Abstract: Background/Purpose: In recent times, Sub-Sahara Africa (SSA) had been rated by the World Health Organization, (WHO), as the most malaria endemic region in the world. Evidence synthesis of the risk factors associated with malaria among children aged under-five in SSA is urgently needed. This would help to inform decisions that policy makers and executors in the region need to make for the effective distribution of scare palliative resources to curb the spread of the illness. This scoping review is aimed to identify studies that have used multivariate classical regression analysis to determine risk factors associated with malaria among children under-five years old in SSA. Methods/Design: The search terms followed PICOTS, (Population, Intervention, Comparator, Outcome, Timing, Setting), and were used in searching through the following databases: PubMed, MEDLINE, Web of Science, Cumulative Index of Nursing and Allied Health Literature (CINAHL), Scopus, and MeasureDHS. The databases were searched for published articles from January 1990 to December 2020. Results: Among the 1154 studies identified, only thirteen (13) studies met the study’s inclusion/exclusion criteria. Narrative syntheses were performed on the selected papers to synchronise the various risk factors identified. Factors ranging from child-related, (age, birth order and use of bed net), parental/household-related, (maternal age and education status, household wealth index) and community-related variables, (community wealth status, free bed net distribution), were some of the identified
significant risk factors. Conclusion: It is timely to have a synthesis of risk factors that influence the malaria status of children under-five in SSA. The outcome of the review will increase the knowledge of the epidemiology of morbidity that will form the basis for designing efficient and cost-effective distribution of palliatives and controls of malaria in SSA.

1. **Introduction**

Malaria has remained one of the major global public health challenges in the last two decades, especially in low- and medium-income countries putting almost half of the world population at risk of infection [1]. In 2015, over 214 million estimated cases of malaria were reported with over 450,000 deaths worldwide [2,3]. Surprisingly, in 2018, the number of malaria cases has risen to over 300 million worldwide [4], and in 2019 the estimated malaria cases from 87 endemic nations were approximately 230 million [3]. It is on record that the world experienced steady decline in the number of deaths from malaria cases from over 730,000 in 2000 to over 400,000 in 2019[3,5]. In 2017, with the estimated 430,000 deaths, Sub-Sahara Africa (SSA) contributed over 90% of the global malaria deaths and with over 260,000 being children under-five years of age, translating into one child dying every two minutes [2,6]. By 2019, under-five years deaths from malaria were over 60% of the total estimated deaths [3]. It is worthy of note that in the last decades, a lot of programmes and strategies have been implemented to control malaria both at the global and country levels which has resulted in the prevention of over 6 million deaths between 2000 and 2015 in SSA [4].

Deaths and the burden of malaria cases among children under-five years old varies across the various countries in SSA. Malaria alone contributes to more than 30 per cent of under-fives mortality in Nigeria [5]. With over 51 million cases and 200,000 death annually, Nigeria has become the most malaria burden nation in the world, with more than 30% of child mortality as a result of malaria cases [2,5]. In Tanzania, malaria is responsible for more than 10% of under-five deaths and is the second
largest contributor to childhood morbidity and mortality [7] and is the leading cause of death in Mozambique accounting for over 30% of all deaths [8]. Ethiopia on the other hand is recorded amongst the countries with the highest under-five mortality in SSA [9], with almost a quarter of the areas being malaria-endemic, such that greater proportion are exposed to malaria infection [4]. In 2016, Cameroon contributed to about 3% of the total number of global deaths from malaria-related cases and most of these deaths are amongst under-five years old children [10].

Apart from SSA, some other regions of the world contribute to the global burden of malaria. For instance, in 2019 out of the 107 malaria-endemic countries in the world, the South East Asia region has nine countries [3] making the area second to Africa in terms of estimated malaria cases [11]. The South Asian region records between 90-167 million malaria cases with over 125,000 deaths per annum [3,12]. Bangladesh is one of the four malaria-endemic country in South East Asia [11], with over 17 million people at risk of malaria infection [13].

Plasmodium falciparum (pf) and Plasmodium vivax (pv) are the most predominant malaria parasites causing malaria with over 60% and 40%, respectively of cases in Ethiopia [14]. In India, this is estimated to be in the ratio 10:7 [12]. The reverse is the case for Brazil where more than 60% of the 170 million people in the American region at risk of malaria cases reside, and over 70% of the cases are traceable to pv and pf contributing more than 25% [15]. However, Plasmodium falciparum alone accounts for more than 95% of malaria cases in Nigeria [5,16].

Researchers have attributed the prevalence of malaria in SSA to several factors, which include medical condition, environmental factors/seasonal influences and human status, (such as age, gender, pregnancy, blood group and rhesus factors among others), socioeconomic, demographic and area-related characteristics [4,17]. Malaria infection is said to be more prevalent in rural areas than in urban centres [14]. Until recently, malaria was believed to be a rural area disease because the transmitting vectors are said to breed more in the rural areas [14]. On a contrary note, Baragatti et al 2009 [18] observed that malaria has remained a serious public health concern in urban areas. This is not unconnected with the general belief that developing urban centres will reduce the transmission of malaria infection [14].
Unfortunately, this is not the situation for most African countries with limited resources to provide adequate infrastructural amenities that will cope with the rate of urbanization experienced, resulting in poor housing, sanitation and drainage systems which could increase vector breeding and human contacts [14]. Reports from studies on gender differences have also found mixed conclusions. For instance, a higher prevalence of malaria among boys than among girls has been reported in [19], while, another study reported a higher prevalence among females than males [20]. The occurrence of mosquitoes, the vector for malaria appears to be higher during the wet season than in the dry season [17]. However the transmission rate of malaria is relatively higher in hotter regions but with mountainous areas providing protection from transmission [8].

In Nigeria, for instance, as in most SSA, the need to measure the impact of National Malaria Strategic Plan (NMSP), 2014-2020, to reduce malaria-related mortality to zero by 2020 has resulted to a rise in the number of aged related studies on malaria [5]. As much as these studies are essential towards evidence-based health care decisions on malaria fever control in Nigeria and SSA, much more critical is the scoping of these studies. This has not been done, especially concerning determinants of the prevalence of malaria among children under-five years in SSA. Therefore, this study aims to bridge this knowledge gap.

1.1 The purpose of the scoping review

This scoping review aimed to find and evaluate the studies that describe the association between the socioeconomic, demographic, and contextual factors and the prevalence of malaria fever among children of under-five years in Sub-Saharan Africa.

2. Materials and Methods

2.1 Criteria for Inclusion and Exclusion of Studies

The scoping review followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) checklists [21,22]. The review question was in line with the PICOTS (Population, Interventions, Comparators, Outcomes, Timing and Study Design).
(i) The population of the study was any child under-five years in SSA countries, irrespective of their gender.

(ii) The exposures include socioeconomic, demographic, and contextual risk factors. These interventions were either classified as child-related, parental/household-related or community-related. Where the study reported both adjusted and crude effect sizes, the adjusted was selected.

(iii) The comparator was between the children under-five years in SSA that had malaria infection versus those that did not have malaria infection.

(iv) The outcome variable was the malaria status. What was considered in this review were studies on socioeconomic, demographic, and environmental determinants of malaria fever among under-five children of both sexes, that used standard testing procedures in identifying malaria fever status. The usual method of testing for the presence of Plasmodium parasites was by measuring the axillary temperature of 37.5 °C [23]. And, carry out a microscopic examination of thick and thin blood smears that were positive with several asexual parasites per 200 white blood cells, while if white blood cells had a count of 8000 cell/ul [24]. Also, studies which identified malaria status through Rapid Diagnostic Test (RDT) were included.

(v) The time interval used for inclusion of studies were articles written in English and published between 1 January 1990 and 31 December 2020.

(vi) The study designs covered all observational studies (cross-sectional and cohort studies).

2.2 Search Strategy

The search strategy was first carried out in PubMed with the following terms as displayed in table 1 and combined with appropriate Boolean connectors.
Table 1 Search terms combinations

| S/N | Search terms |
|-----|--------------|
| 1   | demographic health survey OR AIDS indicator survey OR malaria indicator survey OR multiple indicator cluster surveys OR health survey OR MIS OR DHS |
| 2   | sub-Sahara Africa OR SSA |
| 3   | logistic regression OR multilevel regression OR multinomial logistic OR random-effects OR hierarchical OR fixed effects OR Linear regression |
| 4   | Malaria OR fever OR plasmodium falciparum OR P. malariae OR P. ovale OR P. vivax) |
| 5   | 1 AND 2 AND 3 AND 4 |

2.3 Sources of Information

The online databases for literature search using the search terms of PICOTS produced the following results as displayed in figure 1. The results identified a total of 1154 publications. PubMed (867 results), Cumulative Index to Nursing and Allied Health Literature (CINAHL) (14), Scopus (0) MEDLINE(WOS) (122), Measure DHS (154). The databases were searched for published works from 1 January 1990 to 28th December 2020. The searches were done on the 13th and 14th December 2020.
2.4 Study Selection

The selection processes followed the PRISMA-ScR recommendation [25]: Identifying all potential papers from databases and other sources; screen to remove duplicate publications; eligibility consideration to
exclude those that did not meet up with inclusion criteria and inclusion for the review.

2.5 Data Selection Process

The reviewer PEO extracted relevant data from selected studies into a Microsoft Excel spreadsheet, (Microsoft Corporation, Washington, USA), designed for this extraction and was verified by the supervisory team.

3. The Results

3.1 Description of Study Records

This review aimed to synthesize evidence from published articles describing the determinants, (socioeconomic, demographic and contextual), of the malaria status of children of under-5 years in SSA between January 1990 and December 2020. The flowchart diagram in figure 3 shows the selection of studies included for review. A total of 1157 records were identified from all the databases consulted. Ninety-three (93) were retained for full-text examination, and only thirteen (13) unique publications, (with 18 country-specific studies), met the inclusion criteria and were examined for this review.

3.1.1 Study characteristics

Table 2 describes the characteristics of the 13 extracted papers considered for this review. The information includes the author’s name and date of publication, the title of the paper, study location, survey type, target sample, the prevalence of the outcome, sample size, statistical methods, and software used for computation. The prevalence of malaria in under-five as reported in the papers reviewed ranged from 18% in Tanzania to 39% in Uganda as reported in Njau et al (2013) [26]. The mean sample size per study was 30,775 participants.

| Table 2. Characteristics of the Included Studies |
| Authors & Dates | Titles | Country | Survey* | Target Population | Prevalence (Sample size) | Participants | Malaria Diagnostic Method** | Methods | Software | Funding source |

*Surveys: MIS=Malaria Indicator Survey, DHS= Demographic and Health Survey; ** RDT=Rapid Diagnostic Rest, MT=Microscopic Test
Fig 2 displays in charts A to G, the various study characteristics. Chart A describes that the publication years for the included studies were between 2013 and 2020. In 2016 there was no publications extracted, and 2018 period had the highest number of publications (23%), while 2013 and 2019 had one publication each (representing 7.7%) and the remaining years had 15% each. On study setting (chart B), the number of studies from multi-country (33%) were more than every other country-specific studies. Nigeria, Malawi, Tanzania and Uganda had two studies (11%) each, and the remaining countries had one study each.
Fig 2: Charts (A-G) represent the distributions of the characteristics of included studies.

With more than 70% of the number of country-specific studies, malaria indicator survey (MIS) was the most used surveys among the included studies (chart C), followed by multi surveys (16%) and Demographic and Health Survey (11%). Likewise, chart (D) indicates that multivariate logistic regression methods (46%) was the most used statistical method. Furthermore, with 38%, STATA was the most preferred statistical software used in the selected publications. This was followed by SAS, SPSS and combined softwares. The least popular was JMP (7.6%). Funding sources (chart F) shows that multiple sources of funding was the highest (38%), while no funding was reported in 30% and two of the studies did not disclose any funding source. Three diagnostic methods reported to detect malaria infection status in children under-five years among the studies included were Rapid Diagnostic Test (RDT),
Microscopic Test (of thin and thick blood smear), and Polymerase Chain Reaction (PCR). The chart (G) shows that RDT and the combination of RDT and MT were more popular. One study reported using PCR.

3.2 Data Synthesis Method

The narrative/tabulation syntheses of the outcomes/findings from multiple reports for this review following the narrative guidelines given in Popay et al.[38] was used. The objective of the review was to collate pieces of evidence on the association between the socioeconomic, demographic, and contextual indicators on malaria fever among under-five children in SSA from 1990 to 2020. The results were appraised using the narration of the descriptive statistics and odds of the likelihood of the risk factors and the outcome variable (Malaria status).

3.2.1 Risk Factors associated with Malaria Status

The socioeconomic, demographic, and contextual determinants of malaria status among children under-five in SSA were grouped into child-related variables, mother or care-giver-related variables, household-related variables, and environmental or Area-related variables and interaction terms. These variables include: age of the child, weight, anaemia status, birth order status; maternal age and education statuses, parent’s knowledge, attitude and practices of some basic facts about malaria fever; the type of material used to construct the building, distance from a health facility and cluster altitude as factors identified that are associated with malaria status among children under-five years in SSA. A factor was considered statistically significant concerning what each paper considered as the P-value cut off (0.01, or 0.05, or 0.001). In a situation where the factor was classified into different categories or dummies, the factor was labelled as statistically significant if at least one of the categories or dummies compared to the reference category was statistically significant.

Child-related Variables

Table 3 shows the evidence found on child-related variables. This study revealed the role that the age of the child plays in the tendency that the child could be infected with the malaria parasites. Eleven (11) of the country-specific studies investigated a child’s age being under-five years as risk factor of their potential malaria status. Nine of the studies
found that the child’s age in at least one of the age groups was significantly associated with the prevalence of malaria among under-five years in SSA. In most of the studies it was found that as the child’s age increases, the odds of contracting malaria fever also increases [24,33,35,37,39]. However, Semakula et al [32] in their multi-country study found no statistical significance in Tanzania [OR:1.26, CI: 0.94-1.70, p<0.128] and Burundi [OR:0.79 CI: 0.60-1.05, p<0.108], but found significant effect in Malawi [OR: 1.85 CI: 1.33-2.56, p< 0.001] and Liberia [OR: 2.10 CI: 1.59-2.80, p<0.001]. Three studies investigated the sex of a child as a risk factor of the prevalence of malaria among under-five years old children in SSA. Surprisingly, these three studies, [OR:0.96 CI: 0.91-1.02, p<0.18] [39], [OR:0.927, p< 0.2627] [35], and [OR:1.04 CI: 0.82–1.32, p<0.764] [24] found no statistically significant effect. Also, three studies that explored the effect of birth order found statistically significant effects, [OR:1.03 CI: 1.01-1.06, p<0.011] [27], when the child was second-order compared to the 1st child born: [OR:1.43 CI: 1.04-1.96, p<0.03] [28] and [Marginal Effect: 0.045, p<0.01] [31].

Table 3: Association between child-related variables and malaria status

| S/N | Variables            | Significant levels | Number of studies | Association Effect (95% CI)                                                                 |
|-----|----------------------|--------------------|-------------------|------------------------------------------------------------------------------------------|
| 1   | Age of the child     | S:                 | 9                 | Increased Risk Factors                                                                  |
|     |                      |                    |                   | OR:1.05 (1.04-1.06)[27]                                                                  |
|     |                      |                    |                   | OR:1.03 (1.02, 1.04) [28]                                                                |
|     |                      |                    |                   | 7-23: OR:2.29 (1.21–4.34), 24-59: OR:5.67 (3.01–10.70) [30]                                |
|     |                      |                    |                   | OR:1.85 (1.33-2.56) [32]                                                                 |
|     |                      |                    |                   | OR: 2.10 (1.59-2.80) [32]                                                                |
|     |                      |                    |                   | 6-11: OR:2.22 (1.88, 2.62); 12-23: OR:3.70 (3.12, 4.37) 24-35: OR:5.00 (4.25, 5.87) [33] |

|   | NS: 5 [27,32,32,33,37] |

OR: Odd Ratio, ME: Marginal Effect, β: Coefficient estimate, S: Significant, NS: Not Significant

Contrary to expectation, whether or not a child slept under a long-lasting insecticide-treated net was reported in five out of nine studies, [OR:0.93 CI: 0.84-1.02, p<0.13] [27]; [(in Malawi study), OR:0.88 CI: 0.73-1.07, p<0.202] [32]; [(in Liberia study), OR:0.99 CI: 0.85-1.17, p<0.945] [32]; OR:0.93 CI: 0.81-1.07] [33]; [OR:1.5 CI: 0.9–2.4 p<0.146] [37], not to be a significant predictor of malaria infection among children under-five years in SSA.

**Maternal Variables**

Table 4 describes the various risk factors predicting the likelihood that a child would contract malaria fever at maternal-related variables level. Out of three studies that analysed maternal age as a risk factor of
contracting malaria fever among children under-fives in SSA, two studies (Njau et al., 2014 and Siri et al, 2014) [31,33] found no statistically significant effect. While, Berendsen et al, 2019 [27] found a statistically significant effect, [OR: 0.99 CI: 0.98-0.99, p<0.00047] of maternal age [27]. Maternal education was the most considered risk factor in maternal-related variables. Children of under-5 years in SSA whose mothers or caregivers had a low level of education significantly suffered more malaria fever than their counterparts [42]. But Zgambo et al, 2017 [37] did not find any statistically significant effect of maternal education on the likelihood of malaria infection among children under-five years in SSA.

**Table 4 Association between maternal-related variables and malaria status**

| 4   | Maternal ANC               | S: 1               | DRF:  | β: −0.029[31]              |
|     |                            | NS:                |       |                            |
Also, maternal knowledge of malaria fever was found to be a statistically significant predictor of under-five malaria cases in SSA. Children whose mothers showed having knowledge of malaria fever were less likely to be infested with malaria parasitaemia, $[\beta: -0.013, p<0.01]$ [31] and $[\text{OR: } 0.78 \text{ CI: } 0.62-0.99, p<0.037]$ [24].

**Household-related variables**

Table 5 describes the distribution of significant effects of household-related variables on the likelihood of developing malaria infections among children under-five years in SSA. The most widely assessed household-related risk factors are: Household socio-economic status (designated as household wealth), place of residence (whether urban or rural area), Household size, improved water source and improved toilet facilities. All the eleven country-specific studies that investigated household wealth as risk factor found at least one of the categories being a statistically significant predictor of malaria status. The higher the household wealth quintile, the less likely that the child in the household would contract malaria fever. The thirteen country-specific studies that found a statistically significant effect of the place of residence, all reported that it was more harmful for a child under-five years in rural SSA than in urban areas in contracting malaria fever. Though Wanzira
et al. 2017 [24] and Zgambo et al. 2017 [37] found no statistically significant effect of place of residence, yet they reported a more protective effect for urban children than rural children, [OR: 1.74 CI: 0.92–3.29, p<0.089] [24], [OR: 2.3 CI: 0.9–6.0, p<0.075] [37].

OR: Odd Ratio, ME: Marginal Effect, β: Coefficient estimate, S: Significant, NS: Not Significant
It is worthy of note that access to mass media, number of rooms in the household and type of wall material were found not to be statistically significant risk factors of malaria fever among children under-five in SSA [26,35]. The variations in household ownership of livestock was a statistically significant predictor of malaria status in children under-five years in SSA. Semakula et al, 2015 [32] reported consistent findings in their four country-specific studies that a child from a household that owns cattle has a lower odd of contracting malaria parasitaemia than a child from a household without livestock, (Tanzania, [OR: 0.55 CI: 0.45-0.67, p<0.001]; Burundi, [OR: 0.51 CI: 0.40-0.65, p<0.001]; Malawi, [OR: 0.54 CI: 0.35-0.83, p<0.005]; Liberia, [OR: 0.74 CI: 0.55-1.00, p<0.047]).

**Environmental/Area-related Variables**

In consideration of environmental-related risk factors, three variables, (regional variations, malaria endemicity, and community free bed net distribution), were attractive for investigation among the included studies. Table 6 reports that Njau et al 2013 [26] found that the predicted marginal effects of malaria-endemic areas for malaria fever in Angola, Tanzania and Uganda were significantly 1.0 (p<0.10), 9.5 (p<0.05) and 28.8 (p<0.01) percentage points, respectively. Additionally, the same authors [26] reported an insignificant increase in the predicted marginal effects of 25.1% points for free bed net in the community among malaria positive children in Angola, but significant reduction of 1.5% (p<0.1) and 8.2% (p<0.05) in Tanzania and Uganda, respectively.

### Table 6 Association between environmental-related variables and malaria status

| S/N | Variables                          | Significant levels | Number of studies | Association Effect (95% CI)                       |
|-----|-----------------------------------|--------------------|-------------------|-------------------------------------------------|
| 1   | Community wealth status           | S: 1               |                   | IRF: Cluster level: OR: 0.984 (0.979, 0.988)[33] |
|     |                                   | NS: -              |                   |                                                 |
| 2   | Community female education status | S: -               | 1 [33]            |                                                 |
|     |                                   | NS: 1              |                   |                                                 |
| 3   | Community distance to health facilities | S: 2         |                   | IRF: ME: 0.084, (0.0560–0.1128) [26] ME: 0.102, (0.0525–0.1521) [26] |
|     |                                   | NS: -              |                   |                                                 |
| 4   | Cluster altitude                  | S: 1               | 1 [28]            | IRF: OR 1.0003 (0.991-1.1003) [35]                |
|     |                                   | NS: 1              |                   | IRF: OR 0.43 (0.27, 0.70)[29]                     |
Also, significant regional variations were reported across the six geopolitical zones of Nigeria. Morakinyo et al 2018 [30], which found reduced odds of malaria infections among children 6-59 months in North Central, [OR: 0.61 CI: 0.47–0.79, p<0.01]; North East, [OR: 0.35 CI: 0.27–0.46, p<0.01]; North West, [OR: 0.49 CI: 0.37–0.64, p<0.01]; South East, [OR: 0.59 CI: 0.44–0.79, p<0.01]; South-South, [OR: 0.42 CI: 0.31–0.55, p<0.01], when compared with children from South West. Contrary to Morakinyo et al 2018 [30] report on Nigeria study, Ugwu et al 2018 [35] found insignificant effects on regional variations in South East, South-South, South West, and North Central when compared with North West, but found significant odd of malaria positive cases among 6-59 months in North East (OR: 0.3059, p<0.015) when compared with North West.
**Interactions-related Variables**

Interaction-related risk factors were reported by two papers in four county-specific studies (table 7). Njau et al 2013 [26] reported a significant decrease of 4.6% (p<0.05) points in the predicted marginal effects among malaria positive children in Angola with respect to interaction terms of free bed net and wealth status but found insignificant reduction of 0.9% and 6.4% in Tanzania and Uganda, respectively.

*Table 7: Association between interaction-related variables and malaria status*

| S/N | Variables                                      | Significant levels | Number of studies | Association Effect (95% CI)                                                                 |
|-----|-----------------------------------------------|--------------------|-------------------|-------------------------------------------------------------------------------------------|

|     |                                               | NS:                |                   |                                                                                           |

**OR:** Odd Ratio, **ME:** Marginal Effect, **β:** Coefficient estimate, **S:** Significant, **NS:** Not Significant

Ugwu et al 2018 [35] found significant interaction effects of wealth index (poorest, poorer, middle, richer and richest) and place of residence (rural or urban). In consideration of the report, the middle and richer household group in the rural area (OR: 0.448 CI: 0.2197-0.9124, p<0.027 and OR: 0.417 CI: 0.2213 – 0.7871, p<0.007) displayed a higher odd of malaria positive than the poorest and poorer household group in the rural area (OR: 0.3567 CI: 0.1319-0.0429, p<0.0429 and OR: 0.2770 CI: 0.1149-0.6677, p<0.004) using richest and urban as a reference category.
There were no significant interaction effects of region and place of residence on the odds of contracting malaria parasitaemia among children 6-59 months in Nigeria.

4. Discussion

This study aimed to conduct a scoping review of the risk factors that affect the malaria status of children under-five years in SSA. The review found thirteen studies that identified factors associated with malaria fever among the under-five children in SSA. The risk factors associated with malaria status were classified as child-related, (the nine significant risk factors identified include the age of the child, child’s place of delivery, BCG vaccination status, preceding birth interval, birth order, child anaemia status (haemoglobin level), breast feeding status, whether the child had had a fever in the last two weeks before the survey, and whether the child slept under a net). While among the maternal-related variables were 8 significant risk factors which include maternal age, maternal education status, maternal knowledge of malaria, number of birth in the last five years, maternal body mass index, maternal antenatal care attendance for the child, the number of children ever born and maternal access to a phone. Additionally, the 19 identified significant household-related risk factors include household wealth status, household place of residence, whether or not a household has bed net, age of household head, household size, improved water source, improved toilet facility, household ownership of livestock, household head educational status, improved building material, improved housing, a household is connected to electricity, type of roofing material, insecticide residual spray of household, number of under-five children in the household, source of water outside the house, sex of household head, household use of biomass fuel for cooking and under-five sleeping under a bed net the night prior to the survey. Furthermore, among the environmental-related risk factors extracted, the eight that were significant include community wealth status, community distance to healthcare facilities, regional variations, malaria endemicity, community free bed net distribution, cluster altitude, community Long Lasting Insecticide Net (LLIN) and country-specific factors.

Though the search strategies covered the period from 1990 to 2020, the distribution of the publication years shows that papers conducted on
risk factors affecting the occurrence of malaria among children under-five in SSA were carried out in the last decade. All the publications (meeting the inclusion criteria) were from 2013 to 2020, and no publications in 2016 or 2012 and earlier were found. This may relate to the fact that the data set from nationally representative individual and household surveys in SSA, such as from Malaria Indicator Surveys (MIS) were not often available until around 2012 and beyond [43], and most of the MIS datasets collected from 2005 to 2012 remained unavailable [43]. Furthermore, this review shows that the countries of the study were more concentrated in Southern and Central Africa with just two recorded in West Africa. The reasons for this disparity are not clear. However, from a UNICEF report, the reduction in changes in the percentage of under-five mortality resulting from malaria between 2000 and 2017 were more drastic among the countries in Southern and Central Africa [6]. Also, the regional disparity in the number of studies may be related to the fact that it is much easier for researchers to secure funding for their studies in Southern and Central Africa than in West African countries. There were more studies from the Malaria Indicator Surveys (MIS) data set than from Demographic and Health Surveys (DHS) data set. These differences are likely related to the fact that the timing of MIS is usually in the season where malaria infections are high [44,45], and it includes the use of biomarkers on the field and laboratory [45]. These reasons notwithstanding, technical assistance for both DHSs and MISs was provided for by DHS. In recent times, some country’s surveys combined both surveys into one. For instance, Nigeria conducted Nigeria Malaria Indicator Survey (NMIS) in 2010 and 2015, conducted Nigeria Demographic and Health Survey (NDHS) in 2008 and 2013 separately, but NDHS 2018 was a combination of both NDHS and NMIS [46].

From this review, the most vulnerable, in the under-five children in terms of age, are those between 2 to 5 years [24,30,33,35,37]. This finding agrees with reports from [41,47]. The reasons may not be unconnected with the fact that most families when they have new-born, intra-family attention and use of resources are shifted to the new-born. Another factor of importance, as revealed by this review, is the significance of the increase in the maternal/care-giver educational status has on protecting the child from having malaria parasitaemia
[24,27,28,31,33,35,37]. This is also in line with the findings in [48]. One of the pathways in which this can affect the malaria status of under-5 is through adequate knowledge of malaria symptoms, prompt response to seek healthcare attention [24,31,40,41].

5. **Strengths and Limitations**

There are several strengths identified in this scoping review. (i) This is the first scoping review that has been carried out on risk factors affecting the malaria status of under-five years in SSA that used classical statistical regression methods on data from secondary analysis of nationally representative surveys. (ii) The review has been rigorous with intense supervision from the team that cuts across two institutions.

It is acknowledged that this review has some limitations. (i) All the studies considered in this review are the secondary analysis of nationally representative cross-sectional surveys. Causal effects are not established in the studies, and cross-sectional studies which are carried out for a time point are not able to determine trend [49]. (ii) Very few studies reviewed in this project considered the contextual factors that may be associated with malaria status of under-five with appropriate statistical technique; this may have reduced the reliability of the results attained. Studies that can investigate the contextual factors related to malaria fever among under-5 in SSA countries are urgently needed. (ii) Only thirteen studies were identified that met the inclusion/exclusion criteria. The study may not have successfully identified all the papers as the only considered studies were those that were written in the English language [50]. (iii) In view of the scoping review study design applied [51], we also acknowledged that there was no publication bias and quality of study assessment done. (iv) Only studies that applied frequentists statistical methods were included, therefore, the exclusion of studies that applied Bayesian statistical methods could have resulted in limitations in the findings. (v) The intervention terms were omitted in the search; this may have excluded some potential studies.

6. **Future Work**

There are a few areas not covered in the papers included in this review that require future investigations. Considering the limitations stated above, scoping review that will take care of them should be the basis for future study. Malaria infection in children is comorbid and as such may
have overlapping associative risk factors. Studies that could explore this area are a potential study area for the future.

7. Conclusion

SSA is one of the high endemic malaria regions in the world, with a high mortality rate resulting from malaria morbidity. There is a more significant commitment on the part of government and partners to ensure that morbidity and mortality resulting from malaria fever in some countries is reduced to zero by the end of 2020 [5]. The target year is now passed but it does not seem to have been achieved. The knowledge derived from a careful analysis of these many factors that have contributed to the rising burden could be used to fast track appropriate intervention mix as they become available [52]. Generally, some population settings especially the under-5 children are more at risk than others where over 70% of mortality from malaria occurs [53], and measures are needed to protect these vulnerable groups [54]. Vector control (such as insecticide-treated mosquito nets, drug treatments and indoor residual spraying), is one of the main approaches most SSA governments have adopted to prevent and reduce the spread of malaria [53–55]. Inadequate knowledge of how the individual and contextual factors are associated with malaria contraction may jeopardize the ability of governments to eliminate the malaria parasite [55].

Author Contributions: The conceptualization of this study was done by PEO and KK; the formal literature searching, screening and drafting of manuscript were carried out by PEO; while SJW, RJ and KK participated in supervising, revising and editing of the manuscript. All authors have read and agreed to the published version of the manuscript.

Funding: This study is an integral part of PEO’s doctoral study at the School of Health and Related Research of the University of Sheffield, United Kingdom. The funding for the doctoral study was granted by TETFUND (Nigeria).

Acknowledgements: The authors acknowledged the contributions received from ScHARR community (especially Joanna Leaviss, Anthea Sutton and Mark Clowes). PEO would like to appreciate the Rector and the management staff of Niger State Polytechnic, Nigeria, for the nomination and the receipt of the TETFUND (Nigeria) sponsorship of his doctoral program.
Conflicts of Interest: The authors declare no conflict of interest.
