Abstract
Asthmatics are highly susceptible to respiratory viral infections, possibly due to impaired innate immunity. However, the exact mechanisms of susceptibility are likely to differ amongst viruses. Therefore, we infected primary nasal epithelial cells (NECs) from adults with mild-to-moderate asthma, with respiratory syncytial virus (RSV) or human metapneumovirus (hMPV) in vitro and investigated the antiviral response. NECs from these asthmatics supported elevated hMPV but not RSV infection, compared to non-asthmatic controls. This correlated with reduced apoptosis and reduced activation of caspase-9 and caspase-3/7 in response to hMPV, but not RSV. The expression of heat shock protein 70 (HSP70), a known inhibitor of caspase activation and subsequent apoptosis, was amplified in response to hMPV infection. Chemical inhibition of HSP70 function restored caspase activation and reduced hMPV infection in NECs from asthmatic subjects. There was no impairment in the production of IFN by NECs from asthmatics in response to either hMPV or RSV, demonstrating that increased infection of asthmatic airway cells by hMPV is IFN-independent. This study demonstrates, for the first time, a mechanism for elevated hMPV infection in airway epithelial cells from adult asthmatics and identifies HSP70 as a potential target for antiviral and asthma therapies.

Introduction
Human metapneumovirus (hMPV) and respiratory syncytial virus (RSV) cause acute respiratory tract disease in children and adults [1–3]. These viruses have been linked to the development of asthma in children [4] and are reported to exacerbate asthma in both children and adults [5, 6]. Asthmatics are more susceptible to respiratory viral infections [7], reportedly due to deficient antiviral immunity. In cultured primary bronchial epithelial

Key Words
Asthma · Primary nasal epithelial cells · Human metapneumovirus · Apoptosis · Interferon · Heat shock protein 70
cells (BECs) from asthmatics, type I (β) and type III (λ) interferon (IFN) production is reduced in response to rhinovirus (RV) infection [8–10]. However, the association between asthma and reduced IFN production in response to other respiratory viruses remains unclear and controversial, particularly for those with mild-to-moderate asthma [11, 12].

Respiratory viruses first infect the airway epithelial cells (AECs) in the upper respiratory tract. However, less is known concerning the potential defects in antiviral defense associated with asthma in this compartment relative to the lower respiratory tract. We recently demonstrated that nasal epithelial cells (NECs) from atopic, wheezy children were IFN-competent in response to hMPV, although they produced significantly less IFN in response to RSV than NECs from healthy children. Regardless of differences in the IFN response, NECs from atopic, wheezy children supported elevated replication of both hMPV and RSV [13]. This suggests that IFN-independent mechanisms may contribute to elevated virus susceptibility of the asthmatic airway epithelium, and that virus-specific interactions influence the antiviral response of AECs. Due to the lack of understanding of antiviral responses in the upper airways and of AECs from adult asthmatics infected with viruses other than RV, we investigated the susceptibility of in vitro cultured primary NECs from adults with mild-to-moderate atopic asthma, to RSV and hMPV infection.

In addition to IFN-dependent antiviral responses, programmed cell death responses, such as apoptosis, are an integral part of innate immunity as they restrict viral replication and spread. Apoptosis occurs downstream of endoplasmic reticulum (ER) stress, which is triggered by viral protein synthesis and leads to the activation of the unfolded protein response (UPR) [14]. Sustained UPR signalling dysregulates the mitochondria and leads to the assembly of the apoptosome, which activates the intrinsic caspase cascade [15]. In this study, we found that NECs from atopic asthmatic adults were more susceptible to hMPV infection, but not RSV infection, than NECs from non-atopic non-asthmatics (or ‘healthy controls’). We further demonstrate that this was independent of the IFN response. We therefore investigated cell death responses induced by ER stress and demonstrated that intrinsic apoptosis induced by active caspase-9 and caspase-3/7 was reduced in association with asthma. This lack of caspase-activated apoptosis correlated with hMPV-induced expression of heat shock protein 70 (HSP70), which is known to dysregulate the function of the apoptosome [16]. Our study describes a mechanism for elevated susceptibility of AECs from the upper respiratory tract of atopic asthmatic adults to hMPV infection, and identifies HSP70 as a potential therapeutic target to overcome this response to hMPV infection.

Materials and Methods

Study Design, Subjects and Sample Collection
Twenty community volunteers (10 atopic asthmatics and 10 non-atopic, non-asthmatics) 20–47 years of age were recruited with 100% participation. The mean age was 26 years and 41% were male. Subjects with mild-to-moderate asthma were defined as those who had been diagnosed with asthma and used asthma medication on an as-needed basis. All of the subjects had well-controlled asthma, and none was using steroid medication at the time of enrollment. All asthmatic subjects reported aeroallergen sensitization (atopy). Active and former smokers were excluded from the study. None of the subjects was experiencing symptoms of respiratory tract infection at the time of study enrollment. Nasal epithelium scrapings were obtained from the inferior turbinate of each nare, using a purpose-designed curette as described previously [13]. Patients from the study population were chosen randomly where there were <10 samples in an experiment.

Submerged Culture of Primary Epithelial Cells
Sampled NECs were initially seeded into 25-cm² cell-culture flasks in steroid-supplemented bronchial epithelial growth medium (BEGM; Lonza). At passage 2, cells were seeded into 12- or 96-well plates and cultured as submerged monolayers until 75% confluent [13]. The culture medium was then replaced with steroid-free medium 24 h prior to infection with RSV or hMPV.

Infection with RSV or hMPV
NECs were infected with either RSV (A2) or hMPV (CAN 97–83) at a multiplicity of infection (MOI) of 3 plaque-forming units/cell. Uninfected control cells were exposed to virus-free media. Virus stocks were prepared as previously described through sucrose-cushion concentration followed by high-speed pelleting of viral particles to remove the sucrose [13]. Cells were incubated with virus for 2 h at 37°C, and then washed 3 times with PBS, and then steroid-free culture medium (BEGM; Lonza) was added. Cells in 12-well plates were lysed for total RNA extraction. Supernatants were stored for IFN secretion quantification. Cells in 96-well plates were used for live-cell caspase activation assays. Cells were sampled at indicated time points within 24 h post-infection (p.i.).

Quantification of Viral RNA and Shed Virus
Total RNA was extracted using RNazol® (Molecular Research Center, Inc.) according to the manufacturer’s instructions, and then reverse-transcribed using random hexamers (Applied Biosystems). RSV and hMPV intracellular RNA was quantified using SYBR green dye (QIAGEN), specific primers (online suppl. table S1; for all online suppl. material, see www.karger.com/doi/10.1159/000449101) and standard curves were generated using 10-fold serial dilutions of expression plasmids encoding the nucleocapsid (N) gene of RSV or hMPV (Biomatik). A plasmid encoding the β-actin gene (Biomatik) was used as a housekeeping standard. Viral gene copy number was calculated by plot-
ER Stress and the UPR

Total cellular RNA extracted as described above for viral RNA quantification was also used to quantify mRNA for markers of ER stress; Gpr78 and xBP1 by qRT-PCR at 8, 12 and 24 h.p.i. (hMPV) and at 24 h.p.i. alone (RSV). Downstream UPR markers CHOP, GADD34, BIM, PUMA and NOXA were quantified by qRT-PCR at 8, 12 and 24 h.p.i. with hMPV. Regulators of the apoptosome, Smac and XIAP, were quantified in the same way at 24 h.p.i. with hMPV. Primers are listed in online supplementary table S1. Phosphorylation of the UPR marker e-Jun NH2-terminal kinase (JNK) was quantified at 12 and 24 h.p.i. with hMPV by in-cell Western blotting of 96-well plate cultures using a commercial kit (Face™ JNK, Active Motif).

Western Blot

HSP70 expression was quantified by Western blot analysis prior to infection and then at 16 h.p.i. with hMPV. Whole-cell lysates were obtained using RIPA buffer supplemented with protein inhibitor cocktail (Thermo Scientific) and proteins were resolved using 4–12% Bis-Tris gels (Life Technologies) according to the manufacturer’s recommendations. Proteins were then transferred onto PVDF membranes (0.45 μm, Millipore) and probed with primary antibody against HSP70 (Enzo Lifesciences) and GAPDH (Cell Signaling). Secondary antibodies conjugated with IRDye 800CW (Rockland) were used and images were captured with the Odyssey Infrared Imaging System (LI-COR Biosciences). For densitometric quantification, the intensity of the bands was determined using Image Studio Lite software (LI-COR Biosciences).

Statistical Analysis

Clustered and longitudinal data was analyzed using generalized estimating equations (GEE) [17]. Normal distribution was used as a model and an independent correlation structure as the working correlation matrix. The interactions between viral and host factors (clustered data) or time and viral factors (longitudinal data) were assessed with the Wald test (type III analysis). The Sidak test was used to adjust for multiple comparisons where a significant interaction was detected and p < 0.05 was considered statistically significant. All data analyses were conducted using IBM SPSS software v22 (Armonk, N.Y., USA).

Results

Asthma Was Associated with Elevated hMPV Infection Independent of the IFN Response

hMPV infection, as quantified by total intracellular viral RNA, was 2.5-fold (0.4 log10) higher in NECs from asthmatic compared to non-asthmatic subjects at 24 h.p.i. (p < 0.05; fig. 1a). RSV infection was not elevated compared to non-asthmatic subjects (fig. 1a).

Both hMPV and RSV significantly induced IFN-β (fig. 1b) and IFN-λ1 (fig. 1c) production by NECs (compared to uninfected NECs; p < 0.0001), with IFN-β production being elevated in response to hMPV compared to RSV (p < 0.01). However, IFN-β and IFN-λ1 production in response to either virus was not affected by asthma status (fig. 1b, c), and there was no relationship between IFN-β or IFN-λ1 production and viral RNA in NECs from asthmatic subjects (online suppl. fig. S1a, b). This demonstrates that NECs from asthmatic adults were IFN competent in response to RSV and hMPV, although this did not prevent elevated hMPV infection.
To address the possibility that viral attachment and entry by hMPV was elevated in NECs from asthmatics, hMPV N mRNA was quantified from 2 to 24 h p.i. as an indicator of early transcription events immediately after viral entry. Viral transcription was the same in NECs from asthmatic and non-asthmatic subjects for the first 12 h p.i., indicating no difference in the amount of viral genomic template available for transcription early in infection (online suppl. fig. S2). However, N mRNA was elevated in NECs from asthmatics compared to non-asthmatics at 24 h p.i. (p < 0.05), as it was when total intracellular viral RNA was quantified (fig. 1a).

Asthma Was Associated with Delayed and Reduced Apoptosis in Response to hMPV

HMPV induced apoptosis, as quantified by flow cytometry of Annexin-V-positive cells from both asthmatic and non-asthmatic subjects compared to uninfected cells at 24 h p.i., indicating no difference in the amount of viral genomic template available for transcription early in infection (online suppl. fig. S2). However, N mRNA was elevated in NECs from asthmatics compared to non-asthmatics at 24 h p.i. (p < 0.05), as it was when total intracellular viral RNA was quantified (fig. 1a).

Asthma Was Associated with Delayed and Reduced Apoptosis in Response to hMPV

HMPV induced apoptosis, as quantified by flow cytometry of Annexin-V-positive cells from both asthmatic and non-asthmatic subjects in comparison to uninfected cells at 24 h p.i. (2.8-fold, p < 0.0001 and 1.5-fold, p < 0.0001, respectively; fig. 2; online suppl. fig. S3b). Interestingly, the percentage of Annexin-V-positive uninfected NECs from asthmatics was significantly higher than from non-asthmatics. This may reflect a heightened sensitivity of asthmatic cells to the handling required for flow cytometry. Therefore, the percentage of hMPV-infected, Annexin-V-positive NECs from asthmatics was normalized against uninfected baseline expression for each subject group. Annexin-V detection was significantly lower in NECs from asthmatics than from non-asthmatics subjects (1.9-fold, p < 0.0001; fig. 2b). This impaired apoptotic response to hMPV associated with asthma correlated with retention of the viable cells at 24 h p.i. (3.3-fold and 1.8-fold loss of viable NECs from non-asthmatics and asthmatics, respectively; online suppl. fig. S3c). RSV also induced significant apoptosis in NECs from both asthmatic and non-asthmatic subjects compared to uninfected cells (online suppl. fig. S3b). However, there was no significant difference in response between the subject groups (fig. 2b).

To identify the mechanism of defective apoptosis of NECs from asthmatic subjects, activation of the final executors of apoptosis, caspase-3 and caspase-7, was quantified together from 2 to 24 h p.i with either RSV or hMPV. Caspase-3/7 was not activated in uninfected NECs from either asthmatics or non-asthmatics for 24 h p.i. (online suppl. fig. S4a), therefore, the activity in hMPV-infected cells was expressed as fold induction compared to uninfected cells. HMPV significantly induced caspase-3/7 activity in NECs from non-asthmatic subjects at 12 h p.i. compared to uninfected NECs (3-fold, p < 0.0001) and infected NECs from asthmatic subjects (2.8-fold, p < 0.01; fig. 3a). Caspase-3/7 activity in NECs from non-asthmatics then increased steadily from 12 to 24 h p.i. (4.7-fold at 16 h, p < 0.0001 and 8-fold at 24 h, p < 0.0001, compared to uninfected NECs). However, caspase-3/7 activity in NECs from asthmatic subjects remained significantly lower than in NECs from non-asthmatic subjects at 16 and 24 h p.i. (p < 0.0001 and p < 0.001, respectively). Only at 24 h p.i. was caspase-3/7 activity significantly induced by hMPV in NECs from asthmatic subjects (1.5-fold compared to uninfected NECs, p < 0.05; fig. 3a). RSV did not activate caspase-3/7 in NECs from either asthmatic or non-asthmatic subjects.
(fig. 3b), suggesting that RSV and hMPV induce cell death via different mechanisms.

The initiators, caspase-9 and caspase-8 lead to the downstream cleavage and activation of caspase-3/7. HMPV induced significantly elevated caspase-9 activity in NECs from non-asthmatic subjects at 24 h p.i. (3.4-fold compared to uninfected NECs, p < 0.01; fig. 3c). Caspase-9 activity was lower in asthmatic subjects than in non-asthmatic subjects at 24 h p.i., although this difference did not reach statistical significance (2.2-fold, p = 0.399). RSV did not induce caspase-9 activation, again suggesting a different mechanism of apoptosis (fig. 3d). Caspase-8 activation was poorly induced by hMPV in NECs from both asthmatic and non-asthmatic subjects (online suppl. fig. S4c). These data demonstrate that hMPV induced apoptosis in NECs via an intrinsic caspase-9 and caspase-3/7 activation pathway, and that this response was impaired in NECs from asthmatic subjects. In addition to a disease-specific response, these data demonstrate a virus-specific response, as RSV induced significantly less apoptosis in non-asthmatic NECs and did not induce intrinsic caspase activation in NECs from either asthmatic or non-asthmatic subjects.

The Execution of Apoptosis in Asthmatic NECs Is Not Intrinsically Defective

To investigate whether defective caspase activation and apoptosis represented an inherent defect associated with asthma, NECs were treated with AT-101, which induces intrinsic apoptosis via the inhibition of Bcl2 proteins and up-regulation of the BH3-only proteins, PUMA and NOXA [18]. AT-101 significantly induced caspase-3/7 (fig. 3e) and caspase-9 (fig. 3f) activation within 8 h p.t., with sustained activation to 12 h p.t., in NECs from both asthmatic and non-asthmatic subjects. This demonstrates that there was no inherent defect in the ability of asthmatic NECs to undergo apoptosis. Rather, impaired caspase activation and apoptosis by NECs from asthmatics is an hMPV-specific mechanism.

HMPV Induced ER Stress in NECs from Both Asthmatic and Non-Asthmatic Subjects

Intrinsic apoptosis is induced by sustained ER stress [15], which was identified in this study by elevated transcription of Grp78 (fig. 4a) and sXBPI (fig. 4b) from 8 to 24 h p.i. in NECs from both asthmatic and non-asthmatic subjects. This suggests that hMPV did not suppress
apoptosis in NECs from asthmatics via suppressed ER stress. As RSV did not induce caspase-3/7 or caspase-9 activity, we investigated if this correlated to poor up-stream ER stress induction. RSV was a poor inducer of ER stress compared to hMPV, as both Grp78 (fig. 4a) and sXBP1 (fig. 4b) transcription were significantly lower at 24 h p.i. regardless of asthma status (non-asthmatic: 4.4-fold, p < 0.0001 and asthmatic: 3.3-fold, p < 0.0001; non-asthmatic: 2.8-fold, p < 0.0001 and asthmatic: 3-fold, p < 0.0001, respectively).

**HMPV Induced a Maladaptive UPR in NECs from Both Asthmatic and Non-Asthmatic Subjects**

Prolonged ER stress induces a maladaptive UPR through protein kinase RNA-like ER kinase (PERK) and inositol-requiring protein 1α (IREα) pathways [15].

---

**Fig. 3.** Caspase-3/7 and caspase-9 activity in NECs from asthmatic subjects is reduced in response to hMPV. Caspase-3/7 (a, b) and caspase-9 (c, d) activation was quantified by luminescence detection at the indicated time points within 24 h following hMPV or RSV infection (MOI 3). n = 5 for both asthmatics and non-asthmatics; median ± range. Caspase-3/7 (e) and caspase-9 (f) activation were quantified at 4, 8 and 12 h after treatment with 10 μM AT-101. n = 5 for both asthmatics and non-asthmatics; median ± range. A GEE approach was used to compare groups and the interaction between disease status and time following hMPV infection was significant. Statistical significance between asthmatic and non-asthmatic NECs is indicated by ** p < 0.01 and **** p < 0.0001. Statistical significance between infected (or treated) and uninfected (or untreated) NECs is indicated by † p < 0.05, †† p < 0.01, ††† p < 0.001 and †††† p < 0.0001.
Fig. 4. HMPV induced the expression of ER stress and unfolded protein response markers in NECs from both asthmatic and non-asthmatic subjects. Grp78 (a), sXBP1 (b), CHOP (c), GADD34 (d), PUMA (e) and NOXA (f) mRNA expression in NECs at 8, 12 and 24 h following infection with hMPV or RSV (Grp78 and sXBP1 only; MOI of 3). RT-qPCR was performed using total cellular RNA. Fold induction was calculated using $2^{-\Delta\Delta C_t}$ normalized to the expression of β-actin gene. n = 5 for both asthmatic and non-asthmatic subjects. The bottom and top of the box plots represent the 5th and 95th percentiles, the bar represents the median and the whiskers represent minimum and maximum. A GEE approach was used to compare groups and the interaction between disease status and time (hMPV time course) or between disease status and virus (hMPV vs. RSV at 24 h p.i.) was not significant. * p < 0.05, ** p < 0.01, *** p < 0.001 and **** p < 0.0001 indicate statistical significance.
HMPV did not activate the IRE1α signalling pathway for UPR. This pathway induces apoptosis via phosphorylation of JNK, which then activates BIM and down-regulates anti-apoptotic Bcl-2. HMPV did not induce phosphorylation of JNK (online suppl. fig. S5) or induce the expression of BIM (not shown). In NECs from both asthmatic and non-asthmatic subjects, HMPV induced the PERK pathway with elevated levels of the transcription factor CHOP in all NECs, from 8 to 24 h p.i. (p < 0.0001; fig. 4c). CHOP promotes sustained ER stress by increas-
ing protein synthesis through GADD34 [15], which was also significantly induced in all NECs from 8 to 12 h p.i. (p < 0.0001) and then remained steady up to 24 h p.i. (fig. 4d). CHOP also disrupts mitochondrial integrity by transcriptional up-regulation of the pro-apoptotic BH3-only proteins PUMA and NOXA [15]. PUMA was induced at 8 h p.i. and further induced by 12 h p.i. but by 24 h p.i., induction had fallen (fig. 4e). NOXA was induced at 8 h p.i. and did not significantly increase between 8 and 24 h p.i. (fig. 4f). Asthma was not associated with any modulation in the expression of these ER stress markers.

HSP70 Expression Was Elevated in NECs from Asthmatics and Further Amplified by hMPV Infection

Impact ER stress signalling, but impaired caspase-9 and caspase-3/7 activation suggested that the formation or function of the apoptosome was impaired in NECs from asthmatics. Apoptosome function is regulated by Smac/Diablo inhibitor of apoptosis family proteins (XIAP) [19] and HSPs such as HSP70 [16]. Smac transcription was undetectable in NECs (not shown). XIAP transcription was induced by hMPV but was not differentially regulated in NECs from asthmatic subjects (online suppl. fig. S6). Conversely, we found that the expression of HSP70 protein in NECs from asthmatics was significantly elevated compared to those from non-asthmatics, even prior to virus infection (2.6-fold, p < 0.01; fig. 5a, b). When infected with hMPV, HSP70 expression was further elevated in the NECs from asthmatics, but not in those from non-asthmatics, compared to uninfected NECs (4-fold, p < 0.001). HSP70 transcription in response to hMPV was not detectable on qPCR, despite utilising multiple primer sets (not shown). To assess the role of HSP70 in hMPV-mediated inhibition of the apoptosome, hMPV-infected NECs were treated with VER-155008, which inhibits HSP70 activity by competitively binding to its ATPase domain and subsequently activating caspase-3/7 [16, 20]. Treatment with VER-155008 restored caspase-3/7 activity in the hMPV-infected NECs from asthmatics to a level similar to that of non-asthmatic NECs either infected with hMPV alone or infected and treated with VER-155008 (fig. 5c). The inhibition of HSP70 activity reduced total intracellular viral RNA by approximately 50% in NECs from asthmatics (p < 0.0001) and 30% in those from non-asthmatics (p < 0.001; fig. 5d). Shed infectious virus was also reduced in VER-155008-treated NECs from asthmatics (online suppl. fig. S7). The reduction in viral RNA in non-asthmatic hMPV-infected NECs treated with VER-155008, with no corresponding increase in caspase-3/7 activation (fig. 5b), indicates that VER-155008 also has an independent effect on hMPV replication. These data demonstrate that hMPV infection amplified an inherent overexpression of HSP70 in NECs from asthmatic adults, which then interfered with apoptosome formation to suppress the activation of caspase-9 and caspase-3/7 that is required for the intrinsic apoptosis of infected cells. Impaired apoptosis then resulted in elevated hMPV infection in the NECs from asthmatic adults (fig. 6).

Discussion

In this study, we demonstrated a significant association between mild-to-moderate adult asthma and elevated hMPV infection in AECs from the upper respiratory tract. We further identified that elevated hMPV in association with asthma was due to a specific host-viral interaction in which hMPV induced HSP70 expression and inhibited the activation of caspases required for intrinsic apoptosis and viral clearance (fig. 6). This mechanism was independent of the IFN response, as NECs from both asthmatics and non-asthmatics produced IFN-β and -λ1, similarly, and the level of intracellular viral RNA was not correlated to the IFN response. An impaired IFN response by asthmatic individuals has been associated with increased viral susceptibility [8–10] and there is significant evidence that this impairment exists in haematopoietic cells, such as plasmacytoid dendritic cells [21]. However, our data adds to the accumulating evidence [11, 13, 22] that AECs from mild-to-moderate asthmatic individuals are IFN-competent and that IFN-independent mechanisms contribute to elevated susceptibility to infection.

Programmed cell death pathways are activated by viral infection and play an important role in host defence by decreasing the number of infected cells and therefore limiting viral spread [23]. ER stress-induced apoptosis occurs via 2 main pathways: PERK and IRE1α. IRE1α signalling leads to the phosphorylation of JNK, which suppresses the anti-apoptotic function of Bcl-2 proteins [15]. PERK signalling leads to the up-regulation of pro-apoptotic CHOP/GADD153 transcription factors and the subsequent transcriptional activation of BH3-only proteins (BIM, PUMA and NOXA) [15], which alter mitochondrial integrity to initiate apoptosis through formation of the apoptosome. Here, we demonstrated that hMPV activated the PERK pathway of apoptosis via apoptosome formation in NECs, rather than the IRE1α pathway. The apoptosome is composed of cytochrome c released by dysregulated mitochondria, apoptotic protease activating...
factor 1 (APAF-1) and pro-caspase-9. Its function is to cleave and activate caspase-9, which then initiates cleavage of the apoptosis effector caspase-3/7. The function of the apoptosome in NECs from asthmatics in this study was impaired in response to hMPV, such that the activation of caspase-9 and caspase-3/7 was delayed and reduced. Interestingly, we observed caspase-3/7 activation 4 h earlier p.i. than caspase-9 activation. This may be explained by the molecular timer function of the apoptosome. Pro-caspase-9 causes the displacement of active caspase-9 from the apoptosome complex, thereby limiting apoptosome activity and the accumulation of free, active caspase-9 [24]. In addition, the positive feedback loop of caspase-3/7 activation following its own cleavage may further contribute to this difference [25].

In this study, the lack of caspase-8 signalling, which is mediated by cell surface death receptors, indicated that hMPV did not activate the extrinsic apoptosis pathway. Therefore, we investigated the mechanisms of intrinsic apoptosis that may be modulated by hMPV. ER stress and mitochondrial dysregulation induce intrinsic apoptosis in response to viral infection. However, the induction of key ER stress markers, maladaptive UPR markers and pro-apoptotic factors indicated that there was no hMPV-induced modulation of the PERK pathway that leads to apoptosome formation in association with asthma. We therefore investigated mechanisms by which hMPV may inhibit apoptosome function.

After demonstrating that the classic apoptosome modulators Smac and XIAP were not involved in apoptosome regulation in hMPV-infected NECs, we investigated HSP70 expression, as this is also known to inhibit apoptosome formation and subsequent intrinsic apoptosis to promote cell survival in lethal conditions [16]. We found that the NECs from asthmatic subjects inherently expressed more HSP70 protein than those from non-asthmatics. Interestingly, BECs from asthmatics have also been reported to express elevated baseline levels of HSP70.

Fig. 6. Proposed model for impaired apoptotic response to hMPV infection in NECs from asthmatics. HMPV induced sustained ER stress and activated the maladaptive UPR through the PERK pathway. GADD34 maintained the ER burden and the pro-apoptotic BH3-only proteins NOXA and PUMA altered mitochondrial integrity. However, downstream formation of the apoptosome was compromised by hMPV-induced HSP70, which impaired caspase-9 and caspase-3/7 activation. This defect in the execution of intrinsic apoptosis resulted in elevated infection in NECs from asthmatic subjects.
HMPV infection induced further HSP70 expression in NECs from asthmatic subjects, suggesting a mechanism for impaired apoptosome function associated with HMPV infection in asthma. Importantly, we were able to inhibit the HSP70-binding function by treatment with VER-155008, which restored caspase-3/7 activation in NECs from asthmatics and suppressed HMPV infection. Although reduced HMPV infection following VER-155008 treatment is likely the result of elevated apoptosis, a reduced binding efficiency of HSP70 may have a direct impact on HMPV replication. HSPs are known to interact directly with viruses; for example, HSP90 is an integral part of the RSV replication complex [28]. However, the role of HSP70 in HMPV replication, if any, is unknown.

This study also demonstrated the specificity of viral-cellular interactions. Unlike hMPV, asthma was not associated with elevated susceptibility to RSV infection, also reported in other studies [22]. RSV induced limited caspase-9 and caspase-3/7 activation in NECs regardless of asthma status but, according to Annexin-V staining, it did induce cell death. This suggests that RSV employs a different mechanism of cell death and warrants further investigation. RSV can suppress apoptosis by the function of the 2 non-structural proteins NS1 and NS2 [29], and is known to induce the peroxidation of lipids in AECs through oxidative stress [30], which was recently associated with non-apoptotic cell death [31]. RSV was also a poor inducer of ER stress compared to hMPV, potentially due to the ability of RSV to prevent phosphorylation of eIF2α, and therefore the UPR, in order to ensure continuous global protein translation [32]. RSV is less prevalent in the exacerbation of adult asthma than of child asthma; this corresponds with our findings, in that RSV infection was not elevated in NECs from asthmatic subjects. RV, however, is a common cause of asthma exacerbation in adults, and RV-infected BECs from asthmatic subjects have demonstrated delayed and reduced caspase-3/7 activity and apoptosis [8]. These findings suggest that viruses interact differently with AECs from asthmatics to influence cell death responses and subsequent susceptibility to infection. Our study also revealed the absence of an inherent defect in the ability of NECs to undergo apoptosis when treated with a BH3 mimic to induce caspase-9 and caspase-3/7 activity, further supporting the hypothesis that impaired apoptosis of NECs in association with asthma is the result of specific viral mechanisms.

These data also suggest that asthmatic adults may be more susceptible to upper respiratory tract infection by HMPV than is currently considered to be the case. The true nature of the association between HMPV and asthma is not clear, as few epidemiological studies have been undertaken since hMPV was identified in 2001 [33].

A limitation of this study is the use of laboratory strains RSV-A2 and hMPV-CAN97–83. Other studies using primary adult BECs have demonstrated differences in cytopathogenicity and cytokine response amongst RSV strains [34]. Although similar studies using hMPV clinical isolates are lacking, the virus strain is an important determinant of the antiviral response and requires further investigation. Therefore, these data demonstrate a mechanism for elevated infection and reduced caspase driven intrinsic apoptosis in NECs from asthmatics in response to the CAN97–83 strain. Whether this is relevant for infection by other hMPV isolates will require further investigation.

Our in vitro modelling of infection of AECs was performed using submerged cultures and a MOI of 3. This approach ensured synchronicity of initial infection and response within an infected cell population, thus maximizing the identification of differences based on disease status. However, a direct effect of high MOI is the rapid death of a population of cells within a few viral life cycles. This does not necessarily reflect a physiological response in which a virus will initially only infect some cells and then undergo several rounds of replication within a cell population. Also, submerged monolayers of cells are less physiologically relevant. Further investigation of cell death in response to RSV and HMPV infection in fully differentiated air-liquid interface cultures is worthwhile as this is a more physiologically relevant model.

Another factor that needs to be acknowledged in this study is the elevated Annexin-V staining amongst uninfected NECs from asthmatics. These same NEC cultures did not demonstrate intrinsically higher caspase-3/7 activity in the absence of hMPV. It is possible that apoptosis was induced in these cells by the manual handling required for flow cytometry, as apoptosis is more readily induced in asthmatic BECs than non-asthmatic BECs when exposed to non-viral stress [35].

Our data indicates that HSP70 may be a viable target to reduce HMPV infection in the asthmatic airway epithelium. HSPs are associated with tumour growth in cancer and elevated resistance to chemotherapy [36]. HSP70 is overexpressed in pancreatic cancer cells, confers resistance to apoptosis and is currently a target for a promising anti-cancer strategy [37]. HSP70 is also involved at multiple stages of viral life cycles [38], and disrupting this interaction by inhibiting HSP70 [39] or knocking it down [40] has already demonstrated promising antiviral outcomes. A therapeutic approach to asthma based on inhib...
itting the interaction between HSP70 and hMPV may be a potential strategy for decreasing the burden of hMPV-induced asthma exacerbations.
