Fusarium wilt, caused by the fungus *Fusarium oxysporum* f. sp. *lycopersici* (*Fol*), is one of the most destructive soil-borne diseases of tomatoes. Infestation takes place on the roots and the process starts with contact between the fungus and the roots hairs. To date, no detailed studies are available on metabolic activity in the early stages of the *Fol* and tomato root interaction. Spatial and temporal patterns of oxygen consumption could provide new insights into the dynamics of early colonization. Here, we combined planar optodes and spatial analysis to assess how tomato roots influence the metabolic activity and growth patterns of *Fol*. The results shows that the fungal metabolism, measured as oxygen consumption, increases within a few hours after the inoculation. Statistical analysis revealed that the fungus tends to grow toward the root, whereas, when the root is not present, the single elements of the fungus move with a Brownian motion (random). The combination of planar optodes and spatial analysis is a powerful new tool for assessing temporal and spatial dynamics in the early stages of root-pathogen interaction.

**INTRODUCTION**

*Fusarium* wilt, caused by the soil-borne fungus *Fusarium oxysporum* f. sp. *lycopersici* (Sacc.) W.C. Snyder & H.N. Hans (*Fol*), is one of the most devastating diseases of the tomato. It is indeed responsible for severe losses in the greenhouse, open field crops and hydroponic cultures. *Fusarium oxysporum* f. sp. *lycopersici* infects tomato roots, starting from a contact with the root hairs and ending with the colonization and necrosis of the root tissue and wilting of the plant (Lagopodi et al., 2002; Mandal et al., 2009). Root colonization by *Fol* is, therefore, a crucial aspect in a successful pathogenesis (Lagopodi et al., 2002). Because of its economic importance, *Fol* has received considerable attention from researchers, especially in terms of root colonization patterns by pathogenic and non-pathogenic strains (Bao and Lazarovits, 2001; Lagopodi et al., 2002; Olivain et al., 2006), with and without the presence of microbial biocontrol agents (Bolwerk et al., 2003, 2005).
Fungal growth has traditionally been studied under the microscope, e.g., by measuring spore germ tube elongation during spore germination, by monitoring radial growth on jellified growth media in Petri dishes or by determining variations in fungal biomass (Cole, 1994; Dhingra and Sinclair, 1995). Moreover, colorimetric and spectrometric methods and microtitre plate assays have also been utilized (Hadacek and Greger, 2000). Oxygen consumption in three fungal species was recently studied with an indirect fluorimetric method, that was found to be highly sensitive and reliable in quantifying fungal activity (Rubol et al., 2016; Rudolph-Mohr et al., 2017). Besides consuming O$_2$ for respiratory activities, root O$_2$ emissions have been observed in plants inhabiting freshwater biomes, such as wetlands or flood-prone environments (McNamara and Mitchell, 1990; Colmer, 2003; Xu et al., 2013; Rudolph-Mohr et al., 2017).

Many biogeochemical processes occur in the roots. As an example, the roots influence the surrounding soil environment by releasing a blend of exudate compounds, which act as signals in plant-pathogen interaction (both for defense and/or pathogen stimulation) and can stimulate, for example, the germination of Fol microconidia (Bais et al., 2006; Steinkellner et al., 2009; Baetz and Martinova, 2014). Besides consuming O$_2$ for respiratory activities, root O$_2$ emissions have been observed in plants inhabiting freshwater biomes, such as wetlands or flood-prone environments (McNamara and Mitchell, 1990; Colmer, 2003; Xu et al., 2013; Rudolph-Mohr et al., 2017).

Traditionally, root metabolic activity has been quantified by changes in oxygen concentration using microsensors, which provide local pointwise information, but are invasive. Thus this approach does not make it possible to study biological samples over a large area, or during prolonged periods of time (Tschiersch et al., 2011). Recent advances in imaging methodologies including cameras, scanners, fluorescence, and radiation-based techniques have enabled non-destructive exploration of root growth, including root interaction with soil-borne pathogens (Downie et al., 2015). Fluorescence-based optical sensors, such as non-invasive planar optodes, allow real time measurements of physiological processes offering manifold advantages over other methods including: spatial coverage (from mm$^2$ to cm$^2$), micrometric level of resolution and an extended period of measurement (from a few seconds to several days) (Tschiersch et al., 2012). Optodes have been successfully employed to quantify biological O$_2$ exchange in seagrasses and other aquatic plants (Jovanovic et al., 2015; Larsen et al., 2015; Han et al., 2016), in the roots of terrestrial living plants (Blossfeld et al., 2011; Tschiersch et al., 2011; Rudolph et al., 2012; Rudolph-Mohr et al., 2015), in photosynthetically active leaves (Tschiersch et al., 2011; Ulqodry et al., 2016) and in the sapwood of woody trees (Gansert et al., 2001), as well as to assess oxidative metabolism in soils (Rubol et al., 2016) and biofilm (Rubol et al., 2018). Despite these research efforts, no planar optode studies have assessed soil-borne microorganism activity, either considering the pathogen alone or the pathogen interacting with plant roots. To fill this gap in research and explore the early stages of root-fungus interaction, we combined the use of non-invasive planar optode technology and geostatistical spatial analysis. We investigated how the temporal and spatial dynamics of Fol growth (assumed to be proportional to O$_2$ consumption) are altered by the presence of tomato roots, and, vice-versa, how root physiology is affected by fungus colonization. The interaction was further examined using spatial analysis, to describe the dynamics of the fungus colony during root colonization and to quantify the nature of this interaction.

**MATERIALS AND METHODS**

**Experimental Setup**

Seeds of *Lycopersicum esculentum* Mill. var. Marmande were surface disinfected in a 70% ethanol (30 s) and 1% sodium hydrochloride solution (1 min) (both from Sigma Aldrich, USA), carefully rinsed twice in sterile distilled water, and placed in a Petri dish (Ø = 90 mm) on 1/2-strength Murashige and Skoog medium (Murashige and Skoog, 1962). The seeds were then kept in a climate chamber at 23°C, with a day:night cycle of 14:10 h until the plant was at least 90 mm long (25 mm shoot and 65 mm root; reached in approximately 3–5 days).

The fungal material (Fol strain FGSC 9935) was acquired from Fungal Genetics Stock Center (US) and stored long-term at −80°C in glycerol (Sigma Aldrich). A conidial suspension obtained from the stock solution was transferred onto 1/4-strength potato dextrose agar (PDA; Oxoid, Italy), incubated for seven days at 25°C and the resulting colonies were used in the experiments. A square Petri dish (10 × 10 × 2 cm; L × W × H) was prepared the day before each measurement session, according to the following procedure. A 2 × 2 cm O$_2$ sensor foil (SF-RPSu4 Oxygen sensor foil for imaging; Presens, 2013b) was glued to the inside of the Petri dish in the position where the root was supposed to grow and elongate during the experiment. The sensor foil was calibrated according to the Presens instruction manual (Presens, 2013a,b): a droplet of oxygen-free water obtained from a water solution of sodium sulfite (Na$_2$SO$_3$; Sigma Aldrich) and cobalt nitrate [Co(NO$_3$)$_2$; Sigma Aldrich] in nitric acid (HNO$_3$; Sigma Aldrich) was used as the 0 point, whereas air saturated O$_2$ (ambient air) was the reference for 100% O$_2$. Then, a 0.3% agar (Sigma-Aldrich) solution, cooled to 55°C in order to avoid damages to the optode, was poured on the dish until it reached a thickness of 5 mm. Before pouring the medium into the Petri dish, the surface of the sensor foil was gently disinfected with 70% ethanol. Once the agar solution had cooled down to room temperature, a single tomato plant was carefully positioned inside the Petri dish, under the agar layer, so that the root adhered to the sensor foil whilst the stem and leaves were left to protrude outside, through a small hole made in the plastic (Figure 1). Similarly, at the same time, a 6 mm plug of fungal mycelium was placed under the agar layer in the upper right corner of the sensor foil (opposite to the aeral part of the plant). This root-fungus interaction experiment was repeated twice (on March 14 and May 21, 2014). Two controls were also performed: on the plant root without the fungus (on April 4, 2014) and on the fungus alone (on April 7, 2014), utilizing a 6 mm mycelium plug positioned in the center of the optode.

The Petri dish was sealed with Parafilm (Sigma Aldrich) along the perimeter and enclosed in a black cardboard to avoid light interference during measurement and at the same time, to protect...
The tomato plant was positioned with the root adhering to the optode and the aerial part protruding from the Petri dish through a small hole. The inserted overlay false color image shows the O$_2$ distribution and position of the fungus.

**Images Post-processing**

Oxygen measurements were expressed as the percentage of O$_2$ saturation in freshwater at atmospheric equilibrium (% air saturation). Oxygen images were first analyzed with image processing software (VisiSens Analytical 1 VA1.12-RC05; Presens, 2013c), which calculates the ratio of red to green in the emitted fluorescence response (the so-called R-value) provided by the color channels of the CMOS (complementary metal-oxide-semiconductor) chip (Presens, 2013c). The RGB images were calibrated by using the reference images obtained as described above and transformed into a 8-bit gray scale (256 levels of luminance). In the resulting figures white and black correspond to 0 and 100% O$_2$ saturation, respectively. Subsequently, the images were cropped to remove the crown external to the sensor foil and transformed into a matrix of O$_2$% air saturation using the Matlab function `imread` (MathWorks, 2012).

**Determination of O$_2$ Consumption Rates**

The O$_2$ consumption rates were calculated based on the decline of O$_2$% air saturation over time (i.e., the slope of the interpolating regression line) as reported by Tschiersch et al. (2011). We selected only specific time intervals where the regression line between O$_2$% air saturation and time was highly significant ($p < 0.01; R^2 > 0.90$). The slope ($\sigma$) was then used to calculate the O$_2$ content in air-saturated water at temperature ($\theta$) and pressure ($p_{atm}$) according to the following equation (Presens, 2009):

$$c_S(p_{atm}, \theta) = \frac{p_{atm} - p_w(\theta)}{\sigma 0.2095 \alpha(\theta)} \frac{M_O2}{V_M}$$ (1)

where: $c_S$ is the water O$_2$ content in mg l$^{-1}$; $p_w$ is the water vapor pressure at the temperature $\theta$; $p_N$ is the standard pressure (1013.26 mbar); $\sigma$ is the slope of the regression line; 0.2095 is the volume of O$_2$ content in air; $\alpha(\theta)$ is the Bunsen absorption coefficient (Benson and Krause, 1980) i.e., the volume of gas dissolved in a unit volume of solvent at standard partial pressure of the gas (1013.26 mbar) at the temperature $\theta$; $M_O2$ is the molecular mass of O$_2$ and $V_M$ is the molar volume of O$_2$. The atmospheric pressure values ($p_{atm}$) was recorded at
the nearby weather station (San Michele all’Adige; 46.18349–11.120220) with a PTB220 digital barometer (Vaisala, Finland) whereas temperature (θ) was monitored close to the Petri dish (as explained above). Knowing the time step of image acquisition (5 min) and the surface area (selected for the root and fungus), we could then transform $c_S$ from mg $O_2 l^{-1}$ into g $O_2 m^{-2} d^{-1}$. Since our agar medium was 0.3%, we performed the above calculations treating the medium as pure water: indeed, according to Van der Meeren et al. (2001), the diffusion coefficient of $O_2$ in a 0.7–2.0% agar solution only decreases by 1.7 and 2.8%, respectively.

**Statistical Analysis**

The collected images were transformed into a matrix of oxygen concentration, with each value attributed to the center of the corresponding pixel. The position of each pixel is therefore identified by two indexes $(i,j)$, referring respectively to the row and the column of the matrix (Figure 2) whereas $N_1$ and $N_2$ are the number of pixels along the horizontal and vertical directions, $\Delta x_1$ and $\Delta x_2$ are the respective dimensions of the pixels. The origin of the reference system was fixed in the upper left corner of the cropped image, with the $x_1$ axis going from left to right and the $x_2$ axis from top to bottom (Figure 3).

**Temporal Dynamics of Oxygen Concentration**

To quantify the dynamics of fungus and root $O_2$ concentration, we selected targeted portions of the sensor foil: i.e., the area including the root and its adjacent surroundings (defined as the inner core) and the area including the fungus and its surroundings (upper corner or central part of the optode; Figure 3). We then assumed that the density of the fungus, was linearly proportional to the deficit in the $O_2$ concentration:

$$\rho_{ij} = \Delta C_{ij} = (100 - C_{ij})$$  

where $\rho_{ij}$ is the $O_2$ deficit compared to saturation and $C_{ij}$ is the concentration of $O_2$ expressed as a percentage of air saturation (the two indexes identify the position within the sensor foil, with $j\Delta x_1$ and $i\Delta x_2$ being the coordinates of the pixel center $(i,j)$, having an $O_2$ concentration $C_{ij}$. We also assumed that the mass of the fungus was proportional to its $O_2$ consumption. Given the above assumptions, we characterized the fungus dynamics by computing the spatial moments of the oxygen deficit $\rho$. 

![Figure 2](https://example.com/figure2.png)

**Figure 2** | The reference system used to calculate the temporal dynamics of $O_2$ concentration (A) was constituted by a computational grid with $\Delta x_1$, $\Delta x_2$ mesh coinciding with the pixel dimensions in the horizontal and vertical directions respectively (the color of the pixel represents the saturation deficit). (B) If the spatial growth of the fungus colony is uniform, the principal directions $x_I$ and $x_{II}$ coincide with $x_1$ and $x_2$ respectively, and angle $\alpha$ is 0 compared to the reference axis $x_1$. (C) If the growth of the colony has a preferential direction (e.g., along axis $x_{II}$) the principal directions are rotated clockwise by an angle $\alpha \neq 0$ (e.g., $\alpha = \pi/4$). In all cases, the tensor of second moments is diagonal when evaluated in relation to axes $x_I$ and $x_{II}$ instead of $x_1$ and $x_2$, (i.e., $X_{II} > X_{I} > X_{II}$).
**Spatial Moments**

Spatial moments were chosen because they are useful indicators for describing (i) in which direction the fungus is propagating, (ii) how the fungus grows (as expressed by second moments), and (iii) how the fungus is propagating (e.g., whether it is following a diffusive process or not). The first spatial moment illustrates the evolution in time of the center of mass of the fungus of coordinates $\bar{x}_1$ and $\bar{x}_2$, which is also described by the spatial distribution of the $O_2$ deficit:

$$\bar{x}_1 = \frac{1}{M} \sum_{i=1}^{N_2} \sum_{j=1}^{N_1} i \rho_{ij} \Delta x_1 \Delta x_2$$

$$\bar{x}_2 = \frac{1}{M} \sum_{i=1}^{N_2} \sum_{j=1}^{N_1} i \rho_{ij} \Delta x_1 \Delta x_2$$

where $M = \sum_{i=1}^{N_2} \sum_{j=1}^{N_1} \rho_{ij} \Delta x_1 \Delta x_2$ is proportional to the total mass of the fungus. Similarly, the 2s order moments $X_{11}$, $X_{12}$, and $X_{22}$, which are descriptors of colony spatial distribution (i.e., spreading around the central mass) compared to the two reference axes $x_1$ and $x_2$, are given by:

$$X_{11} = \frac{1}{M} \sum_{i=1}^{N_2} \sum_{j=1}^{N_1} (j \Delta x_1 - \bar{x}_1)^2 \rho_{ij}$$

$$X_{12} = \frac{1}{M} \sum_{i=1}^{N_2} \sum_{j=1}^{N_1} (i \Delta x_2 - \bar{x}_2) \rho_{ij}$$

$X_{11}$, $X_{22}$, $X_{12}$, represent respectively longitudinal, transversal, and cross-directional spreading around the central mass of the fungus.

**RESULTS**

**O$_2$ Dynamics During Root-Fungus Interaction**

In the first experimental run, the $O_2$% air saturation in the upper right corner of the sensor foil decreased for about 12 h, from 37.1 to 19.7% ($\Delta = 17.4$%: Figure 4A). This was the consequence of an initially high fungal respiration rate (e.g., $O_2$ consumption), which was quantified in $18.2 \text{ g} O_2 \text{ m}^{-2} \text{ d}^{-1}$, reaching a minimum and then recovering to the initial value (Figure 4A). The $O_2$ level in the inner core peaked at 38.2% at 5.5 h ($t = 5.5 h$) then decreased due to a high consumption rate, quantified as $19.9 \text{ g} O_2 \text{ m}^{-2} \text{ d}^{-1}$ (Figure 4A). Through visual inspection of the image sequence, we observed that the fungus colonized the root between 15 and 20 h from the beginning of the test; subsequently, changes in $O_2$% air saturation were the result of the combined oxidative metabolic activity of two overlapping organisms, quantified as $0.5-1.2 \text{ g} O_2 \text{ m}^{-2} \text{ d}^{-1}$. When the root-fungus interaction experiment was repeated, similar behavior was observed (Figure 4B): fungal respiration increased, with $O_2$ falling from 36.7% at the beginning of the experiment to 24.1% at $t = 12 \text{ h}$ ($\Delta = 12.6$%) and recovered afterwards. The $O_2$ concentration in the inner core (root) peaked at $t = 8.5 \text{ h}$ (37.9%) and then decreased (Figure 4B). The fungal and root respiration rates were $18.1$ and $4.5 \text{ g} O_2 \text{ m}^{-2} \text{ d}^{-1}$, respectively.

In the control with the plant alone, the root $O_2$% air saturation varied between 27.9 and 32.2% ($\Delta = 4.3$%; Figure 5A). The $O_2$ peaks were in phase with temperature peaks (temperature ranged from 20 to 25.4°C; $\Delta = 5.4$; correlation analysis: Pearson $r^2 = 0.44$, $p < 0.01$, $N = 141$; from $t = 0$ to $t = 70 \text{ h}$), whereas the concentration fluctuated broadly around 13.5% $O_2$ for about 15 h (Figure 5B). A release phase followed, coinciding with a decrease in temperature. From $t = 16 \text{ h}$ to $t = 70$, the oxygen trend largely reflected the temperature trend (i.e., $O_2$ concentration decreased with increasing temperature; correlation analysis: Pearson $r^2 = -0.05$, $p < 0.01$, $N = 141$) with $O_2$% air saturation ranging from 13.0 to 21.6% ($\Delta = 8.6$%) and temperature ranging between 19.2 and 24.9°C ($\Delta = 5.7^\circ$C). Respiration rates varied between 37.4 and 101.0 g $O_2 \text{ m}^{-2} \text{ d}^{-1}$.

**Temporal and Spatial Activity of the Fungus**

In the presence of the root, the trajectory of the fungus’ center of mass rotated counter-clockwise with the maximum distance from the original position recorded 18 h after inoculation (Figure 6A). During this period the barycenter of the colony moved slightly away from the root (from left to right and upwards), the mass grew almost uniformly in the upper corner of the sensor foil. Initially the movement of the center of mass was very fast (after 12 h the distance traveled by the barycenter was about 0.8 mm), while it took about 60 h to return to its original position. At each time step the second moments were computed in the reference system ($x_1$, $x_{12}$) rotated by the angle $\alpha$ the reference...
The results obtained in the two root-fungus interaction experiments demonstrate the consistency and related reliability of the planar optode technique in monitoring O
subscript 2 continuously, over a prolonged period of time and without perturbing the system. In both tests, an initially high level of fungal respiration (e.g., O
subscript 2 consumption), peaking after 12 h was seen. The respiration rates were almost identical in the two control tests (18.2 and 18.1 g O
subscript 2 m
superscript -2 d
superscript -1 respectively). A similar trend in Fol O
subscript 2 consumption was reported by Nell et al. (2006). However, direct comparison with the values recorded by Nell et al. (2006) is not possible, since their data are expressed in terms of relative fluorescence units and the rates measured in our work are the result of different factors, such as root stimulation and presumably root exudates (Bais et al., 2006). Root exudates can indeed stimulate the germination of Fol microconidia (Steinkeller et al., 2005, 2009). The peak in fungal respiration was followed by a phase of lower respiration caused by a decrease in fungal metabolic activity present in the reference area (upper corner) due to the fact that the fungus moved out of the investigated area and colonized the root.

Root O
subscript 2 consumption at the beginning of the first experiment (19.9 g O
subscript 2 m
superscript -2 d
superscript -1) was similar to that of the fungus alone, whereas, in the second root-fungus experiment it was lower (4.5 g O
subscript 2 m
superscript -2 d
superscript -1), probably due to lower physiological activity of the plant (Lai et al., 2016). The measured root respiration rates were of the same order of magnitude as those observed by Dong et al. (2011), in a wetland mesocosm for the aquatic plant Acorus calamus L. (14.4–30.3 g O
subscript 2 m
superscript -2 d
superscript -1). The small number of available studies and the lack of experimental details (e.g., area, temperature, pressure) (Hadas and Okon, 1987; Tschiersch et al., 2011; Han et al., 2016; Rudolph-Mohr et al., 2017; Lenzewski et al., 2018) does not allow additional comparison with in vitro respiration rates. The change in O
subscript 2% air saturation for the fungus alone (Δ = 8.6) was lower than that measured in the fungus during root-fungus interaction (12.6 < Δ < 17.4). This difference can be explained by the sudden peaks in air temperature recorded during the experiment with the fungus alone. The increase in temperature indeed promoted an increase in respiration rates (up to 101.0 g O
subscript 2 m
superscript -2 d
superscript -1). The variation in O
subscript 2% air saturation of the root alone was even lower (Δ = 4.3) than that measured during interaction. The low rates of O
subscript 2 consumption can be related to potential root O
subscript 2 emissions. Several studies have shown aerenchyma tissue development and O
subscript 2 emissions from tomato roots and for other cultures as well, as a consequence of waterlogging (Kawase and Whitmoyer, 1980; McNamara and Mitchell, 1990; Xu et al., 2013; Vidot et al., 2016).

Statistical analysis of the data allowed quantification of the aforementioned observations, making it possible to distinguish...
three distinct phases in particular: (i) a peak in oxygen consumption reached at 12 h occupying about 50% of the upper corner area; (ii) occupation of the whole area between 22 h (minimum of \( X_{II,II} \)) and 25 h (maximum of \( X_{I,I} \)); (iii) root colonization (Figure 7A). We cannot define the precise moment of contact between the fungus and root, because this would have required microscope investigation at a higher magnification, however we can say that this happened between 12 and 22 h.
Concentration Changes in Root-Pathogen Interaction

FIGURE 6 | Time evolution of the barycenter (center of mass) of the fungus’ O$_2$ deficit relative to its initial position, in the presence of the root (A; March 14, 2014) and without the root (B). The deficit is considered to be proportional to the mass of the fungus and provides information on fungal growth.

(i.e., the fungus started to move after reaching peak activity). This behavior of *Fol* in colonizing tomato roots is in line with that observed by Lagopodi et al. (2002), although they used a destructive method, using a new biological sample for each subsequent observation and not showing the dynamics of metabolic activity for the two organisms. These complex dynamics ended at about 40 h, when both moments stabilized. From this time on the colony reduced its density uniformly in space. This behavior demonstrates that growth is stimulated by perception of the root and presumably by the diffusion of root exudates through the medium (Bécard and Piché, 1989).

In the experiment with the fungus alone, the barycenter of the object did not move, while second order moments along the principal directions grew linearly with time (Figures 6B, 7B respectively), apart from two sudden drops at 18 and 40 h due to abrupt changes in temperature (data not shown). Angle $\alpha$ oscillated between $-40^\circ$ and $+40^\circ$. The linear, in time, growth of the second moments is indicative of a Brownian motion which is characterized by random movement of a population of particles (Einstein, 1956). This behavior was expected, since fungus has been shown to grow radially on jellified nutritional medium (Trinci, 1969).

CONCLUSIONS

Overall, the planar optode technique proved to be a useful tool for investigating the O$_2$ dynamics of root-fungus interaction, due to the flexibility of the system, which technically allows testing of the effect of virtually infinite perturbing factors in interaction and the possibility of studying other plant and fungal species. However, one limitation of the approach presented is the need to work in dark conditions to protect the sensor foil from light interference. This aspect, together with the need for a layer of water between the sample and the optode, make the approach unsuitable for open field studies at the moment. For the first time our work visualizes and quantifies the dynamics of O$_2$ consumption and related metabolic activity characterizing root-fungus interaction, with the considerable advantage, as compared to standard methods, of not being destructive. Geostatistical analysis made it possible to describe and quantify the spatial motion of the fungus, which was stimulated by the presence of the root and oriented its growth.
This situation was completely different in the experiment with the fungus alone, which was characterized by random Brownian motion.

We conclude that combining optodes and geostatistical analysis is a powerful tool for understanding the temporal and fine scale root-fungus interaction, especially to complement functional studies carried out with other approaches. Translation to real soils needs caution, given the significant effect of heterogeneity in soil and nutrient distribution, which affects the magnitude and direction of fungal growth.

**AUTHOR CONTRIBUTIONS**

MR, SR, DG, and ET planned and designed the research. MR and ET performed experiments and conducted fieldwork. MR, SR, AB, ET, IP wrote the paper. MR, SR, AB, ET, GM, and IP revised the paper.
