Abstract – Analytical formulae for de Haas-van Alphen (dHvA) oscillations in linear chain of coupled two-dimensional (2D) orbits (Pippard’s model) are derived systematically taking into account the chemical potential oscillations in magnetic field. Although corrective terms are observed, basic ($\alpha$) and magnetic-breakdown–induced ($\beta$ and $2\beta-\alpha$) orbits can be accounted for by the Lifshits-Kosevich (LK) and Falicov-Stachowiak semiclassical models in the explored field and temperature ranges. In contrast, the “forbidden orbit” $\beta-\alpha$ amplitude is described by a non-LK equation involving a product of two classical orbit amplitudes. Furthermore, strongly non-monotonic field and temperature dependence may be observed for the second harmonics of basic frequencies such as $2\alpha$ and the magnetic breakdown orbit $\beta+\alpha$, depending on the value of the spin damping factors. These features are in agreement with the dHvA oscillation spectra of the strongly 2D organic metal $\theta$-(ET)$_4$CoBr$_4$(C$_6$H$_4$Cl$_2$).

Introduction. – Quasi–two-dimensional (q-2D) multi-band organic compounds (ET)$_2$X (where ET stands for the bis-ethylenedithio-tetrathiafulvalene molecule and X is a monovalent anion) exhibit very rich-phase diagrams with ground states ranging from antiferromagnetic insulator to Fermi liquid. In particular, superconducting and magnetic ordered phases are observed close to each other, which is reminiscent of cuprates and iron-based superconductors (for a recent review, see [1] and references therein). These compounds share the same Fermi surface (FS) topology which is an illustration of the linear chain of coupled orbits introduced by Pippard in the early sixties [2]. Such FS is liable to give rise to a network of orbits coupled by magnetic breakdown (MB) in large magnetic fields. Quantum oscillations in such systems have been extensively studied during the last two decades (for a review, see, e.g., [3] and references therein). The main feature of the oscillation spectra of these compounds is the presence of frequency combinations that are forbidden in the framework of the semiclassical model of Falicov-Stachowiak [4]. Theoretical studies have demonstrated that these Fourier components result from both the formation of Landau bands due to coherent MB, instead of discrete levels, and the oscillation of the chemical potential enabled by the 2D character of the FS. However, easy-to-handle analytic tools necessary to quantitatively account for the data are still lacking. As a matter of fact, comprehensive theoretical tools taking into account coherent MB and oscillation of the chemical potential have been reported in ref. [5] and implemented in de Haas-van Alphen (dHvA) data of the above-mentioned compound. Nevertheless, as pointed out in ref. [5], equations are complex and data could be analyzed only numerically.
The aim of this paper is therefore to provide analytical formulae accounting for quantum oscillation spectra of these systems. In the first step, analytical calculation of the Fourier amplitude of the various dHvA oscillations predicted for the FS illustrating Pippard’s model is reported. In the second step, the FS of the recently synthesized strongly 2D charge transfer salt \( \theta-(ET)_4\text{CoBr}_4(C_6H_4Cl_2) \) [6] is presented and, in the third step, analysis of the observed field- and temperature-dependent quantum oscillation spectra are reported. An excellent agreement with the calculations is obtained.

**Experimental.** – The studied crystals were synthesized by electrocrystallization technique as reported in ref. [6]. They are elongated hexagonal platelets with approximate dimensions \( 1.5 \times 0.5 \times 0.04 \text{mm}^3 \). X-ray diffraction data were collected both at room temperature in Chernogolovka with a KM-4 single-crystal diffractometer (Kuma Diffraction) and at 100 K with an Xcalibur diffractometer (Oxford Diffraction) at the Laboratoire de Chimie de Coordination in Toulouse. Tight-binding band structure calculations were based upon the effective one-electron Hamiltonian of the extended Hückel method [7], as reported, e.g., in ref. [8]. Magnetic torque and magnetoresistance were measured in pulsed magnetic fields of up to 55 T with a pulse decay duration of 0.32 s. Magnetic torque measurements were performed with a commercial piezoresistive microcantilever [9] in the temperature range from 1.4 K to 4.2 K. The size of the sample studied was approximately \( 0.12 \times 0.1 \times 0.04 \text{mm}^3 \). Variations of the cantilever piezoresistance were measured with a Wheatstone bridge with an ac excitation at a frequency of 63 kHz. The angle between the normal to the conducting plane and the magnetic-field direction was \( \theta = 7^\circ \). Magnetoresistance was measured thanks to a contactless radio frequency measurement technique based on tunnel diode oscillator as reported in ref. [10].

A pair of counter-wound coils made with copper wire of 50 \( \mu \text{m} \) in diameter was used. As pointed out in [11], in the case where the interlayer resistivity is much larger than the in-plane resistivity, the contribution of the former parameter to the measured signal is negligible. The time evolution of the oscillatory frequency during the field pulse is deduced from successive short-term fast Fourier transforms of the raw signal. In contrast, analysis of the oscillatory magnetoresistance and magnetic torque is based on discrete Fourier transforms of the field-dependent data, calculated with a Blackman window after removal of a non-oscillating background. Zero-field interlayer and in-plane 4-point resistance was measured with 1 \( \mu \text{A} \) ac current at 77 Hz. Electrical contacts were made using annealed platinum wires of 20 \( \mu \text{m} \) in diameter glued with graphite paste.

**Calculation of de Haas-van Alphen amplitudes.** – We consider a two-band system with band extrema \( \Delta_{0(1)} \) (see fig. 1(c)) and effective masses \( m_{0(1)} \). In the low temperature limit, the grand potential \( \Omega \) of a two-dimensional slab with area \( \mathcal{A} \) is given by a series of harmonics \( p \) of classical frequencies \( \Phi_\eta \):

\[
\Phi_\eta \in \frac{u_0}{\mathcal{A} k_B T} \Omega(T, \mu) = -\frac{m_0}{2} (\mu - \Delta_0)^2 - \frac{m_1}{2} (\mu - \Delta_1)^2
+ \frac{(B \cos \theta)^2}{2} \sum_{p \geq 0} \sum_{\eta} \frac{C_\eta}{p^2 m_\eta} R_{\eta,p}(T, B)
\times \cos \left( 2\pi p \frac{F_\eta}{B \cos \theta} + p \Phi_\eta \right),
\]

where \( \Phi_0 = h/e \) is the quantum flux and \( u_0 = 2\pi^2 m_e k_B / e \) is 14.694 T/K. Effective masses are expressed in \( m_e \) units and chemical potential \( \mu \) in tesla. The index \( \eta \) stands for all the possible classical orbits \( \alpha, \beta, \beta + \alpha, 2\beta - \alpha \), etc., excluding their harmonics, with frequencies \( F_\eta = m_\eta (\mu - \Delta_\eta) \) and effective masses \( m_\eta \). Frequencies \( F_\eta \) depend on the chemical potential \( \mu \) since they represent a filling factor corresponding to classical
orbits. Coefficient $C_\eta$ is the symmetry factor of the orbit $\eta$. For example, $C_{\alpha} = C_{\beta} = C_{\beta-\alpha} = 1$ and $C_{\beta+\alpha} = 2$. $\varphi_\eta$ is the phase of the orbit $\eta$, i.e., $\pi/2$ times the number of extrema of the orbit in the $k_x$ or $k_y$ direction, for example, $\varphi_\alpha = \varphi_\beta = \varphi_{2\beta-\alpha} = \pi$ and $\varphi_{\beta+\alpha} = 2\pi$. These phases are important for determining the sign of amplitudes. In particular, we define two fundamental orbits with frequencies, $F_\eta = m_1(\mu - \Delta_1)$ (i.e., $m_\alpha = m_1$) and $F_\beta = m_0(\mu - \Delta_0) + m_1(\mu - \Delta_1)$ which can be written as $F_\beta = m_\beta(\mu - \Delta_\beta)$ (see, fig. 1(d)). Therefore, $m_0 + m_1$ is identified to the effective mass $m_\beta$ of the MB orbit $\beta$. The damping factors can be expressed as $R_{\eta,p}(T,B) = R_{\eta,p}^D R_{\eta,p}^D R_{\eta,p}^M$, where the thermal, Dingle, MB and spin damping factors are given by

$$R_{\eta,p}^D = \frac{\eta_0 T pm_\eta}{B \cos \theta \sinh\left(\frac{\eta T pm_\eta}{B \cos \theta}\right)},$$

$$R_{\eta,p}^M = \exp\left(-\frac{\eta_0 T pm_\eta}{B \cos \theta}\right),$$

$$R_{\eta,p}^D = (i \phi_0)^{n_\eta^c}(q_0)^{n_\eta^v},$$

$$R_{\eta,p}^s = \cos\left(\pi m_\eta^{g^*}/2 \cos \theta\right),$$

respectively. $T_D$ is the Dingle temperature ($T_D = h/2\pi k_B T$, where $\tau$ is the relaxation time). Integers $n_\eta^c$ and $n_\eta^v$ are the (even) number of MB tunnelings and reflections, respectively, encountered by the quasiparticle along its closed trajectory. The MB tunneling and reflection probabilities are given by $p_0 = \exp(-B_0/2B)$ and $q_0^g = 1 - p_0^g$, respectively, where $B_0$ is the MB field. $g^*$ is the effective Landé factor. The electron density per surface area $n_e$ is given by $d\Omega/dp = -n_e$. In zero field, eq. (1) yields $n_e = (m_0 + m_1)\mu_0 - m_\beta \Delta_0 - \Delta_1$. In presence of a magnetic field, $\mu$ satisfies the following implicit equation:

$$\mu = \mu_0 + \frac{B \cos \theta}{m_\beta} \sum_{p \neq \eta} \sum_{\eta} \frac{1}{p} C_\eta R_{\eta,p}(T,B) \times \sin\left(2\pi p \frac{F_\eta}{B \cos \theta} + p \varphi_\eta\right).$$

The oscillating part of the magnetization can be computed systematically by inserting eq. (6) in eq. (1) and deriving the resulting expression with respect to the magnetic field. Direct numerical resolution of this implicit equation could be done. Besides, a more user-friendly controlled expansion in terms of damping factors $R_{\eta,p}$ can be derived systematically at any possible order. Keeping successive terms in powers of $R_{\eta,p}$ up to the second order, yields

$$m_{osc} = -\sum_{\eta \neq \eta} \sum_{p \neq \eta} F_\eta C_\eta R_{\eta,p}(T,B) \sin\left(2\pi p \frac{F_\eta}{B \cos \theta} + p \varphi_\eta\right) + F_\eta C_\eta R_{\eta,p}(T,B) R_{\eta',p'}(T,B) \times \left[\sin\left(2\pi p F_\eta + p \varphi_\eta + p' \varphi_\eta\right) \right] + \cdots,$$

where frequencies $F_\eta$ are evaluated at $\mu = \mu_\beta$, namely, $F_\eta = m_\beta(\mu_0 - \Delta_\eta)$. Equation (7) can be written as a sum of periodic functions with frequencies $F_\eta$ and Fourier amplitudes $A_i$, where the index $i$ stands for either classical orbits $\eta$ or “forbidden” orbits such as $\beta - \alpha$. Relevant examples for experimental analysis are given below:

$$A_\alpha = \frac{F_\alpha}{2\pi m_\beta} R_{\alpha,1} + \frac{F_\alpha}{2\pi m_\beta} R_{\alpha,1} R_{\alpha,2} + \frac{F_\alpha}{6\pi m_\beta} R_{\alpha,3} + \frac{2}{2\pi m_\beta} R_{\alpha,1} R_{\alpha,1} R_{\alpha,1} R_{\alpha,1},$$

$$A_\beta = \frac{F_\beta}{2\pi m_\beta} R_{\beta,1} + \frac{F_\beta}{2\pi m_\beta} R_{\beta,1} R_{\beta,2} + \frac{F_\beta}{6\pi m_\beta} R_{\beta,3} + \frac{2}{2\pi m_\beta} R_{\beta,1} R_{\beta,1} R_{\beta,1},$$

$$A_{\beta - \alpha} = \frac{F_{\beta - \alpha}}{2\pi m_\beta} R_{\alpha,1} R_{\beta,1} + \frac{F_{\beta - \alpha}}{2\pi m_\beta} R_{\alpha,2} R_{\alpha,1} R_{\alpha,1},$$

$$A_{\beta + \alpha} = \frac{F_{\beta + \alpha}}{2\pi m_\beta} R_{\beta,2} + \frac{F_{\beta + \alpha}}{2\pi m_\beta} R_{\beta,2} R_{\beta,2},$$

$$A_{2\beta - \alpha} = \frac{F_{2\beta - \alpha}}{2\pi m_\beta} R_{\alpha,1} R_{\beta,1} + \frac{F_{2\beta - \alpha}}{2\pi m_\beta} R_{\alpha,2} R_{\alpha,1} R_{\alpha,1} R_{\alpha,1} R_{\alpha,1} R_{\alpha,1},$$

$$A_{2\beta + \alpha} = \frac{F_{2\beta + \alpha}}{2\pi m_\beta} R_{\beta,2} + \frac{F_{2\beta + \alpha}}{2\pi m_\beta} R_{\beta,2} R_{\beta,2} R_{\beta,2}.$$
and neglected (where data are analyzed on this basis. However, the absolute value of the spin damping factor is considered in the case observed on either side of spin-zero angles as reported in [15]).

This statement also stands for $2\beta - \alpha$ since $R_{2\beta - \alpha}$ is significantly higher than the product $R_{\alpha,1}R_{3,2}$ (see eq. (14)). As a consequence, the Falicov-Stachowiak model should apply for this component as well. In contrast, algebraic sum of damping terms in eqs. (9) and (13), where minus signs account for $\pi$ dephasings, may cancel at field and temperature values dependent on the effective masses, Dingle temperature, MB field, etc. as displayed in fig. 2 relevant to $2\alpha$. This point has already been reported for the second harmonic of the basic orbits both for compensated [13] and uncompensated [14] metals. In that respect, since algebraic sums are involved, care must be taken of the spin damping factor sign$^2$. Indeed, the value of the spin damping factor, which is changed through the value of $g^*$ in fig. 2, can have a drastic effect on the field and temperature dependence of the amplitude in this case. Finally, the Fourier amplitude of the “forbidden orbit” $\beta - \alpha$ is accounted for by eq. (12). Although a non-LK behaviour is evidenced, a monotonic field and temperature dependence is expected owing to the negligibly small value of the high-order terms. The consistency of eqs. (8) to (14) with experimental data is examined in the next section.

Results and discussion. – Even though the organic metal $\theta-(ET)\textsubscript{4}CoBr\textsubscript{3}\textsubscript{4}(C\textsubscript{6}H\textsubscript{4}Cl\textsubscript{2})$ undergoes a phase transition at 343 K [6], no additional phase transition is revealed by X-ray diffraction below room temperature, at which crystals are synthesized, down to 100 K. As displayed in fig. 1, the central feature of the crystalline structure at room temperature is that the unit cell has two different donors planes labeled A and B. According to band structure calculations, layer A is insulating while layer B is metallic. FS of layer B is composed of one closed tube centered at $Y$ with an area of 18% of the first Brillouin zone (FBZ) area (yielding $\alpha$ orbit in magnetic field) and two q-1D sheets with rather small gap in between. Therefore, it is expected that the MB orbit $\beta$, which corresponds to the hole tube centered at $\Gamma$ with an area equal to that of the FBZ is observed in moderate fields, giving rise to the textbook linear chain of coupled orbits. In addition, since layers A are insulating, conducting planes are strongly separated from each other which suggests a strongly 2D behaviour. In line with this statement, the room temperature resistivity anisotropy $\rho$(interlayer)/$\rho$(in plane) is as large as $10^4$ [6]. Furthermore, according to the data in fig. 3, this anisotropy further increases up to $\rho$(interlayer)/$\rho$(in plane) $= 10^8$ as the temperature decreases down to liquid helium temperatures.

Magnetic torque (dHvA oscillations) and tunnel diode oscillator (Shubnikov-de Haas (SdH) oscillations) data are displayed in fig. 4. Besides Fourier components linked to the closed orbit $\alpha$ and to the MB orbit $\beta$, few frequency combinations typical of the FS displayed in fig. 1 are observed in the high-field range of the torque spectra. In contrast, numerous combinations are observed in SdH spectra. As an example, the Fourier component $2\beta - 3\alpha$ is clearly detected in fig. 4(b). This frequency, which to our knowledge is observed for the first time, could correspond to a quantum interferometer path. However, its amplitude is unexpectedly large. The frequencies linked to the $\beta$ and $\alpha$ orbits are $F_\beta(\theta = 0) = 4600 \pm 10$ T, in agreement with the FBZ area at 100 K, and $F_\alpha(\theta = 0) = 944 \pm 4$ T, respectively. The latter value yields a cross-section area of 20.6% of the FBZ area, in satisfactory agreement with the band

\[ R_{\alpha,1} = 1, \quad R_{3,2} = 2.3. \]

\[ g^* = 1.7, \quad g^* = 2. \]

Fig. 2: (Colour on-line) Temperature dependence (mass plot) of the amplitude of the component $2\alpha$. Symbols are data deduced from torque measurements of fig. 4(a) at 48.3 T. Solid lines are deduced from eq. (9) with $m_\alpha = 1.81$, $m_\beta = 3.52$, $T_\Omega = 0.79$ K and $B_0 = 35$ T. Spin damping factor (see eq. (5)) is either neglected ($R_\alpha = 1$, $p = 1$ to 3) or accounted for by various $g^*$ values. All the data are normalized to their values at 12 K.

Fig. 3: (Colour on-line) Temperature dependence of zero-field in-plane (blue lower curve) and interlayer (black upper curve) resistance normalized to the values at 290 K.

\[ g^* = 1.7, \quad g^* = 2. \]
structure calculations of fig. 1. Field- and temperature-dependent Fourier amplitudes can be studied at the light of the results given in the previous section, keeping in mind that dHvA amplitudes $A_\eta$ are related to torque oscillation amplitudes $A_\eta' = A_\eta / B \tan(\theta)$. Effective masses, derived from eq. (8) at various magnetic-field values are field-independent: $m(\alpha) = 1.81 \pm 0.05$, $m(\beta) = 3.52 \pm 0.19$, (see fig. 5(a)). In agreement with results of ref. [16], $m(\beta)$ is twice $m(\alpha)$ within the error bars. At odds with torque results, effective masses deduced from SdH data, in particular those relevant to the $\beta$ component, definitely increase as the magnetic field increases. This behaviour indicates that the above calculations, relevant to dHvA oscillations, cannot account for the SdH data at high field.

Focusing on dHvA oscillations, Dingle plots of $\alpha$ and $\beta$ can be obtained plotting $A_\eta' / B R_{\alpha,1}^2$ versus $B$ at different temperatures, where $R_{\alpha,1}^2$ is given by eq. (2), assuming the LK formalism accounts for the data, i.e. the high-orders terms of eq. (8) can be neglected. As reported in fig. 5, all the data relevant to the $\alpha$ and $\beta$ components lies, respectively, on the same curve within the experimental scattering which suggests that the above assumption holds. Dingle temperature and MB field can be derived for components which do not involve tunneling ($n_\alpha = 0$ in eq. (5)). Although this is the case of $\alpha$, a very broad maximum is observed in fig. 5, leading to a very large uncertainty on the MB field. More specifically, $B_0$ values ranging from 0 to 70 T can account for the data, in which case $T_D$ ranges from 1.4 to 0.5 K, respectively. Assuming the Dingle temperature linked to the $\alpha$ orbit is the same as that of $\beta$ considerably reduces the uncertainty since the well-defined slope $s_\beta = -(\omega_D T_D m_\beta + 2B_0)$ of the Dingle plot for $\beta$ yields an additional relationship between $T_D$ and $B_0$. This assumption yields $B_0 = 35 \pm 5$ T and $T_D = 0.79 \pm 0.10$ K. With these values of effective masses, Dingle temperature and MB field, it is possible to check whether or not the high-order terms of eq. (8) can be neglected. The inset of fig. 5(b) displays the field dependence of $A_\eta' / B R_{\alpha,1}^2$ calculated for the highest-field range covered by the experiments, assuming further that $g^* = 2$ (see footnote 3). Although the contribution of these factors rises as the field increases, it remains smaller than the experimental scattering for both $\alpha$ and $\beta$.

The field and temperature dependence of the Fourier amplitude relevant to frequency combinations is displayed in fig. 6. Since their amplitude is much smaller than that of the $\alpha$ and $\beta$ only mass plots at high field and Dingle analysis at the lowest explored temperature are considered. As already discussed for the second harmonics $2\alpha$ (see fig. 2), amplitudes are strongly dependent on the spin damping factors value. Solid lines in fig. 6 are the best

---

3Effective Landé factor as low as $g^* = 1.5–1.6$ is reported for the strongly correlated compound $\kappa-(ET)_2 Cu(NCS)_2$ [5], nevertheless $g^* = 2$ is consistent with data of other ET salts [17,18].
on the value of the spin damping factor $R$. Frequencies such as $2\alpha$ may be observed for the second harmonics of basic strongly non-monotonic field and temperature dependence of classical amplitudes relevant to $\alpha$ accounted for by a non-LK equation, involving products due to the small value of $F_{\text{Falicov-Stachowiak model}}$. Whereasthis feature is mainly accounted for by the LK and Falicov-Stachowiak field (eqs. (8) to (14)). Although high-orders terms can be accounted for the chemical potential oscillations in magnetic conductor have been derived systematically taking into Pippard’s model and observed in many q-2D organic for $H_{\text{vA}}$ oscillations relevant to a class of FS illustrating both $2\alpha$ and the MB orbit $\beta + \alpha$ are close to the predictions of the Falicov-Stachowiak model. Whereas this feature is mainly due to the small value of $R_{\alpha,1}R_{\beta,2}$ compared to $R_{2\beta - \alpha,1}$ in the former case, it can be attributed to the peculiar set of values of the spin damping factors ($R_{\alpha,1}^s R_{\beta,2}^s / R_{\beta + \alpha,1}^s = -0.22$) in the latter case.

Summary and conclusion. – Analytical formulae for dHvA oscillations relevant to a class of FS illustrating Pippard’s model and observed in many q-2D organic conductors have been derived systematically taking into account the chemical potential oscillations in magnetic field (eqs. (8) to (14)). Although high-orders terms are observed, basic ($\alpha$) and MB-induced ($\beta$ and $2\beta - \alpha$) orbits can be accounted for by the LK and Falicov-Stachowiak semiclassical models, at least at moderate fields and temperatures. In contrast, the “forbidden orbit” $\beta - \alpha$ is accounted for by a non-LK equation, involving products of classical amplitudes relevant to $\alpha$ and $\beta$. Furthermore, strongly non-monotonic field and temperature dependence may be observed for the second harmonics of basic frequencies such as $2\alpha$ and the MB orbit $\beta + \alpha$, depending on the value of the spin damping factor $R_{\gamma}^s$.

These formulae are in agreement with the dHvA oscillation spectra of the strongly 2D organic metal $\theta_-(\text{ET})_4\text{CoBr}_4(\text{C}_6\text{H}_4\text{Cl}_2)$, assuming $g^s = 2$. However, SdH oscillations spectra exhibit a tremendous number of Fourier components suggesting, besides quantum interference contributions, more severe deviations from the LK model that remains to be explained within a SdH theory including quantum interference contribution.
