Abstract

We report experimental and theoretical studies on the magnetoelastic interactions in MnPS₃. Raman scattering response measured as a function of temperature shows a blue shift of the Raman active modes at 120.2 and 155.1 cm⁻¹, when the temperature is raised across the antiferromagnetic-paramagnetic transition. Density functional theory (DFT) calculations have been performed to estimate the effective exchange interactions and calculate the Raman active phonon modes. The calculations lead to the conclusion that the peculiar behavior with temperature of the two low energy phonon modes can be explained by the symmetry of their corresponding normal coordinates which involve the virtual modification of the super-exchange angles associated with the leading antiferromagnetic (AFM) interactions.

1. Introduction

The research dedicated to the so called two-dimensional (2D) materials [1] has been lately expanded to studies of a large class of layered magnetic materials and their ultrathin crystals [2]. This, to great extent, is stimulated by the search for novel effects in the magnetic ordering in the 2D limit and possible design of new devices which take advantage of the spin degree of freedom. Relevant research efforts are, in particular, being focused on antiferromagnetic transition-metal thiophosphates [3], with their representative example, the MnPS₃ compound. Changes in the magnetic ordering are often traced with Raman scattering, a technique which appears to be especially well suited to study small size and ultrathin samples. The elementary excitations which are most often probed with Raman scattering are phonon excitations. Answering the question how and which phonon modes appear to be sensitive to the magnetic order is central for drawing conclusions on the applicability of Raman scattering methods to study magnetic phase transitions.

In this paper we present a first-principle study of magnetoelastic interaction in MnPS₃ antiferromagnets and compare our theoretical expectations with the results of temperature dependent Raman scattering measurements performed on these crystals. The aim of our work is to identify the phonon modes which are sensitive to magnetic order and to enlighten the mechanism of the phonon-spin coupling that is at the origin of this sensitivity.

Experimentally, we confirm [4] a robust sensitivity of the Raman active phonon mode at 155.1 cm⁻¹ (at low temperatures) to the antiferromagnetic to paramagnetic transition in MnPS₃ and clarify a similar property for the other, but weaker, phonon mode observed at 120.2 cm⁻¹. These experimental observations are well accounted for by our theoretical calculations.

This paper is organized as follows. In Sections 2 we present the crystallographic structure of MnPS₃...
Figure 1. (a) Atomic structure of MnPS$_3$. Mn atoms are represented in violet, S in yellow, and P in gray. (b) Detail of the Mn - S bonds in the Mn-S-Mn sandwiches. The S$_1$ sulfur atoms are associated to the super-exchange path that controls the effective magnetic interaction $J_2$. Similarly the S$_2$ sulfur atoms are associated to the effective magnetic interaction $J_1$. (c) Detail of the six intralayer effective exchange interactions considered in this work. The difference between $J_1$ and $J_2$, $J_3$ and $J_4$, and $J_7$ and $J_8$ is a consequence of the distortion of the honeycomb lattice. (d) Detail of the three interlayer effective exchange interactions considered in this work. Atomic structures were drawn with VESTA [5].

and the details of the Raman experiments. In section 3 we discuss the methods that we used for the calculation of the effective exchange interactions and the phonons modes. In Sections 4 we present and discuss our Raman experiments versus temperature and in Section 5 the results of our calculations. Section 6 is devoted to the discussion and conclusion.

2. Experimental details

2.1. MnPS$_3$ structure

MnPS$_3$ has a monoclinic structure, space group C2/m with lattice parameters $a = 6.077$ Å, $b = 10.524$ Å, $c = 6.796$ Å, and $\beta = 107.35^\circ$ [6]. The atomic structure is shown in figures 1(a) and (b). There are 4 MnPS$_3$ units in the monoclinic C2/m unit cell, giving a total of 20 atoms. The C-centring means that the unit cell is not primitive because there are two equivalent positions, one at (0, 0, 0) and the other at (1/2, 1/2, 0). A primitive triclinic unit cell containing 10 atoms and having the minimal volume $V = 1/2 a b c \sin \beta$ can be constructed with, for example, Bravais lattice vectors $\vec{a}_1 = (a \hat{x} - b \hat{y})/2$, $\vec{a}_2 = (a \hat{x} + b \hat{y})/2$, and $\vec{a}_3 = c (\cos \beta \hat{x} + \sin \beta \hat{z})$.

In the paramagnetic phase all the Mn and P atoms are equivalent by symmetry, while there are two kinds of S atoms. The corresponding Wyckoff positions of the C2/m cell are 4g, 4i, 4i, and 8j for the Mn, P, S1, and S2 atoms, respectively.

As can be seen in figure 1(a), MnPS$_3$ is formed by the stacking along the c axis of PS-Mn-PS sandwiches. The Mn atoms form a distorted honeycomb lattice and the S atoms two distorted triangular lattices. The P atoms can be described as forming P$_2$ dimers penetrating the Mn hexagons (see figure 1(a)). Each Mn atom is octahedrally coordinated to six S atoms which can be associated to super-exchange paths between the Mn atoms (see figure 1(b) and the text below).

2.2. Raman scattering experiments

Raman scattering measurements were carried out on single crystals of manganese phosphorus trisulphide (MnPS$_3$) using, as the excitation source, either a 515 nm line of a continuous wave laser diode or a 514.5 nm line of a continuous wave Ar$^+$ laser. The crystals used for experiments were either home-made (see reference [20] for more details) or commercially available, both types of specimens displaying essentially identical spectra. In accordance to earlier studies [4], the Raman scattering in our samples has been found to be particularly efficient when using the laser excitation wavelengths around 515 nm. The collected signal was dispersed through a 0.5 m monochromator and detected by a CCD camera.

The temperature dependent Raman scattering response was measured at zero magnetic field with the aid of a continuous flow cryostat mounted on x-y motorized positioners. The sample was placed on a cold finger of the cryostat. The excitation light was focused by means of a 50x long-working distance objective with a 0.5 numerical aperture producing a spot of about 1 $\mu$m and the scattering signal was collected via the same objective.
Magnetoo-Raman scattering was measured in Faraday and Voigt configurations using an optical-fiber-based experimental setup. The sample was mounted on top of an x-y-z piezo-stage kept in gaseous helium at $T = 4.2 \text{ K}$ and inserted into a magnet. The excitation light was coupled to an optical fiber with a core of $5 \mu\text{m}$ diameter and focused on the sample by an aspheric lens (spot diameter around $1 \mu\text{m}$). The signal was collected by the same lens, injected into a second optical fiber of $50 \mu\text{m}$ diameter.

In all experiments, the excitation power was kept below $100 \mu\text{W}$, to avoid the sample heating by the laser beam. Multiple test measurements of the power dependence of Raman scattering response have not shown any changes in the shape of spectra in the range of excitation powers up to $500 \mu\text{W}$.

### 3. Calculation details

For the calculations we have used the Quantum Espresso [7] code based on density functional theory, Optimized Norm-Conserving Vanderbilt (ONCV) pseudopotentials and the PBE functional [8] with a plane-wave and charge-density cutoff of 90 Ry and 200 Ry, respectively. An electronic structure calculation with the experimental atomic parameters [6] and a PBE functional gives no gap for the ferromagnetic (FM) order and a gap of $1.30 \text{ eV}$ for the experimentally observed AFM order to be compared with the experimentally reported gap of $2.96 \text{ eV}$ [9].

Including an on-site Hubbard $U_{\text{eff}}$ on the Mn atoms using the simplified method developed by Cococcioni and de Gironcoli [10] increases the AFM gap up to a saturation value of $2.60 \text{ eV}$ when $U_{\text{eff}}$ reaches $7 \text{ eV}$. The same dependence of the electronic gap with the value of $U_{\text{eff}}$ has has been reported by other authors, who use either $U_{\text{eff}} = 4 \text{ eV}$ [11] or $5 \text{ eV}$ [12, 13]. A value of $U_{\text{eff}} = 5 \text{ eV}$ (gap of $2.40 \text{ eV}$) has been used for the calculations of the effective exchange interactions and vibrational modes reported below.

The experimental lattice parameters and internal coordinates [9] has been used to calculate the effective exchange interactions. As mentioned above, the non primitive $1 \times 1 \times 1$ base centered monoclinic cell contains 20 atoms. Double monoclinic super-cells ($1 \times 1 \times 2$, $1 \times 2 \times 1$, and $2 \times 1 \times 1$) containing 40 atoms and 8 Mn have been used to be able to separate the different exchange interactions (see below). We have used a $8 \times 4 \times 2$ Monkhorst-Pack [14] grid for the first Brillouin zone sampling of the 40 atoms monoclinic cell and adapted equivalent samplings of $8 \times 4 \times 2$ and $4 \times 4 \times 4$ for the $1 \times 2 \times 1$ and $2 \times 1 \times 1$ unit cells.

The phonon modes have been calculated in the primitive 10 atoms triclinic cell with the experimental lattice parameters but fully relaxed internal coordinates under the constraint of keeping the unit cell symmetry invariant. After relaxation, the calculation has been performed using the frozen phonon procedure with a $8 \times 8 \times 8$ Monkhorst-Pack [14] grid for the first Brillouin zone sampling.

### 4. Experimental results

The representative Raman scattering spectra of our MnPS$_3$ crystals, measured at low ($5 \text{ K}$) temperature in the range of 100 to 650 cm$^{-1}$ from the laser line, are presented in figure 2. A number of relatively sharp Raman scattering peaks, labeled X1 ... X8 are
observed, in fair agreement with previously reported
observations of the specific phonon modes in MnPS$_3$
crystals [4, 15–18].

The temperature evolution of all but the X1 and X2 peaks is rather smooth. Indeed, a conventional red shift and broadening of X3 ... X8 phonon modes is observed upon increase of temperature (see Supplementary Material figures S1 and S2 (stacks.iop.org/TDM/7/035030/mmedia)). In contrast, the X1 and X2 Raman scattering peaks appear to be sensitive to the magnetic ordering in our crystals. These peaks display a singular behavior around the expected, critical Néel temperature, $T_N = 78$ K, for the antiferromagnetic to paramagnetic transition in MnPS$_3$ compound [19]. This is illustrated in figure 3. As can be seen, the center positions of the X1 and X2 Raman scattering peaks display an abrupt blue shift in close vicinity of $T_N$. In agreement with previous reports [4, 18], the observed blue shift amounts 5 cm$^{-1}$ in the case of the X2 mode and we report here a similar behavior but with a smaller blue shift of about 2 cm$^{-1}$ for the X1 Raman scattering peak (see figures 3(b) and (c)). More details on temperature evolution of X1 and X2 peaks as well as of all other X3 ... X8 peaks are shown in the Supplementary Material’s figures S1 to S3. Here we note that the X2 peak is relatively intense and well pronounced in the spectra measured in the whole temperature range, though it appears to be significantly broadened (by a factor of 4) around $T_N$ (the maximum in the X2 line-width is observed at temperature of 65 K, slightly below $T_N$). The X1 peak is relatively weak. It does not display any obvious broadening around $T_N$ but displays a relatively abrupt broadening (by a factor of 2) at $T \approx 110$ K. The intensity of X1 peak initially weakens but significantly increases when temperature is raised above 100 K.

It is interesting to note that, as illustrated in figure 4, both X1 and X2 peaks are not sensitive to the applied magnetic field. As already perceived in a recent work [4] the low temperature Raman scattering spectra of MnPS$_3$ crystals show an additional weak but intriguing feature at energies slightly above the X2 phonon peak. This additional feature marked as X' in figure 2(b), might be seen as a continuous-like spectrum with a peak-like, high-energy onset around 183.3 cm$^{-1}$ at low temperatures. A weak, Raman scattering feature centered at 185 cm$^{-1}$ has been previously observed in MnPS$_3$ compounds studied at room temperature [15], though it is not observed in our experiments. Instead, as shown in figure 5, our Raman scattering studies performed with longer accumulation time and fine temperature intervals, show that the X’ feature exhibits a characteristic narrowing effect (red shift of the high energy onset) upon the increase of temperature. It merges with the X2 phonon peak at temperatures around $T_N$ and it is not observed in the spectra measured above $T_N$.

The X’ feature is likely of a magnetic origin, and the first guess would be that it is a due to a coupled phonon (X2)-spin-wave (magnon) excitation. Such coupling would be favored for $k \approx 0$ spin-wave modes whose energy as measured by the spin gap in the magnon dispersion relation [20, 21] is only a few cm$^{-1}$ (~ 0.5 meV ~ 4.03 cm$^{-1}$). This is in contradiction to the rather large extension (~ 20 cm$^{-1}$) of the X’ feature as measured at low temperatures (see figure 5). The above hypothesis can also be ruled

![Figure 3](image-url)

Figure 3. (a) False-color map of Raman scattering response (logarithmic scale for the intensity) together with a few characteristic spectra measured as a function of temperature and focused on the spectral region encompassing the X1 and X2 phonon modes which are sensitive to the magnetic order in MnPS$_3$ crystals. Temperature evolution of central positions of the (a) X1 and (b) X2 peaks, as extracted from fitting the shapes of these peaks with Lorentzian functions. $T_N$ denotes the critical Néel temperature for the antiferromagnetic to paramagnetic transition in MnPS$_3$. 

Figure 4. Evolution of the X2 and X’ peaks with an applied magnetic field oriented perpendicular (left) and parallel (right) to the reciprocal lattice vector $c^*$. The experiment was performed at 5 K.

Figure 5. False-color map of Raman scattering response (logarithmic scale for the intensity), together with few selected spectra, measured with long acquisition times and fine temperature interval of 2 K in the spectral region 100 to 200 cm$^{-1}$ and temperature range from 5 K to 100 K. The presented data emphasize a characteristic “narrowing” of the X’ feature with temperature (red shift of its high energy onset), which eventually merges with the X2 phonon mode at $T_N$. This behavior suggests that the X’ feature is due to spin (possibly two-magnon) excitations in the antiferromagnetic phase of MnPS$_3$.

out by our experiments performed as a function of the magnetic field (see figure 4) in which we do not observe any magnetic-field-induced change in the form of the X’ feature. Very likely, and in accordance with the recent report [4], the X’ feature is due to two-magnon excitations. Indeed, as deduced from neutron scattering studies [20] the (single) magnon excitations at the Brillouin zone boundary saturate at energies $\sim$ 11.5 meV $\sim$ 92 cm$^{-1}$, thus the two-magnon density of states is expected to peak at around 184 cm$^{-1}$, in accordance to the energy position of the onset of the X’ feature measured at low temperatures. Notably, the magnon dispersion in the long-wavevector limit, i.e. close to the zone-boundary, may persist in the paramagnetic phase (above $T_N$) but the Raman scattering response due to two-magnon excitations can be modified at the antiferromagnetic or paraferromagnetic phase transition [22, 23]. Nevertheless, it remains surprising that our experiments do not show any trace of these two-magnon excitations at temperatures above $T_N$ [22, 23].
5. Calculation results

5.1. The magnetic Hamiltonian

To understand the possible link between the vibrational modes and the magnetic order in MnPS₃, one needs to determine the model magnetic Hamiltonian of the interacting Mn²⁺ ions.

If one considers that these ions are in a 3dε electronic configuration corresponding to a high spin S = 5/2 ground state [19], the effect of the spin–orbit coupling would be negligible [24]. The observation of a highly isotropic magnetic susceptibility above T_N sustains this idea [20, 24–27] and suggests that the effective exchange interactions Jᵢⱼ between the magnetic centers are isotropic in nature.

Nevertheless, the AFM order below T_N is anisotropic. It was first reported with the Mn spin moments pointing along the reciprocal lattice vector c*, i.e. perpendicular to the honeycomb lattice in the ab plane [19, 20, 25, 26, 28] but later on, a more careful analysis of the neutron diffraction data has shown a small tilt (~ 8°) of the Mn²⁺ magnetic moments with respect to c* [29]. Two possible energetic contributions can be proposed to explain the anisotropic order, the dipolar interactions between the magnetic moments or a single ion anisotropy arising from a non negligible spin–orbit coupling. Theoretical analysis [30–33] and recent magnon band measurements [21] suggest that the dipolar interaction would be the leading source of anisotropy responsible of the observed long-range order. While other experimental results (electron spin resonance [25, 34], critical behavior [19, 35], and the observation of a non negligible orbital contribution to the total magnetic moment [26, 28]), support the idea that the single ion anisotropy is also playing an important role.

In conclusion the full magnetic Hamiltonian should contain a spin-independent contribution H₀, a rotational invariant Heisenberg part \( H_{\text{Hei}} \), a dipolar term \( H_{\text{dip}} \), and a single ion anisotropy contribution \( H_{\text{son}} \):

\[
\hat{H} = \hat{H}_0 + \hat{H}_{\text{Hei}} + \hat{H}_{\text{dip}} + \hat{H}_{\text{son}}
\]

\[
\hat{H}_{\text{Hei}} = \sum_{i > j} J_{ij} \hat{S}_i \cdot \hat{S}_j
\]

\[
\hat{H}_{\text{dip}} = -\frac{\mu_0}{4\pi} \sum_{i > j} \frac{1}{r_{ij}} \left[ \hat{\mathbf{m}}_i \cdot \hat{\mathbf{r}}_{ij} (\hat{\mathbf{m}}_j \cdot \hat{\mathbf{r}}_{ij}) - \hat{\mathbf{m}}_i \cdot \hat{\mathbf{m}}_j \right]
\]

\[
\hat{H}_{\text{son}} = D \sum_i (\hat{S}_i \cdot \hat{\mathbf{n}})^2
\]

where \( J_{ij} \) are the magnetic couplings, \( \hat{S}_i \) and \( \hat{S}_j \) are the \( S = \frac{5}{2} \) spin operators localized on the Mn atoms at site i and j, respectively, \( \hat{\mathbf{m}}_i = g\mu_B \hat{S}_i \) and \( \hat{\mathbf{m}}_j = g\mu_B \hat{S}_j \) the corresponding spin only magnetic moments, and \( \hat{\mathbf{n}} \) the direction of the single ion easy axis. Notice that our Heisenberg interaction is defined as \( J S_i \cdot S_j \) similar to Le Flem et al [36], Sivadas et al [12], and Chittari et al [11], while other authors use \( -2 J S_i \cdot S_j [20, 24–27] \).

5.2. Effective exchange interactions

The full analysis of the magnetic Hamiltonian will be discussed in a forthcoming paper. To understand the link between the vibrational and magnetic properties we will only focus here on the rotational invariant Heisenberg contribution \( H_{\text{Hei}} \).

We have classified the effective exchange interactions according to the Mn–Mn distances and we have calculated 9 different interactions up to interaction distances of 7.647 Å (see table 1 and figures 1(c) and (d)). It is important to note that the distinction made here between the six (three pairs) of intralayer interactions is a consequence of the small distortion of the 2D honeycomb lattice. Indeed, \( J_1 \) and \( J_2 \) can be associated to a single intralayer first neighbors interaction in an undistorted honeycomb lattice \( J_1, J_3 \) and \( J_4 \) to a single second neighbors interaction \( J_2 \), \( J_5 \) and \( J_6 \) to a third neighbors interaction \( J_3 \). Concerning the interlayer interactions, \( J_b \) is the one strictly parallel to the c axis that can be associated to the single interlayer interaction \( J' \) considered by other authors.

The calculations of the exchange interactions were performed using a broken-symmetry formalism, i.e. by mapping total energies corresponding to various collinear spin arrangements within a supercell onto a Heisenberg Hamiltonian [37–42]. Different supercells were needed to distinguish the exchange interactions between two different Mn atoms which are connected by translation symmetry. For example, the 40 atoms \( 2 \times 1 \times 1 \) unit cell, whose total energy can be written as:

\[
E^{121} = E_0 + \left( \frac{5}{2} \right)^2 \left[ a_1 (J_1 + J_3) + a_2 (J_2 + J_5) + a_3 J_3 + a_4 (J_4 + J_6) + a_5 J_b + 8 J_b \right]
\]

where neither allow the calculation of \( J_b \) nor the separation of \( J_1 \) and \( J_3 \); \( J_2 \) and \( J_5 \); and \( J_4 \) and \( J_6 \). Similar limitations arise with the 40 atoms \( 1 \times 2 \times 1 \) and \( 1 \times 1 \times 2 \) unit cells, whose total energies are:

\[
E^{121} = E_0 + \left( \frac{5}{2} \right)^2 \left[ b_1 J_1 + b_2 (J_2 + J_5 + 2 J_b) + b_3 J_3 + 8 J_4 + b_5 J_5 + b_6 (J_b + J_6) \right]
\]

and

\[
E^{312} = E_0 + \left( \frac{5}{2} \right)^2 \left[ c_1 (J_1 + J_3) + c_2 (J_2 + 2 J_b) + c_3 J_3 + 8 J_4 + 8 J_6 + c_7 J_5 + 8 J_b \right]
\]

The coefficients \( a_i \), \( b_i \), and \( c_j \) depend on the spin arrangements of the Mn atoms. As every double
Table 1. Effective exchange interactions. The nine interactions calculated in this work between the Mn atoms obtained using density functional theory are listed in the first column. The Mn–Mn distances appear in the second column. The third column gives the interaction type, either, intra or interlayer. In the fourth column, the effective interactions are given in units of K. A positive value is associated to an antiferromagnetic interaction (see text and equation (2) for the definition of the exchange interactions used in this work). In the last column we show some reported values of the corresponding interactions considering the system as having a 2D undistorted honeycomb lattice. The leading exchange interactions are in-plane and correspond to the first $J_1 (J_2, J_3)$ and third $J_7 (J_8)$ neighbors interactions of the undistorted honeycomb lattice. Interestingly, in this system, the in-plane second neighbor interactions $J_2 (J_3, J_4)$ is almost negligible.

| $d_{\text{Mn–Mn}}$ [Å] | Type    | $J_i$ [K] | $J_i$ [K] |
|----------------------|---------|-----------|-----------|
|                      |         |           |           |
| $J_1$                | 3.500   | intralayer | 12.9      | 19.2 [36] 18.0 [25] 18.2 [24] |
| $J_2$                | 3.523   | intralayer | 12.5      | 16.2 [24] 17.9 [20] 18.3 [12] |
| $J_3$                | 6.076   | intralayer | 0.6       | 1.6 [20] 0.9 [12] |

| $J_6$                | 6.796   | interlayer | 0.5       |           |
| $J_7$                | 7.000   | intralayer | 5.5       | 4.2 [20] 5.3 [12] |
| $J_8$                | 7.025   | intralayer | 5.0       |           |
| $J_9$                | 7.648   | interlayer | 0.1       |           |

Figure 6. Upper panel: projection of the optical phonon modes in the three virtual modes shown in figure S4 in Supplementary Material. Lower panel: relative atomic participation in the optical phonon modes of MnPS$_3$ of the three atom’s types. The colors in the bars represent the contribution of the two Mn atoms (violet), the six S (yellow), and the two P atoms (gray). The symmetry of the modes is shown in the upper part of the figure.

supercell contains 8 Mn atoms there are a total of 256 distinct spin configurations. However, on taking crystal and spin reversal symmetries into account this number can be reduced to 22, 28, and 25 for the $2 \times 1 \times 1$, $1 \times 2 \times 1$, and $1 \times 1 \times 2$ supercells respectively.

The application of a least-squares minimization procedure to the three supercells allows us to calculate the nine exchange interactions. A summary of the calculated values is shown in table 1. There are four leading interactions ($J_1$, $J_2$, $J_7$ and $J_8$), which are all positive (AFM). They do not lead to frustration and they are compatible with the experimentally observed AFM order at low T [25]. As mentioned above, for an undistorted lattice they would correspond to the intralayer interactions $J_1 \approx 12.7$ K, $J_2 \approx 0.3$ K, and $J_3 \approx 5.3$ K which are in good agreement with reported values in the literature.

The distinction between the exchange interactions due to the small distortion will be important in the analysis of the magnetoelastic interactions because the distortion splits the energy of some two-fold degenerate Raman modes.

5.3. Phonon modes

To understand the reasons of the peculiar dependence with temperature of some Raman modes presented in section 4, the 30 phonon modes of MnPS$_3$ have been calculated using the frozen phonon method in the 10 atoms primitive cell. The irreducible representations at the $\Gamma$-point are $\Gamma_{\text{tot}} = 8A_g + 6A_u + 7B_g + 9B_u$, where only the 8 $A_g$ and 7 $B_g$ modes are Raman Active.

The calculated 27 optical phonon frequencies that span from 46 to 557 cm$^{-1}$ are shown in figure 6.
Table 2. Comparison between the calculated Raman active modes versus experimentally observed phonon modes (see figure 2 and Supplementary Material figure S1).

In the lower panel we show schematically the energy of the modes, their symmetry and the relative participation weight of the three atom’s types. For every mode, the corresponding bars are calculated with the normalized eigenvectors \( \vec{q} \) of the standard eigenvalue problem:

\[
\mathbf{M}^{-1/2} \mathbf{H} \mathbf{M}^{-1/2} \vec{q} = \omega^2 \vec{q}
\]  

(5)

where \( \vec{q} = \mathbf{M}^{1/2} \vec{x} \), \( \mathbf{M} \) is the mass matrix, \( \mathbf{H} \) the Hessian of the potential energy, and \( \vec{x} \) the vector with the atomic displacements. As can be seen from the histogram, the high energy modes are mostly localized in the P and S atoms while the low energies ones concern vibrations of the Mn atoms (see figure 6).

The symmetry and energy of the calculated Raman active modes are also shown in table 2. They compare reasonably well with several reported values obtained from previous calculations [4, 16]. As can be seen, the energies of some pairs of modes, separated by horizontal lines in table 2, are almost equal because they would be double degenerate \( E_q \) modes in a perfect honeycomb lattice. Experimentally, it is not always easy to resolve the splitting, even though the splitting has been successfully resolved on feature X3 in figure 2(b) (see also Supplementary Material figure S1).

The correspondence between the experimental features X1 ... X8 and the calculated Raman modes is also shown in table 2. There is an overall good agreement between the corresponding energies, the discrepancy becoming slightly larger for the high energy modes. For the modes above 200 cm\(^{-1}\), the energy difference increases with energy giving rise to an overall difference of 5% for the majority of the modes while the deviation of the mode around 110 cm\(^{-1}\) corresponds to a larger relative difference of about 9%. These relative deviations of about 5 to 10% are frequently found when comparing state-of-the-art DFT calculations with experimental measurements. It is important to note here that the approximations used in our calculations have been chosen to have a good overall description of the magnetic, electronic and structural properties of the system. A different choice of the DFT input parameters (pseudopotentials, Hubbard Hamiltonian, functional), may slightly change the calculated phonon energies and/or the distribution of deviations between the theoretical and experimental energies of different modes. The two calculated modes with irreducible representation Bg around 46 and 200 cm\(^{-1}\) are not visible in the experimental spectra.

6. Discussion and summary

The two Raman modes whose frequencies increase when crossing the Néel temperature at about 120 (X1) and 155 cm\(^{-1}\) (X2) are associated to the two pairs of calculated Raman active modes at 109.8 (Bg) and 110.4 (Ag) for X1 and 152.5 (Bg) and 153.6 cm\(^{-1}\) (Ag) for X2 (see table 2). As mentioned above, these two pairs of almost degenerate modes are split in energy due to the small distortion of the honeycomb and triangular lattices. For every pair, the eigenvectors of these almost degenerate modes have very similar weights in the Mn, S, and P atoms (see lower panel in figure 6) and the relative displacements of the Mn and S atoms for the four modes is shown in figure 7.

If we consider the six Mn atoms forming the hexagons in the honeycomb lattice as six consecutive Mn pairs. The effective exchange interactions of the pairs are either the first or the second neighbors intralayer interactions \( J_1 \) and \( J_2 \) respectively. These AFM interactions, which participate to stabilize the Néel AFM order at low temperature, can be associated to superexchange paths between the Mn atoms through the S atoms (see figure 1(b)).

One can imagine that the modification with temperature of these superexchange paths can be the mechanism at the origin of the magnetoelastic interactions responsible for the temperature dependence of the X1 and X2 modes. Above \( T_N \), due the thermal excitations, the spins localized in some Mn pairs would orient parallel to each other. As the interaction is AFM, the system would try to decrease the superexchange angle in order to decrease the interaction. The slight modification of the angles would explain the energy change of the Raman modes.
In order to visualize this effect, we have considered three virtual phonon modes: each one affecting the superexchange angle associated to two opposite exchange interactions (see Supplementary Information’s Figure S4). The upper panel in figure 6 shows the projections of the 27 optical modes on the three virtual phonons. The projections are significative for four pairs of Raman active modes and clearly larger for the two pairs of modes associated to peaks X1 and X2.

In conclusion, we have presented a comprehensive picture which largely accounts for the observed sensitivity of the particular phonon modes to the magnetic ordering in layered MnPS₃ antiferromagnet. More specifically, we have identified, both in the experiment and theory, that there are essentially two, phonon modes of MnPS₃ which appear at 120.2 cm⁻¹ and 155.1 cm⁻¹ in the low temperature Raman scattering spectra, and which show a pronounced change in the vicinity of the critical Néel temperature. The present approach can be extended to other magnetic materials including their thin layers, in reference to tracing the magnetic properties with Raman scattering response due two phonon excitations.
