1. Introduction

Hard X-ray emission from compact X-ray binary systems is a distinct signature of a hot plasma accreting onto a black hole. In an attempt to explain the X-ray emission from the stellar mass black hole Cygnus X-1, Shapiro et al. (1976) developed an accretion disk model (the SLE model) whose inner region was considerably hotter and geometrically thicker than previous models. Accretion plasma is optically thin and is gas-pressure dominated. This model naturally yields a two-temperature plasma in which the electron temperature is about $kT_e \sim 100$ keV and the ion temperature is one or two orders of magnitude larger. However, later developments have shown that the SLE model is thermally unstable (see, e.g., Abramowicz et al. 1995, 2000) and that the advection of heat plays an important role in the viscous and thermal stability of the plasma (see, e.g., Ichimaru 1977; Paczynski & Bisnovatyi-Kogan 1981; Abramowicz et al. 1988, 1995; Narayan & Popham 1993; Narayan & Yi 1994; Chen et al. 1995).

Another group of very hot and optically thin accretion disk solutions is linked to the so-called advection-dominated accretion flows (ADAF) Narayan & Yi (1994, 1995a,b). These models are radiative inefficient because most of the plasma heat is advected into the black hole. In ADAF models, plasma is geometrically thick with a quasi-spherical flow. The electron temperature for ADAF can be as high as $kT_e \sim 300$ keV, whereas ion temperature is close to the virial temperature and can be on the order of $kT_i \sim 100$ MeV.

Nuclear reactions play an important role in such high temperature accretion plasmas. These reactions change the plasma chemical composition and produce a characteristic $\gamma$-ray emission, (Aharonian & Sunyaev 1984; Aharonian & Sunyaev 1987; Yi & Narayan 1997; Kafexhiu et al. 2012). Because of the high ion temperature, the nuclear spallation processes dominate. Therefore, plasma evolves toward a lighter composition. The $\gamma$-ray emission of the accretion plasma is governed by prompt nuclear de-excitation $\gamma$-ray lines. Their emissivities depend strongly on nuclear abundances. Therefore, their computation requires a detailed consideration of the chemical evolution of the accretion plasma (see, e.g., Kafexhiu et al. 2018).

When the ion temperature of plasma is $10$ MeV, it starts to produce $\pi^0$-mesons. Their decay produces an additional $\gamma$-ray emission component at higher energies (see, e.g., Dahlbacka et al. 1974; Kolykhavol & Syunyaev 1979; Bisnovatyi-Kogan et al. 1980; Giovannelli et al. 1982; Dermer 1986; Mahadevan et al. 1997; Yi & Narayan 1997; Oka & Mannmoto 2003; Kafexhiu et al. 2018). Pions have a higher threshold energy than nuclear reactions. Pions are produced by energetic particles that populate the high energy tail of the plasma distribution function. Therefore, the $\gamma$-ray emission from $\pi^0$-meson decay is sensitive to the high energy tail of the plasma distribution function. Nuclear $\gamma$-ray lines, on the other hand, carry information about the plasma temperature because the most important part of their cross section is covered by the central part of the Maxwellian distribution function. Thus, the combined information about the prompt $\gamma$-ray lines and the $\pi^0 \rightarrow 2\gamma$ emissions should allow reconstruction of the plasma energy distribution function for a wide energy range.

In this paper, we present the results of our study of the $\gamma$-ray emission related to two-temperature accretion plasma within the framework of the ADAF and SLE models. For this task, we utilize a massive nuclear reaction network and the recent parametrizations of $\pi$-meson production cross sections at low (close to the kinematic threshold) energies. We study the radial chemical evolution of the accretion flow and compute the
resulting γ-ray emission. We also discuss the efficiency of evaporation of free neutrons from the disk and the maximum amount of the secondary Li, Be, and B nuclei produced in the ADAF accretion plasma.

2. Radial evolution of the chemical composition

2.1. Nuclear reaction network

Low density accretion plasma, unlike, for example the central core of a star, is dominated by binary nuclear collisions. For a binary reaction \( i + j \rightarrow l + \ldots \), the production rate per unit volume of the nucleus \( l \) is written as (see, e.g., Fowler et al. 1967)

\[
n_l = \frac{n_i n_j}{1 + \delta_{ij}} (\sigma v)^{ij}_l.
\]

In this equation \( n_i, n_j, \) and \( n_l \) are the number densities of species \( i, j, \) and \( l \), respectively; \( \delta_{ij} = 1 \) if nucleus \( i \) and \( j \) are identical, and zero otherwise. The \( (\sigma v)^{ij}_l \) is the thermal reaction rate, which is computed from

\[
(\sigma v)^{ij}_l (T) = \frac{8}{\pi} \mu_{ij} (kT)^{3/2} \int_0^\infty \sigma^{ij}_l (E) E \exp \left( -\frac{E}{kT} \right) dE,
\]

where, \( \mu_{ij} = m_i m_j / (m_i + m_j) \) is the reduced mass of the two incoming nuclei, \( \sigma^{ij}_l \) is the \( i + j \rightarrow l + \ldots \) reaction cross section, \( kT \) is the temperature in units of energy, and \( E \) is the collision energy.

Equation (1) is more convenient to solve in terms of the mass fraction abundance. For an element \( i \), the mass fraction abundance is defined as \( X_i = A_i n_i / \rho \), where \( A_i \) is the mass number, \( n_i \) is its number density, and \( \rho = \sum A_i n_i \) is the nucleon number density of the plasma. If the accretion plasma is initially composed of \( N \) nuclei, then we have to sum up over all possible channels that produce a given nucleus \( l \). Moreover, nuclear reactions can produce nuclei that were not initially present in the plasma. Therefore, we have to consider all possible nuclear species that can be produced during the plasma lifetime and all their most important nuclear reaction channels. This system forms a so-called nuclear reaction network. For calculating the cross sections \( \sigma^{ij}_l \), we use the nuclear code TALYS (Koning et al. 2005) and experimental data, for more details see Kafexhiu et al. (2012). We note that the recent version of the code TALYS can calculate cross sections for energies up to \( 1 \) GeV. This has allowed us to extend the computation of the reaction rates \( (\sigma v)^{ij}_l \) for temperatures on the order of \( 10^{12} \) K. In addition, the nuclear reaction network considers \( p + p \rightarrow p + n + \pi^+ \) and \( p + p \rightarrow D + \pi^0 \) channels, which can significantly change the abundances of neutrons and deuterium in case of a proton plasma with temperatures \( kT_p > 10 \) MeV; see Kafexhiu et al. (2018) for more details.

The solutions of the nuclear network are obtained by solving the following system of differential equations:

\[
\frac{dX_l}{dR} = \sum_{i,j} \left( \frac{\rho}{1 + \delta_{ij}} \nu \right) \left( \frac{A_j}{A_i A_j} \right) (\sigma v)^{ij}_l X_i X_j.
\]

(3)

We converted the time derivative into the radial derivative using \( X'_l = r^2 X_l dR/dR \), thus solving \( X'_l \) as a function of the disk radius.

In addition, our nuclear reaction network considers reactions \( i + j \rightarrow l + \ldots \), which produce nucleus \( l \) in different excited states that lead to different prompt γ-ray lines emission. The cross sections for the most important prompt nuclear γ-ray lines are calculated using TALYS code and experimental data (see, e.g., Kozlovsky et al. 2002; Murphy et al. 2009). The number of γ-rays produced per unit volume \( n_\gamma \) for a specific \( l^l \) transition, is calculated using Eq. (1). The reaction rate \( (\sigma v)_l \) is calculated from the specific \( \sigma^{ij}_l \) cross section. Since the accretion plasma temperatures are \( kT_p > 1 \) MeV, the Doppler broadening from thermal motion of \( l^l \) is larger than the natural width of the prompt γ-ray line. Therefore, the γ-ray line profile is well described by a Gaussian and its emissivity is given by

\[
\phi_l (E_l, r) = \frac{n_\gamma(r)}{\sqrt{2\pi \sigma^2_l (r)}} \exp \left[ -\frac{(E_l - E_l^0)^2}{2 \sigma^2_l (r)} \right].
\]

(4)

In this equation, \( E_l^0 \) is the central γ-ray energy obtained by the energy difference of the two transition levels of the nucleus, \( \sigma^G = E_l^0 \sqrt{kT_p/m c^2} \) is the Gaussian broadening, and \( m_l \) is the mass of the excited nucleus \( l^l \).

With the exception of nuclear lines, nuclear collisions produce a γ-ray continuum. For \( E_l \gg 10 \) MeV, the nuclear continuum is composed of mainly nuclear bremsstrahlung and the production and decay of the \( \pi^0 \)-mesons. Calculation of the emissivity \( \phi_l \) for these channels is described in Kafexhiu et al. (2018). To compute the differential luminosity of the disk, we have to integrate \( \phi_l (E_l, R) \) over the entire volume of the disk, i.e., \( \Phi_l (E_l) = \int \phi_l (E_l, R) 2 \pi R dR \).

2.2. Principal parameters of the accretion disk

Accretion disk is described by the following set of key parameters: (1) the viscosity parameter \( \alpha \); (2) the scaled black hole mass \( M = M/M_\odot \), where \( M_\odot \) is the solar mass; (3) the scaled accretion rate \( \dot{m} = M/M_\text{edd} \), where \( M_\text{edd} \) is the so-called Eddington accretion rate; (4) the radius of the gas pressure to the total pressure \( \beta \); (5) the adiabatic index \( \gamma \); (6) the viscous heat parameter \( \delta \), which gives the ratio of electron heating to total heating; and (7) the advection parameter \( f \), which gives the ratio of the advection heating to the total heating (see, e.g., Narayan & Yi 1995b). Apart from the system specific parameters such as the \( m \) and \( n \), most of the other parameters are constrained from numerical simulations or are limited by other parameters in a consistent way.

By fixing the values of \( m, n, \alpha, \) and \( \beta \), we can calculate the physical quantities of the plasma such as ion and electron temperatures \( (T_i \) and \( T_e \) ), plasma nucleon number density \( \rho \), plasma radial speed \( v \), and the disk height \( H \), which are required to solve the nuclear reaction network. For the ADAF accretion, the above quantities are calculated from (see, e.g., Narayan & Yi 1995b)

\[
T_i + 1.08 T_e = 6.66 \times 10^{12} \beta c_s^{-1} \text{K},
\]

\[
\rho = 2.28 \times 10^{19} \alpha^{-1} c_s^{-1} m^{-1} \dot{m}^{-3/2} \text{neutrons cm}^{-3},
\]

\[
v = -2.12 \times 10^{10} \alpha c_s^{-1} \text{cm s}^{-1},
\]

\[
H = (2.5 c_s)^{1/2} R.
\]

(5)

In this case, \( r = R/R_5 \), where \( R \) is the disk radius and \( R_5 \) is the Schwarzchild radius. \( c_s = g(a, \varepsilon') \times (5 + 2e')/3a^2 \) and \( c_s = 2c_1/3 \), where, \( e' = e f f' = f f' (5/3 - \gamma)/(\gamma - 1) \) and \( g(a, e') = 1 + 18a^2/5(5 + 2e')^2 - 1 \). The plasma ion and electron temperature profiles are computed from the local balance equations \( q_i = q_e + q_e^e \) for ions and \( q_\gamma = q_\gamma^e \) for electrons. The quantity \( q_i^e \) is the plasma heating energy rate due to
In this equation, $M_T$ computed from (see Shapiro et al. 1976) is the nucleon mass. We note that $q^c$, $q^a$, and $q^i$ are cooled by synchrotron, bremsstrahlung, and Comptonization, the sum of which gives $q^r$; for full details see Narayan & Yi (1995b). The solution of the local balance equations determines the value of $f$.

For the SLE accretion disk model the above quantities are computed from (see Shapiro et al. 1976)

$$ T_i = 5 \times 10^{11} M_s^{5/6} M_{\odot}^{5/6} \alpha^{-7/6} \beta^{-5/6} r^{-5/4}, $$

$$ T_e = 7 \times 10^8 (M_s M_{\odot})^{1/3} \alpha^{-1} \beta^{-1/3} r^{-1/4}, $$

$$ \rho = 3 \times 10^{19} M_s^{3/4} M_{\odot}^{1/4} \alpha^{-3/4} \beta^{-1/4} r^{-9/8}, $$

$$ H = 10^8 M_s^{7/12} M_{\odot}^{5/12} \alpha^{-7/12} \beta^{-5/12} r^{-7/8}. $$

In this equation, $M_s = M/3$, $M_{\odot}$, $M_s = M/(10^{17} g s^{-1})$, $r_s = 2 r$ and $F = 1 - \sqrt{3/r}$. The radial velocity is obtained from the continuity equation and is given by $v = -M/(2H 2\pi r \rho m_n)$, where $m_n$ is the nucleon mass. We note that $H$ is half of the disk height.

2.3. Radial chemical evolution of the accreting flow

In this section, we apply the nuclear reaction network to the ADAF and SLE disk models. Throughout this article, we consider a 10 solar mass black hole, $m_s = 10$, that is typical for binary systems and assume an equipartition magnetic field with $\beta = 0.5$. The ADAF accretion disk exists below some critical values of the accretion rate and plasma density. Therefore, we choose $\alpha = 0.1$ and $\dot{m} = 0.1 \times 10^{-3}$ far from the critical values and $\alpha = 0.3$ and $\dot{m} = 0.17 \times 10^{-2}$ near the critical value. The ADAF and SLE temperature and density profiles for this set of parameters are shown in Fig. 1. In addition, we consider two initial chemical compositions: a solar composition realized when the donor is a normal star and a heavy composition expected when the donor is a Wolf–Rayet type star. More specifically we consider $H$, $^3$He, $^{12}$C, and $^{16}$O with mass fractions $X_p = X_o = 0.3$ and $X_{\odot} = 0.2$.

The radial chemical evolution of the ADAF and SLE accretion disks are shown in Figs. 2–5. Figures 2 and 3 show the results for a solar initial composition and $\alpha = 0.1$ and $\dot{m} = 10^{-3}$ parameters. Figures 4 and 5 show the same results using ADAF accretion parameters near the critical
values\(^1\) with \(\alpha = 0.3\) and \(m = 1.53 \times 10^{-2}\). The results in Fig. 4 are calculated for a solar initial composition, whereas Fig. 5 corresponds to the heavier (H-He-C-O) initial composition.

3. \(\gamma\)-ray emission of the accretion disk

3.1. \(\gamma\)-ray luminosities

The differential \(\gamma\)-ray production rates (“photon luminosity” in units of photons/(MeV s)) calculated for the ADAF and SLE  

\(^1\) The ADAF solution is valid for accretion rates \(\lesssim 0.17 \times \alpha^2\) (see, e.g., Abramowicz et al. 1995, 2000). For higher accretion rates the accretion regime switches to the relatively cold and thin solution of the Shakura & Sunyaev (1973) disk.
For an initial heavy composition plasma with $X_p = X_\alpha = 0.3$ and $X_{C12} = X_{O16} = 0.2$, these upper limits are changed to

$$L_N = 9 \times 10^{33} \left( \frac{m}{10} \right) \text{ erg s}^{-1},$$

$$L_\alpha = 3 \times 10^{35} \left( \frac{m}{10} \right) \text{ erg s}^{-1}.$$ 

For the SLE model, the luminosity radiated by nuclei for an initial solar composition and $\alpha = 0.3$ and $m = 0.171 m_p$, is written as

$$L_N = 6 \times 10^{32} \left( \frac{m}{10} \right) \text{ erg s}^{-1},$$

while in the initially heavy composition plasma,

$$L_N = 1 \times 10^{34} \left( \frac{m}{10} \right) \text{ erg s}^{-1}.$$  

In the SLE model, the luminosity of $\pi^0$-decay $\gamma$-rays is negligible because the relatively low ion temperature, $kT_i \leq 10$ MeV.

### 3.2. Modified high energy tail of the Maxwellian distribution function

Generally, for the thermal plasma, the energy distribution of particles is silently assumed to be described by the Maxwellian distribution. However, this could be not a correct representation...
as long as it concerns the sub-relativistic ion component of the accretion plasma. The particle distribution well above the temperature can be suppressed compared to the Maxwellian distribution if the relaxation time of the tail \( E \gg kT \) supported by the binary elastic scatterings would be longer than the accretion time. In this case, the high energy tail would be underdeveloped and correspondingly, the \( \gamma \)-ray luminosity suppressed, especially at energies well beyond 100 MeV (Aharonian & Atoyan 1983). On the other hand, even a slight acceleration of ions, for example due to plasma instabilities, can produce a suprathermal component well above the “nominal” tail of the Maxwellian distribution. Thus, the shape of the high energy tail of the accretion plasma distribution function can have dramatic effects on the \( \pi^0 \) production rate (Aharonian & Atoyan 1983; Kafexhiu et al. 2018).

In Fig. 2, we demonstrate the impact that this effect has on the spectrum of \( \pi^0 \)-decay \( \gamma \)-rays in the case of the ADAF accretion regime. Aside from the “nominal” Maxwellian distribution, two other ion temperature distributions have been considered: a Maxwellian distribution with a sharp cutoff at \( 4kT_\text{max} \) and a Maxwellian distribution with a suprathermal tail with a power-law index \( p = 2.0 \) for energies above \( 4kT_i \). At energies above a few 100 MeV, the corresponding \( \gamma \)-ray luminosities are significantly suppressed or enhanced compared to the luminosity corresponding to the Maxwellian distribution.

**4. Evaporation of neutrons**

Neutrons are not bounded by the electric and magnetic fields of the accretion plasma. If their energy – the sum of thermal and rotation energies of the accretion disk – is larger than the gravitational binding energy, neutrons can “evaporate” from the disk and reach the companion star before decaying (Aharonian & Sunyaev 1984; Jean & Guessoum 2001; Guessoum & Jean 2002). The ADAF predicts very hot plasma; therefore neutrons can easily escape from the disk almost isotropically. We calculated the neutron evaporation efficiency \( \eta \) in the framework of the ADAF model by adopting the calculations described in Aharonian & Sunyaev (1984), also considering the reduction of neutrons along the accretion disk. Figure 6 shows \( \eta \) as a function of the accretion radius. We find that the \( \eta = f(r) \) profile is universal and does not depend on the accretion parameters. This follows from the fact that the ADAF ion temperature is equal to the virial temperature independent of the accretion parameters.

The primary source of neutrons in the accretion plasma is the destruction of the CNO and heavier nuclei. In addition, ADAF can produce neutrons through the \( p + p \rightarrow p + n + \pi^+ \) channel converting protons into neutrons. The neutrons are primarily produced in the \( r \leq 10 \) region of ADAF. Although this channel is less significant than that of nuclear destruction processes, the \( p + p \rightarrow p + n + \pi^+ \) channel ensures that ADAF can produce neutrons efficiently even if its accretion plasma is composed of merely hydrogen. Similar to the \( \pi^0 \rightarrow 2\gamma \) emissivity, the neutron production rate through the process \( p + p \rightarrow p + n + \pi^+ \) can vary depending on the shape of the high energy tail of the plasma distribution function.

The mass abundance scales of the neutrons such as \( X_n \propto \rho/v \propto m\alpha^{-2} \). The proportionality constant is a function of radius \( r \). Figure 7 shows the function \( X_n = f(m\alpha^{-2}) \) for ADAF computed near the last stable orbit \( r = 3 \), which gives \( X_n^\text{max} \) throughout the disk. The neutron abundance is estimated for two initial compositions: a solar composition and a heavier plasma with \( X_p = X_n = 0.3 \) and \( X_\text{C} = X_\text{O} = 0.2 \). For comparison, \( X_n \) is plotted with and without the \( p + p \rightarrow p + n + \pi^+ \) contribution.

**5. Production of light elements**

Within the ADAF model, the accretion flow has a positive Bernoulli integral. Thus, this model can produce outflows (e.g., Narayan & Yi 1994; Yi & Narayan 1997; Blandford & Begelman 1999). The outflows can carry some of the accretion material and inject it into the surrounding interstellar medium. The accretion material is richer with light elements such as Li and Be. Therefore, the expelled matter can enrich the interstellar medium with these elements in addition to the primordial (cosmological) source of Li and Be. Thus, the accretion disk outflows can, in principle, contribute to the solution of the so-called \(^7\)Li problem (see, e.g., Fields 2011). Figure 8 shows the mass fraction abundance of \(^6\)Li, \(^7\)Li, and \(^7\)Be as a function of \( m \alpha^{-2} \), for
an ADAF plasma close to the last stable orbit $r = 3$. The calculations are performed for the solar and for a heavy ($X_p = X_n = 0.3$ and $X_C = X_O = 0.2$) initial compositions.

6. Discussion

6.1. Radial chemical evolution

The radial chemical evolutions shown in Figs. 2–5, demonstrate that in the ADAF model the nuclear reactions play an important role starting from distances of $100 R_s$. The SLE plasma is colder, and, consequently, the impact of nuclear reactions is limited by the region $r \lesssim 10$. The initial composition of the plasma is significantly modified as the nuclei move toward the inner parts of the accretion disk. In the ADAF model, all heavy nuclei are destroyed before they reach the last stable orbit $r = 3$. As a consequence, the accretion matter that orbits near the black hole is composed of protons, neutrons, and light elements. In addition to $^4$He, the destruction timescale of which is longer than the accretion falling time, the plasma contains traces of $^3$He, D (at the level of $10^{-2}$), somewhat less T, as well as nuclei of the LiBeB group (at the level of $10^{-4}$).

6.2. $\gamma$-rays

Gamma rays produced in nuclear interactions can be observed between $\approx 1$ MeV and 10 MeV. The region below 1 MeV is dominated by the thermal electron bremsstrahlung. The ADAF and SLE accretion models predict different gamma-ray spectra, basically because of differences in the temperature profiles. The plasma in the ADAF model is hotter. Therefore, $\gamma$-ray lines are expected to be broad because of larger Doppler broadening. Within $1–10$ MeV, $\Delta E_\gamma / E_\gamma \approx 8\%$. The spectrum of the ADAF plasma continues above 10 MeV through the $p^0 \rightarrow 2\gamma$ emission. Its emissivity peaks around $E_\gamma \approx 100$ MeV and falls off exponentially at higher energies. The SLE plasma, on the other hand, produces narrower and more intensive nuclear lines and its $\gamma$-ray spectrum has a cutoff at $E_\gamma \approx 10$ MeV.

The ADAF and SLE models have about the same efficiency of converting accretion energy into nuclear $\gamma$-ray lines, that is $L_\gamma / L_{acc} < 5 \times 10^{-4}$. This efficiency decreases if nuclei are destroyed before reaching the inner parts of the accretion disk, where the temperature and density reach their maximum. Therefore, by increasing the plasma accretion rate or density, the nuclear destruction rates become large and, correspondingly, the $\gamma$-ray efficiency drops. The maximum possible efficiency depends on the initial plasma composition. It is larger if the plasma is composed of heavier nuclei. In the ADAF model, the maximum luminosity for a solar initial composition is $\approx 10^{33} \times (m/10)$ erg s$^{-1}$. For a heavier composition, for example, with the mass abundances $X_p = X_n = 0.3$ and $X_{C12} = X_{O16} = 0.2$, the luminosity is larger, $L_{\gamma, max} \approx 10^{34} \times (m/10)$ erg s$^{-1}$. We note that this estimate exceeds, by an order of magnitude, the result published by Yi & Narayan (1997).

The thermal $\pi^0$-meson production efficiency in the ADAF model is on the order of $L_\gamma / L_{acc} < 10^{-2}$. Unlike the nuclear $\gamma$-ray lines, the $\pi^0$-meson production efficiency has a strong dependence on the shape of the high energy tail of the plasma distribution function. The simultaneous observations of nuclear $\gamma$-ray lines and $\pi^0$-decay $\gamma$-rays can offer a unique opportunity to reconstruct the plasma energy distribution function, which can be used to discriminate between different accretion regimes. While, the nuclear $\gamma$-ray lines contain information about the central part of the plasma distribution function, the $\pi^0$ $\rightarrow$ $2\gamma$ spectra provide information about its high energy tail.

The detectability of nuclear radiation from hot accretion flows depends on the accretion model. The most favorable conditions can be realized for the ADAF regime when the expected energy fluxes in the $1–10$ MeV and $50–200$ MeV bands from a source located at the distance $d$ can be as high as $10^{-11} (m/10) (d/1$ kpc)$^{-2}$ erg cm$^{-2}$ s$^{-1}$ and $3 \times 10^{-9} (m/10) (d/1$ kpc)$^{-2}$ erg cm$^{-2}$ s$^{-1}$, respectively (see Sect. 3.1). The flux sensitivities of the planned $\gamma$-ray mission e-ASTROGAM (de Angelis et al. 2018) from the most promising galactic black hole binaries, such as Cyg X-1 ($m \approx 15$ and $d \approx 2$ kpc) are significantly below the above fluxes, especially around 100 MeV. Therefore, e-ASTROGAM can provide meaningful probes of the ion temperature and accretion regimes through nuclear $\gamma$-rays from these objects.

6.3. Evaporation of neutrons

Figure 6 shows the neutron evaporation efficiency $\eta$ in the ADAF model as a function of the accretion disk radius. The $\eta = f(r)$ profile is universal for $r < 100$ because it depends mainly on the plasma temperature, which is equal to the virial temperature for a wide range of the accretion disk parameters. We find that about 70% of the neutrons can escape from the accretion disk.

The main source of neutrons are the CNO and heavier nuclei destruction. In addition, ADAF can effectively produce neutrons through the $p + p \rightarrow p + n + \pi^+$ channel that converts protons into neutrons. Like the $p + p \rightarrow n^0 \rightarrow 2\gamma$ emission, neutrons also originate from the central parts of the accretion disk ($r \lesssim 10$) and their production rate depends on the shape of the high energy tail of the plasma distribution function. Figure 7 shows the maximum neutron fraction in the ADAF model that was obtained at $r = 3$ as a function of accretion parameters.

Using the evaporation efficiency and the neutron content at different distances, we find that the ADAF can expel up to 15 percent of the accretion mass flow in the form of neutrons. Some of these neutrons can reach the companion star before decaying.

![Graph](https://example.com/graph.png)
These neutrons are cooled down and then captured by protons in the atmosphere and produce the 2.22 MeV $\gamma$-rays that can serve as a signature of the discussed scenario (see, e.g., Aharonian & Sunyaev 1984; Jean & Guessoum 2001).

For consistency, we included the neutron evaporation process in our nuclear reaction network solution. We found no significant effect on the nuclear abundances and $\gamma$-ray luminosity of the disk.

6.4. Production of light elements

Light elements are products of spallation of the CNO and heavier nuclei, as well as the synthesis of $^4$He. For example, $p + \alpha$ and $\alpha + \alpha$ reactions. Figure 8 shows the mass fraction abundances of $^6$Li, $^7$Li, and $^7$Be as a function of $m/\alpha^2$ near the last stable orbit for the ADAF accretion disk. For a fixed radius, these abundances are proportional to $m/\alpha^2$. However, for the accretion rates close to the critical rate, the destruction of $^6$Li, $^7$Li, and $^7$Be becomes important and therefore their abundances are reduced; see Fig. 8. Yi & Narayan (1997) estimated lithium production in ADAF; their results are about an order of magnitude larger than the results we obtained via the nuclear reaction network. The reason for this discrepancy could be related to the neglect of Li destruction in their calculations.

Because of the positive Bernoulli integral, ADAF can expel matter into the surrounding interstellar medium providing an additional source of light elements. Detailed quantitative studies of this process could contribute to the solution of the so-called problem of primordial $^7$Li (see, e.g., Fields 2011).

7. Summary and conclusions

Using a large nuclear reaction network and the recent studies of the $\pi$-meson production cross sections at low energies, we computed the radial evolution of the chemical composition of the accreting matter and the $\gamma$-ray luminosities expected within the ADAF and SLE accretion disk models. Nuclear reactions are important within 100 $R_S$. The content of CNO and heavier nuclei decreases as the plasma moves toward the black hole event horizon. In the ADAF scenario, the plasma is sufficiently hot to destroy heavy nuclei before reaching the last stable orbit at $r = 3$. The efficiency of converting accretion energy into nuclear $\gamma$-ray lines is $L_\gamma/L_{\text{acc}} < 5 \times 10^{-5}$ for solar composition and can be increased up to $10^{-3}$ for heavier compositions. The ADAF model can produce $n^0$-decay $\gamma$-rays with an efficiency as high as $L_\gamma/L_{\text{acc}} < 10^{-2}$. This efficiency is sensitive to the high energy tail of the plasma distribution function. The ADAF accretion disk can evaporate about 70% of its neutron content with a rate that can be as large as 15% of the accretion rate. The ADAF model can also produce a considerable amount of elements from the LiBeB group that can be injected into the surrounding interstellar medium and alter its chemical composition.

Acknowledgements. The authors are grateful to the members of the High Energy Astrophysics Theory Group for the very fruitful discussions. The authors are appreciative for the grant from the Russian Science Foundation 16-12-1044, the NSF grant AST-1306672, DoE grant DE-SC0016369, and NASA grant 80NSSC17K0057.
