13, 14, 15]. The time resolution is limited by the noise of the amplifier and the capacitance of the cables, giving our setup a bandwidth of a few kHz. Operating the QPC in a mode analogous to the radio-frequency single electron transistor [16] should make it possible to increase the bandwidth significantly.

The detection bandwidth puts an upper limit on the transition rates that can be measured [17]. In the experiment, we tune the tunneling rates between the QDs and the source/drain leads to be around 1 kHz, while the coupling $t$ between the dots is kept at a relatively large value ($t = 32 \, \mu eV$, corresponding to 7.7 GHz). The large intradot coupling enhances the probability for the photon absorption process sketched in Fig. 1(a), but it also means that intradot transitions will occur on a timescale much faster than what is detectable.

Figure 1(c) shows a measurement of the count rate for electrons entering the DQD versus voltages on gates $G_1$ and $G_2$, with 600 $\mu V$ bias applied between source (S) and drain (D). Resonant tunneling of electrons between the DQD and the source and drain contacts give rise to lines forming a hexagon pattern. At the crossing points of the lines, triangles with electron transport appear due to the QPC conductance than fluctuations in QD1. This enables us to do charge localization measurements [19, 20].

Figure 1(d) shows a few events where electrons enter and leave the QDs to be $\Gamma_\text{in}$, measured along the dashed line in Fig. 2(a). The inset shows a triple point (marked by a blue dot). The inset shows a sketch of the surrounding hexagon pattern. The dashed line denotes the detuning axis, with zero detuning occurring at the triple point. The data was taken with $V_{\text{QPC}} = -300 \, \mu V$.

(b) Blow-up of the lower-right region of (a), measured for different QPC bias voltages. (c) Rates for electron tunneling into and out of the QD, measured along the dashed line in (a). $\Gamma_\text{in}$ falls of rapidly with detuning, while $\Gamma_\text{out}$ shows only minor variations.

The dashed blue line connecting the triangles defines the detuning axis, with zero detuning occurring at the triple point. The time-resolved measurement technique allows the rates for electron tunneling into and out of the QD to be determined separately [22]. Figure 2(c) shows the rates $\Gamma_\text{in}$ and $\Gamma_\text{out}$ measured along the dashed line of Fig. 2(a). The rate for tunneling out stays almost constant along the line, but $\Gamma_\text{in}$ is maximum close to the triple point and falls of rapidly with increased detuning. This suggests that only the rate for electrons tunneling into the QD is related to the absorption process. To explain the experimental findings we model the system using a

**FIG. 2:** (a) Electron count rates for a small region close to a triple point (marked by a blue point). The inset shows a sketch of the surrounding hexagon pattern. The dashed line denotes the detuning axis, with zero detuning occurring at the triple point. The data was taken with $V_{\text{QPC}} = -300 \, \mu V$. (b) Blow-up of the lower-right region of (a), measured for different QPC bias voltages. (c) Rates for electron tunneling into and out of the QD, measured along the dashed line in (a). $\Gamma_\text{in}$ falls of rapidly with detuning, while $\Gamma_\text{out}$ shows only minor variations.
FIG. 3: (a) Energy level diagrams for the three states of the DQD. The labels $L$, $R$ and 2 denote the excess charge population. The levels are raised by the intradot charging energy $E_{C1}$ when the DQD holds two excess electrons. (b) Schematic changes of the detector signal as electrons tunnel into, between and out of the DQD.

rate-equation approach. For a configuration around the triple point, the DQD may hold $(n+1,m)$, $(n,m+1)$ or $(n+1,m+1)$ electrons. We label the states $L$, $R$ and 2 and draw the energy diagrams together with possible transitions in Fig. 3(a). The figure shows the case for positive detuning, with $\delta \gg k_B T$. Note that when the DQD holds two excess electrons, the energy levels are raised by the intradot charging energy, $E_{C1} = 800 \mu$eV.

In Fig. 3(b) we sketch the time evolution of the system. The red curve shows the expected charge detector signal assuming a detector bandwidth much larger than the transitions rates. Starting in state $L$, the electron is trapped until it absorbs a photon and is excited to state $R$ (with rate $\Gamma_{\text{abs.}}$). From here, the electron may either relax back to state $L$ (rate $\Gamma_{\text{rel.}}$) or a new electron may enter QD1 from the source lead and put the system into state 2 (rate $\Gamma_S$). Finally, if the DQD ends up in state 2, the only possible transition is for the electron in the right dot to leave to the drain lead.

The relaxation rate for a similar DQD system has been measured to be $1/\Gamma_{\text{rel.}} = 16 \text{ ns}$, which is much faster than the available measurement bandwidth. Therefore, the detector will not be able to register the transitions where the electron is repeatedly excited and relaxed between the dots. Only when a second electron enters from the source lead [transition marked by $\Gamma_S$ in Fig. 3(a, b)], the DQD will be trapped in state 2 for a sufficiently long time ($\sim 1/\tau_D \sim 1 \text{ ms}$) to allow detection. The measured time trace will only show two levels, as indicated by the dashed line in Fig. 3(b). Such a trace still allows extraction of the effective rates for electrons entering and leaving the DQD, $\Gamma_{\text{in}} = 1/\langle t_{\text{in}} \rangle$ and $\Gamma_{\text{out}} = 1/\langle t_{\text{out}} \rangle$. To relate $\Gamma_{\text{in}}, \Gamma_{\text{out}}$ to the internal DQD transitions, we write down the Master equation for the occupation probabilities of the states:

$$\frac{d}{dt} \begin{pmatrix} p_L \\ p_R \\ p_2 \end{pmatrix} = \begin{pmatrix} -\Gamma_{\text{abs.}} & \Gamma_{\text{rel.}} & \Gamma_D \\ \Gamma_{\text{abs.}} & -(\Gamma_S + \Gamma_{\text{rel.}}) & 0 \\ 0 & \Gamma_S & -\Gamma_D \end{pmatrix} \begin{pmatrix} p_L \\ p_R \\ p_2 \end{pmatrix}.$$  \hfill (1)

Again, we assume positive detuning, with $\delta \gg k_B T$. The measured rates $\Gamma_{\text{in}}, \Gamma_{\text{out}}$ are calculated from the steady-state solution of Eq. 1:

$$\Gamma_{\text{in}} = \Gamma_S \frac{p_R}{p_L + p_R} = \frac{\Gamma_S \Gamma_{\text{abs.}}}{\Gamma_S + \Gamma_{\text{abs.}} + \Gamma_{\text{rel.}}},$$  \hfill (2)

$$\Gamma_{\text{out}} = \Gamma_D.$$  \hfill (3)

In the limit $\Gamma_{\text{rel.}} \gg \Gamma_S, \Gamma_{\text{abs.}}$, the first expression simplifies to

$$\Gamma_{\text{in}} = \Gamma_S \Gamma_{\text{abs.}}/\Gamma_{\text{rel.}}.$$  \hfill (4)

The corresponding expressions for negative detuning are found by interchanging $\Gamma_S$ and $\Gamma_D$ in Eqs. (2-4). Coming back to the experimental findings of Fig. 2(c), we note that $\Gamma_{\text{out}}$ only shows small variations within the region of interest. This together with the result of Eq. 4 suggest that we can take $\Gamma_S, \Gamma_D$ to be independent of detuning. The rate $\Gamma_{\text{in}}$ in Eq. 4 thus reflects the dependence of $\Gamma_{\text{abs.}}/\Gamma_{\text{rel.}}$ on detuning. Assuming also $\Gamma_{\text{rel.}}$ to be constant, a measurement of $\Gamma_{\text{in}}$ gives directly the absorption spectrum of the DQD. The measurements cannot exclude that $\Gamma_{\text{rel.}}$ also varies with $\delta$, but as we show below the model assuming $\Gamma_{\text{rel.}}$ independent of detuning fits the data well.

Equation 4 shows that the low-bandwidth detector can be used to measure the absorption spectrum, even in the presence of fast relaxation. Moreover, the detection of an electron entering the DQD implies that a quantum of energy was absorbed immediately before the electron was detected. The charge detector signal thus relates directly to the detection of a single photon.

In the following, we use the DQD to quantitatively investigate the microwave radiation emitted from the nearby QPC. Figure 4(a) shows the measured $\Gamma_{\text{in}}$ versus detuning and QPC bias. The data was taken along the dashed line of Fig. 3(a), with gate voltages converted into energy using lever arms extracted from finite bias measurements. Due to the tunnel coupling $t$ between the QDs, the energy level separation $\Delta_{12}$ of the DQD is given by $\Delta_{12} = \sqrt{4 t^2 + \Delta^2}$. The dashed lines in 4(a) show $\Delta_{12}$, with $t = 32 \mu$eV. A striking feature is that there are no counts in regions with $|e\text{QPC}| < \Delta_{12}$. This originates from the fact that the voltage-biased QPC can only emit photons with energy $\hbar \omega \leq e\text{V_{QPC}}$. The result presents another strong evidence that the absorbed photons originate from the QPC.

To describe the results quantitatively, we consider the emission spectrum of a voltage biased QPC with one conducting channel. In the low-temperature limit $k_B T < \hbar \omega$, the spectral noise density $S_I(\omega)$ for the emission side ($\omega > 0$) takes the form (see 3 for the full expression)

$$S_I(\omega) = \frac{4 e^2}{h} D(1 - D) \frac{e V_{\text{QPC}} - \hbar \omega}{1 - e^{-(e V_{\text{QPC}} - \hbar \omega)/k_B T}},$$  \hfill (5)

where $D$ is the transmission coefficient of the channel. Using the model of Ref. 4, we find the absorption rate of the DQD in the presence of the QPC:

$$\Gamma_{\text{abs.}} = \frac{4 \pi e^2 k_B T Z^2}{\hbar^2} S_I(\Delta_{12}/h) \frac{\Delta_{12}}{\Delta_{12}}.$$  \hfill (6)
The constant $k$ is the capacitive lever arm of the QPC on the DQD and $Z_l$ is the zero-frequency impedance of the leads connecting the QPC to the voltage source. Equation (6) states how well fluctuations in the QPC couple to the DQD system.

Figure 4(b) shows the measured absorption rates versus $V_{QPC}$, taken for three different values of $\delta$. As expected from Eqs. (5) and (6), the absorption rates increase linearly with bias voltage as soon as $|eV_{QPC}| > \Delta_{12}$. The different slopes for the three data sets are due to the $1/\Delta_{12}^2$-dependence in the relation between the emission spectrum and the absorption rate of Eq. (6). In Fig. 4(c), we present measurements of the absorption spectrum for fixed $V_{QPC}$. The rates decrease with increased detuning, with sharp cut-offs as $|\delta| > eV_{QPC}$. In the region of small detuning, the absorption rates saturate as the DQD level separation $\Delta_{12}$ approaches the limit set by the tunnel coupling. The dashed lines show the combined results of Eqs. (5) and (6), with parameters given in the text. (d) Noise spectrum for different QPC bias. The dashed lines are the results of Eq. (6), with parameters given in the text. (d) Noise spectrum and the absorption rate of Eq. (6). In Fig. 4(c), we present measurements of the absorption spectrum for different values of detuning. The solid lines are guides to the eye. (c) DQD absorption spectrum, measured for different QPC bias. The dashed lines are the results of Eq. (6), with parameters given in the text. (d) Noise spectrum for different values of detuning.

The data for $V_{QPC} = 400 \mu V$ shows some irregularities compared to theory, especially at large positive detuning. We speculate that the deviations are due to excited states of the individual QDs, with excitation energies smaller than the detuning. In Fig. 4(d), we convert the detuning $\delta$ to level separation $\Delta_{12}$ and use Eq. (6) to extract the noise spectrum $S_I$ of the QPC. The linear dependence of the noise with respect to frequency corresponds well to the behavior expected from Eq. (6). Again, the deviations at $\Delta_{12} = 190 \mu V$ are probably due to an excited state in one of the QDs. The single-level spacing of the QD is $\Delta E \approx 200 \mu V$, which sets an upper bound on frequencies that can be detected with this method. The frequency-range can be extended by using DQD in carbon nanotubes or InAs nanowires, where the single-level spacing is significantly larger.

To summarize, we have shown that a DQD can be used as a frequency-selective detector for microwave radiation. Time-resolved charge detection techniques allow single photons to be detected, giving the method a very high sensitivity. The ability to detect single photons also opens up the possibility to investigate the statistics of the absorbed radiation. By fabricating a pair of DQD devices and investigating the cross-correlations, time-dependent photon correlations can be directly measured. To prove the principle of the device we have investigated the high-frequency spectrum of radiation emitted from a voltage-biased QPC. The emission rate was found to increase linearly with applied bias, with a spectrum having a sharp cut-off for frequencies higher than the QPC bias.
