Integrins $\alpha 2\beta 1$ and $\alpha 11\beta 1$ regulate the survival of mesenchymal stem cells on collagen I

C Popov$^1$, T Radic$^1$, F Haasters$^1$, WC Prall$^1$, A Aszodi$^1$, D Gullberg$^2$, M Schieker$^{*1}$ and D Docheva$^1$

Although mesenchymal stem cells (MSCs) are the natural source for bone regeneration, the exact mechanisms governing MSC crosstalk with collagen I have not yet been uncovered. Cell adhesion to collagen I is mostly mediated by three integrin receptors – $\alpha 1/1$, $\alpha 2/1$ and $\alpha 11/1$. Using human MSC (hMSC), we show that $\alpha 11$ subunit exhibited the highest basal expression levels but on osteogenic stimulation, both $\alpha 2$ and $\alpha 11$ integrins were significantly upregulated. To elucidate the possible roles of collagen-binding integrins, we applied short hairpin RNA (shRNA)-mediated knockdown in hMSC and found that $\alpha 2$ or $\alpha 11$ deficiency, but not $\alpha 1$, results in a tremendous reduction of hMSC numbers owing to mitochondrial leakage accompanied by Bcl-2-associated X protein upregulation. In order to clarify the signaling conveyed by the collagen-binding integrins in hMSC, we analyzed the activation of focal adhesion kinase, extracellular signal-regulated protein kinase and serine/threonine protein kinase B (PKB/Akt) kinases and detected significantly reduced Akt phosphorylation only in $\alpha 2$- and $\alpha 11$-shRNA hMSC. Finally, experiments with hMSC from osteoporotic patients revealed a significant downregulation of $\alpha 2$ integrin concomitant with an augmented mitochondrial permeability. In conclusion, our study describes for the first time that disturbance of $\alpha 2\beta 1$- or $\alpha 11\beta 1$-mediated interactions to collagen I results in the cell death of MSCs and urges for further investigations examining the impact of MSCs in bone conditions with abnormal collagen I.

Subject Category: Experimental Medicine

Mesenchymal stem cells (MSCs), derived from bone marrow, have been shown to differentiate into the osteoblast lineage in vitro as well as in vivo.$^1$ As a result of this ability, these cells are considered to be the main cellular players in the processes of bone regeneration and healing. In order to survive, amplify or differentiate into cells with a specialized function, MSC have to establish appropriate contacts with the extracellular matrix (ECM) in the bone marrow, which is mainly composed of collagen type I, IV and fibronectin.$^2$ One of the most important and ubiquitous receptor families mediating cell–ECM interactions is the integrin family. In vertebrates, there exist 18 $\alpha$- and 8 $\beta$-integrin subunits that can assemble into 24 different heterodimers.$^3,4$ Generally, the amount of $\alpha$-subunit determines the amount of receptor that will go to the cell surface as no free $\alpha$- or $\beta$-integrin can be present on the plasmalemma.$^5$ On the basis of the ligand-binding properties, the integrins can be grouped into subgroups as the collagen I-binding group consists of three receptors – $\alpha 1/1$, $\alpha 2/1$ and $\alpha 11/1$.$^5$

Integrins do not only establish cell bonds with a range of ligands but also regulate cytoskeletal dynamics and initiate various signals that are essential for the regulation of cellular processes, such as cell adhesion, migration and differentiation.$^6,7$ Integrin signaling is initiated at the focal adhesion sites, which are membrane-associated platforms consisting of clustered, ECM-bound integrins as well as various enzymes (e.g., focal adhesion kinase, FAK), cytoskeletal and adaptor proteins (e.g., paxillin, p$^{130}$COOH) in the cytoplasm. Integrin adhesion triggers ‘outside-in’ signaling, which frequently synergizes with growth factor-dependent cascades and activates downstream proteins such as extracellular signal-regulated protein kinases 1 and 2 (Erk1/2). Furthermore, integrin-mediated anchorage and signaling can also regulate cell survival processes and prevent cells entering anoikis, which is a special form of apoptosis triggered by inappropriate cell–ECM interactions.$^8,9$ For instance, the integrin-dependent adhesion of mammary and intestinal epithelial cells to the ECM is pivotal to avert anoikis through the activation of protein kinase B (PKB/Akt) survival pathway and the prevention of mitochondrial translocation of the pro-apoptotic protein Bcl-2-associated X protein (Bax).$^{10–12}$

Although collagen I is one of the major proteins in the bone marrow, the precise roles of collagen-binding integrin receptors in human MSC (hMSC) behavior have not been investigated. In this study, we addressed the functions of $\alpha 1/1$, $\alpha 2/1$ and $\alpha 11/1$ integrins in hMSC by applying short
Hairpin RNA (shRNA)-mediated knockdown (KD) of the corresponding \( \alpha \)-subunits and performing all functional analysis on native human collagen type I. Our major finding was that the deficiency of \( \alpha 2 \) or \( \alpha 11 \) integrin in hMSC leads to initiation of cell apoptosis via Akt pathway, while the deficiency of \( \alpha 1 \) integrin was entirely permissible for hMSC survival on collagen I. Furthermore, \( \alpha 2 \)- and \( \alpha 11 \)-shRNA hMSC completely failed to osteogenically differentiate because of the profound loss of cells throughout in vitro osteogenic stimulation (OS). Finally, a pilot investigation with hMSC derived from osteoporotic patients showed a significant downregulation of \( \alpha 2 \) integrin in these cells. Taken together, our study reports for the first time that two of the collagen I-binding integrins, \( \alpha 2 \) and \( \alpha 11 \), transmit essential and non-redundant signaling for hMSCs inhabiting collagen I-rich cell niches and that disturbance of the collagen I-integrin interactions results in stem cell death. Hence, we believe that our findings can open a novel way to interpret, understand and further investigate bone conditions in which the cell access to normal collagen I is affected.

**Results**

hMSC adhesion and proliferation are enhanced on collagen I and two of the collagen I-binding integrins are significantly upregulated in osteogenically differentiated hMSC. First, we investigated the effect of collagen type I on hMSC adhesion and proliferation. For hMSC adhesion (Figure 1a) and proliferation analysis (Figure 1b), cells were cultivated on collagen I, fibronectin, laminin, I, poly-L-lysine (PLL) or 5% milk/PBS (blotto). After 45 min, hMSC attachment to collagen I and fibronectin entered an adhesion plateau (92.6 \( \pm \) 7.2\% and 98.1 \( \pm \) 2.9\%, respectively) whereas the cell adhesion to laminin I and PLL remained lower at all-time points (Figure 1a). Similar to the adhesion data, hMSC proliferation was significantly higher on collagen I and fibronectin demonstrated by bromodeoxyuridine (BrdU) incorporation assay (Figure 1b).

Next, we investigated the basal expression of \( \alpha 1 \), \( \alpha 2 \), \( \alpha 11 \) and \( \beta 1 \) subunits in hMSC and human osteoblasts (hOBs) by semi-quantitative PCR (Figure 1c). Both cell types were found to express all integrins. Quantitative PCR performed in hMSC revealed that, among the \( \alpha \)-subunits, \( \alpha 11 \) had the strongest basal expression on collagen I and the \( \alpha 1 \) mRNA levels were higher than \( \alpha 2 \) (Figure 1d). In addition, we performed western blot analyses of hMSC, hOB and native bone tissue (Figure 1e). The signal for \( \alpha 1 \), \( \alpha 2 \) and \( \alpha 11 \) was strong in cultured hMSC and hOB, while the freshly isolated low-affinity nerve growth factor receptor (CD271)-positive, non-cultured hMSC and human bone tissue revealed a weaker signal. However, we demonstrated for the first time the protein expression of the three collagen I-binding integrins in native hMSC, which were directly isolated and lysed from the bone marrow. Finally, we performed immunostaining for integrins \( \alpha 1 \), \( \alpha 2 \) and \( \alpha 11 \) in hMSC cultured on collagen I (Figure 1f). The cells were positive for all subunits; however, the most robust focal adhesions were observed in the case of \( \alpha 11 \)-specific staining.

In order to investigate if the collagen-binding integrin levels are altered during hMSC commitment into OB lineage, hMSC were osteogenically stimulated. Figures 2a and b demonstrate the osteogenic differentiation, judged by Alizarin Red (AR) cytochemistry, and quantification, of three hMSC donors at day 21. The osteogenic differentiation was further validated by semi-quantitative PCR for osteoblast-specific genes namely, Osterix, osteocalcin and bone sialoprotein (Figure 2c). Quantitative RT-PCR analyses of \( \alpha 1 \), \( \alpha 2 \) and \( \alpha 11 \) integrin expression revealed no changes for \( \alpha 1 \) (Figure 2d), while \( \alpha 2 \) and \( \alpha 11 \) were significantly upregulated on hMSC OS (Figures 2e and f). The increase in \( \alpha 2 \) and \( \alpha 11 \) expression on protein level was confirmed by western blotting (Figure 2g).

Taken together, these findings demonstrate that first, collagen I promotes hMSC adhesion and proliferation; second, among the three collagen-binding integrins, \( \alpha 11 \) has the most pronounced basal expression; and third, when hMSC differentiate toward OB, \( \alpha 2 \) and \( \alpha 11 \) integrins are significantly upregulated, thus suggesting an important role for hMSC functions on collagen I.

Stable and efficient gene KD of \( \alpha 1 \), \( \alpha 2 \) and \( \alpha 11 \) integrins in MSC from human bone marrow. To examine the functional role of collagen-binding integrins, we applied small interference RNA technology. hMSC were stably transduced with control, \( \alpha 1 \), \( \alpha 2 \) or \( \alpha 11 \) shRNAs and cells, which had no pro-virus integration were eliminated by antibiotic selection. RT-PCR and western blot analyses were used to estimate the degree of integrin KD (Figure 3). The overall efficiency of integrin KD was \( >85\% \) in all independent infections of each hMSC donor. Using the quantitative RT-PCR data, we analyzed if the downregulation of a particular integrin subunit leads to expression changes in the other two subunits (Figures 3b–d). We found that following integrin \( \alpha 1 \) KD, the expression levels of \( \alpha 2 \) and \( \alpha 11 \) increased with 1.7 \( \pm \) 0.1 and 3.7 \( \pm \) 0.5-fold, respectively. Similar changes occurred when integrin \( \alpha 2 \) was diminished (at \( \pm 2.4 \pm 0.6 \) and \( \pm 11 \) with 2.1 \( \pm 0.5 \)-fold increase). In contrast, the KD of integrin \( \alpha 11 \) led only to 1.7 \( \pm \) 0.1-fold increase in \( \alpha 1 \) mRNA whereas the level of \( \alpha 2 \) remained unchanged. These results were also apparent on protein levels (Figure 3e).

In conclusion, a very efficient and reproducible KD of \( \alpha 1 \), \( \alpha 2 \) and \( \alpha 11 \) integrins was successfully established in hMSC. In addition, a compensatory upregulation among some of the integrin subunits was observed.

hMSC deficient for \( \alpha 2 \) or \( \alpha 11 \) integrins exhibit a clear defect in adhesion, spreading and migration. Subsequent to the establishment of integrin KD in hMSC, we investigated for changes in their cell attachment (Figure 4a), spreading (Supplementary Figures 2 and 4b) and migration on collagen I (Figures 4c–e). After 120 min, all control-shRNA (con-shRNA) and 91.6 \( \pm \) 6.5\% of \( \alpha 1 \)-shRNA hMSC were attached versus only 79.1 \( \pm \) 2.5\% of \( \alpha 2 \)-shRNA hMSC. The lowest cell adhesion was detected in \( \alpha 11 \)-shRNA hMSC as these cells reached a maximal adhesion of just 30.1 \( \pm \) 3\%.
The 2- and 11-shRNA hMSC had also a migratory deficit. The average path con-shRNA cells took was 171.3 ± 31.3 μm with mean velocity of 11.4 ± 2.1 μm/h (Figure 4c). Similarly, 1-shRNA hMSC migrated to approximately 200 μm distances with 13.9 ± 0.4 μm/h of average speed. In comparison, the migration distance and velocity of 2- and 11-shRNA hMSC were significantly reduced to approximately 50% (Figures 4d and e). In conclusion, hMSC deficient for 2 and 11 integrin receptors exhibited a reduced adhesion, delayed spreading and lower migration velocity.

**Figure 1** hMSC adhesion and proliferation on ECM proteins, and integrin expression profile. (a) Quantitative adhesion assay on collagen I, fibronectin, laminin I, PLL (poly-L-lysine) and blotto (5% milk/PBS). The highest hMSC adhesion was toward fibronectin and collagen I. The data represent two independent experiments. (b) Proliferation analysis. Cells were cultured for 24 h in the presence of 10 μM BrdU. The highest BrdU uptake was detected when hMSC were grown on collagen I. Three independent experiments, each consisting of triplicates, were performed (n = 9; ***P < 0.001; one-way ANOVA). (c) Semi-quantitative PCR analysis of the basal expression of 1, 2, 11 and β1 integrin in hMSC and hOB. Shown is a representative experiment of three independent repeats. (d) Quantitative PCR analysis of collagen I-binding integrin expression revealed that 11 is the most strongly expressed integrin subunit in hMSC cultivated on collagen I. Data consist of three independent quantitative measurements with three donors (n = 9; ***P < 0.001; one-way ANOVA). (e) Representative western blots for integrin 1, 2 and 11 in freshly isolated CD271-MNC and CD271 + hMSC, cultivated hMSC and hOB, and hBone protein extracts confirmed integrin protein expression in vivo and in vitro. (f) Immunofluorescent stainings of 1, 2 and 11 integrins of hMSC cultured on collagen I. Integrin 11 showed the most pronounced focal adhesions (indicated by arrows). The staining was reproduced twice, bar 50 μm and in the inset 20 μm.

KD of 2 or 11 integrin results in a dramatic loss of hMSC numbers and impaired osteogenic differentiation. Throughout hMSC cultivation on collagen I, we detected a persistent decrease in cell numbers within the population of 2- and 11-shRNA-transduced cells (Figures 5a and b). In contrast, the con- and 1-shRNA hMSC continuously increased. In order to estimate the rate of cell regression, cell quantification was performed and the percentage of cell gain or loss between days 0 and 14 was determined (Figure 5b). At day 14, con- and 1-shRNA hMSC increased with 55.8 ± 16% and 76.3 ± 42%, whereas...
$\alpha_2$- and $\alpha_{11}$-shRNA significantly reduced to $83.3 \pm 0.5\%$ and $73.1 \pm 12.4\%$, respectively of the original seeding density.

A viral infection or a presence of double-stranded RNA within the cells can lead to an activation of interferon (IFN) signaling, which then can result in IFN-mediated cell apoptosis. In order to exclude that the observed reduction of $\alpha_2$- and $\alpha_{11}$-shRNA hMSC numbers is due to a triggered IFN pathway, we performed semi-quantitative PCR analyses of genes related to IFN pathway – OAS1, OAS2, retinoic acid-inducible gene I and IFN-induced protein with tetratricopeptide repeats 1. hMSC stimulated with IFN-$\beta$ were used as a positive control. As shown in Figure 5c, none of the tested genes showed distinctive upregulation in the shRNA-transduced hMSC.

Finally, we induced osteogenic differentiation of hMSC and observed that con- and $\alpha_1$-shRNA cells were able to differentiate into osteoblasts indicated by positive AR staining, whereas $\alpha_2$- and $\alpha_{11}$-shRNA hMSC did not deposit mineralized matrix shown by the lack of AR staining. Instead, during the stimulation period, a further significant regression in the cell numbers of both cell types was observed (Supplementary Figure 3).

Hence, we concluded that viral treatment and shRNA transduction in hMSC had no stimulatory effect on IFN pathway and that only the gene KD of $\alpha_2$ and $\alpha_{11}$ integrins leads to a remarkable reduction of hMSC numbers during cultivation as well as OS.

hMSC deficient for $\alpha_2$ or $\alpha_{11}$ integrins exhibit a mitochondrial permeability, BAX upregulation and reduced activation of Akt. The observed decline in $\alpha_2$- or $\alpha_{11}$-shRNA KD hMSC numbers suggested a survival defect on collagen I; therefore apoptosis was evaluated first by 5,5′,6,6′-tetrachloro-1,1′,3,3′-tetraethylbenzimidazolylcarbo-cyanine iodide (JC-1) staining (Figure 6). In viable cells, JC-1 aggregates in the intact mitochondria and produces red fluorescent signal (Figure 6a). In apoptotic cells, which have a mitochondrial leakage, JC-1 resides in the cytoplasm in a monomeric form and stains the cell cytoplasm in green (Figure 6b). Our results showed that con- and $\alpha_1$-shRNA hMSC populations consisted of mostly non-apoptotic cells (Figures 6c and d). In contrast, $\alpha_2$- and $\alpha_{11}$-shRNA hMSC, similarly to the positive control (hMSC treated with CD95 death receptor (FAS) antibody), were predominantly stained in green indicating mitochondrial leakage (Figures 6e and f).

Next, we carried out a western blot analysis for the pro-apoptotic factor Bax, which is responsible for mitochondrial...
membrane permeabilization. A significantly elevated Bax expression was observed only in a2- and a11-shRNA hMSC (Figure 7a).

Finally, we analyzed the activation of the integrin down-stream targets FAK (Figure 7b), ERK (Figure 7c) and Akt (Figure 7d) using phospho-specific antibodies. The pFAK levels were significantly reduced by approximately 50% in all integrin-deficient hMSC, whereas a slight reduction of pERK and almost a complete loss of pAkt were detected only in a2- and a11-KD hMSC. Thus, we concluded that the hMSC shortfall observed after a2 or a11 KD is the consequence of cell apoptosis because of the lack of adhesion-dependent activation of the major survival effector – Akt.

A significant downregulation of a2 integrin revealed in hMSC derived from osteoporotic patients. To investigate a hypothetic relationship between osteoporosis and integrin dysregulation, a pilot study with hMSC derived from older healthy (hMSC OH, n = 3) and older osteoporotic donors (hMSC OP, n = 6) (Supplementary Table 1) was performed. We analyzed the expression profile of the collagen-binding integrins in these cells and compared it with that of hMSC from the younger healthy donors. Hence, an intriguing trend was found: first, a2 and a11 integrins were upregulated during aging (Figure 8a) and second, no changes were detected in a1 expression in hMSC OP whereas a11 was slightly upregulated in hMSC OP (Figure 8b). Most strikingly, a significant, 17-fold downregulation of a2 was detected in hMSC OP (Figure 8b) as well as a notable number of cells exhibited a mitochondrial leakage (Figure 8c) in comparison with hMSC OH (Figure 8b).

Discussion
In this study, we investigated the role of the collagen I-binding integrins, a1b1, a2b1 and a11b1, in human, bone marrow-derived MSC. We applied a stable, shRNA-based integrin silencing and observed significant changes only in the behavior of hMSC deficient for a2 or a11 integrin subunits. The major cellular changes comprises (Figure 9): (i) reduced adhesion, spreading and motility on collagen I; (ii) increased apoptosis associated with mitochondrial leakage and Bax upregulation; and (iii) affected integrin-mediated signaling to Akt, FAK and ERK.

Owing to the high rates of hMSC adhesion and proliferation on collagen I, we first examined the expression levels of the collagen I-binding integrins in hMSC cultivate on collagen I and found that among the three different collagen I-binding subunits, a11 integrin had the highest basal expression. Our study also reported for the first time the in vivo expression of the three a1, a2 and a11 integrins by analyzing freshly isolated, non-cultured hMSC. Furthermore, we clearly demonstrated that a2 and a11 integrins, but not a1, were significantly upregulated on OS of hMSC. Forster et al. have

Roles of collagen I-binding integrins in hMSC
C Popov et al

Cell Death and Disease
previously demonstrated by quantitative proteomic analysis that the amount of collagen I, as well as α2 and α11 integrins, increases during hMSC osteogenic differentiation. Hence, we suggest that the elevation of α2 and α11 might be a consequence of the changes in collagen I production in the differentiating cells.

To investigate the role of these three receptors in hMSC, we next performed a loss-of-function analysis. After the
accomplishment of almost complete silencing of each integrin subunit, we observed that only hMSC deficient for α2 or α11 integrins exhibited adhesion, spreading and migration deficits on collagen I while α1-deficient cells behaved similarly to control hMSC. Changes in adhesion and migration efficacy after the loss of collagen I-binding integrins have been described only in mouse cells derived from integrin knockout models. However, the phenotype of bone marrow-derived MSC has not been investigated so far. Using α2-knockout keratinocytes and dermal fibroblasts, it was shown that α2 integrin regulates the cell attachment and migration on collagen I, whereas adhesion to collagen IV and laminin I is permissive. Popova et al. reported a positive effect of integrin α11 on embryonic fibroblast adhesion and spreading on collagen I. In contrast, the investigators observed that this cell type was actually able to migrate faster on various collagens when α11 was missing. The reported discrepancy in the migratory behavior of integrin-deficient cells could be explained with the notion that collagen-binding integrins might exert different effects on cell adhesion and migration depending on the cell type or on the availability of other compensatory integrin subunits. In our study with human MSC, we observed that in the absence of α2 integrin, α1 and α11 subunits were significantly upregulated, while only a slight increase in α1 was detected subsequent to α11 KD. Hence, we suggest that the adhesion deficit of α2-deficient cells was not as severe as that of α11 because one or both remaining integrins could have a compensatory role.

Integrins have been implicated also in the control of cell differentiation and survival. Salasznyk et al. demonstrated that FAK and ERK signaling regulate the osteogenic differentiation of hMSC on collagen I, however, in these studies the upstream pathway or an integrin involvement was not examined. Integrins are also known to trigger pro-survival signals when cells interact with ECM proteins, but when such contacts are disturbed, integrins can as well initiate cell death. It has been reported in human lung fibroblasts that the disruption of ECM–integrin β1 interactions leads to reduced cell survival because of negatively affected FAK and Akt signaling. Several studies have also coupled integrin signaling with Bcl-2/Bax-dependent apoptotic machinery in keratinocytes and calvaria-derived fibroblasts. It has been shown in rat MSC that transfection of integrin-linked kinase, a downstream effector of β1 integrin, results in

Figure 5  Cell regression of hMSC after integrin KD and investigation of IFN pathway-related genes. (a) Subsequent to the antibiotic selection, cells were pictured every 24 h for a period of 14 days. Shown are representative images at day 0 and 14. (b) hMSC deficient for α2 or α11 integrin decrease in number during cultivation in vitro. In contrast, α1-shRNA and con-shRNA hMSC were able to expand. In the text inset, the total cell gain or cell loss between day 0 and 14 is shown in percentage. The experiment was performed in duplicates with two donors as the total cell number in 1.1 cm² area was automatically counted by ImageJ software. (c) RT-PCR was performed for OAS1, OAS2, retinoic acid-inducible gene I (RIG-I) and IFN-induced protein with tetratricopeptide repeats 1 (IFIT1), genes involved in IFN-related cell death. The PCR results showed that none of the tested genes were upregulated after viral transduction of shRNA. Shown is a representative experiment of three independent infections. Positive control: hMSC treated with 2 × 10³ U/ml IFN/ for 72 h.

Roles of collagen I-binding integrins in hMSC

C Popov et al
reduction of the pro-apoptotic Bax levels and thus, assists the MSC survival in hypoxic conditions. However, our study is the first one to demonstrate that the loss of collagen I–integrin interactions triggers stem cell death; using hMSC, we showed that the downregulation of α2 or α11 integrin, but not α1, leads to induction of apoptosis. As no activation of the IFN pathway was detected, we concluded that the observed cell apoptosis is indeed specific to the KD of α2 or α11 integrin. These cell populations were unable to expand in vitro. Moreover, as a predominant fraction of adherent cells exhibited mitochondrial leakage and a significant elevation of Bax protein levels, we suggest that the cell apoptosis was initiated before cell detachment. We also detected a reduction in the phosphorylation of FAK and ERK in the three integrin KDs. However, the most pronounced reduction of pERK was found in the α2- or α11-deficient hMSC. Furthermore, both cell populations showed a dramatic reduction of pAkt levels. Finally, as α2-deficient cells underwent cell death, despite the upregulation of α1 and α11, we propose that each integrin triggers a specific, non-dismissive downstream signaling cascade. Further studies, however, are required to dissect the exact signaling pathways mastered by α2 and α11 integrins in hMSC and other cell types.

A recent study reported that α11 integrin deficiency in mice results in disorganized periodontal ligament, halted incisor eruption and tooth-dependent dwarfism. The investigators identified a number of apoptotic cells in the periodontal ligaments. This tissue is highly enriched with collagen I and α11 integrin is the only collagen receptor. Interestingly, when fed with soft food, the α11 knockouts only partially overcame their growth retardation. We propose that this tooth-independent growth defect might be linked to insufficient skeletal development because of MSC deficit. In contrast to α11, integrin α1 and α2 knockout mice show no gross developmental abnormalities. Taken together, the relatively mild phenotypes of α1, α2 and α11 mutant mice

Figure 6 Investigation of the mitochondrial integrity of integrin-deficient hMSC. Representative microphotographs of hMSC cultivated on collagen I and stained with JC-1. JC-1 dye aggregates and emits red color in cells with intact mitochondria such as non-treated hMSC (a), con- (c) and α1-shRNA hMSC (d) whereas apoptotic cells are labeled in green as in the positive control – hMSC treated with 1 μg/ml FAS antibody (b). hMSC with α2 (e) or α11 (f) KD are labeled in green indicating that their mitochondria are permeabilized. Cytochemistry was performed twice independently with two donors.
suggest that, under normal physiological conditions, there is a functional redundancy between the individual collagen receptors. However, in certain tissues or cell types, or under disease-like conditions, these receptors might execute indispensable functions. Therefore, our study urges further investigation of the bone marrow niche of the single or double knockout mice as well as on their involvement in experimental models challenging bone development or healing.

Another possible field for further investigation includes bone conditions associated with collagen I abnormalities such as...
Osteogenesis imperfecta and osteoporosis. A recent study has reported mutations causing osteogenesis imperfecta in type I collagen, which are located in the binding sites for integrins and proteoglycans. Another study found in patients with specific collagen I polymorphism that the collagen I α1 and α2 chains were made in an aberrant ratio and suggested that this is relevant for the onset of osteoporosis. Furthermore, it has been shown that the total amount of collagen I protein is decreased in hMSC derived from osteoporotic patients and that osteoblasts isolated from patients with osteoporotic or osteoarthritic condition have reduced attachment and spreading as well as decreased FAK activation. However, several other studies have found no dramatic changes in the hMSC proliferative and differentiation capacity from osteoporotic patients and that osteoblasts isolated from patients with osteoporotic or osteoarthritic condition have reduced attachment and spreading as well as decreased FAK activation. One possible explanation for this discrepancy is the variability in hMSC preparation and validation. On the basis of our results and the literature, we now speculate that in such conditions, one additional factor might be that the MSC population is being gradually exhausted in vivo because of loss of ECM interactions and subsequent cell death. Therefore, we performed a pilot analysis with hMSC derived from osteoporosis-suffering patients and found that, in comparison with hMSC from healthy old patients, the osteoporotic cells have significantly reduced mRNA levels of α2 integrin. Importantly, further experiments involving higher number of patients will be necessary to clarify what role integrin expression and signaling undertake in bone diseases. Such studies are currently ongoing.

In conclusion, our study contains the first cellular and molecular analysis demonstrating the role of collagen I-binding integrins in the survival of MSCs in collagen I-rich environment and calls for future investigations examining the impact of MSCs in bone conditions with abnormal collagen I.

Materials and Methods

Human cells and cell culture. The summary of hMSC donors used in this study is shown in Supplementary Table 1. hMSC were purchased from Lonza (Basel, Switzerland) or were isolated from bone marrow by ficoll gradient centrifugation (the procedure was approved by the LMU ethical commission, grant 311–04). The hMSC characteristics were verified by the producer or by us according to Dominici et al. Briefly, hMSC were proven by FACS to be positive (≥ 98%) for the MSC-related markers, 5'-nucleotidase, GPI-linked glycoprotein and endoglin, and negative for the hematopoietic-related markers, monocytes/macrophages receptor, hematopoietic progenitor marker and protein tyrosine phosphatase receptor type C and by two-lineage differentiation to be multipotent (data not shown). hMSC were cultured in MEM Alpha GlutaMAX medium (Invitrogen, Karlsruhe, Germany) supplemented with 10% fetal bovine serum (Sigma, Taufkirchen, Germany) and were grown on plastic or 10 μg/ml native human collagen I-coated surfaces (BD Biosciences, San Jose, CA, USA). hMSC at passages 5–9 were used in the experiments. hOBs were purchased from PromoCell (Heidelberg, Germany) and maintained in OB-specific growth medium (PromoCell). Cells were maintained at 60–80% confluence in T-75 culture flasks, at 37°C/5%
Roles of collagen I-binding integrins in hMSC
C Popov et al

CO2, CD271-negative mononuclear cells (MNCs) and CD271-positive hMSC were isolated with a CD271 MicroBead kit (Miltenyi Biotec, Bergish Gladbach, Germany) from three human bone marrow MNC fractions (Cat. No. 2M-125C) purchased from Lonza and immediately after the cell separation the freshly isolated cells were lysed for protein analysis.

**shRNA cloning, lentiviral production and infection of hMSC.** shRNA oligonucleotides were designed with Invitrogen’s BLOCK-IT RNAi Designer (Invitrogen) against the human integrin α2, α11 and β1-galactosidase genes (Supplementary Table 2). Double-stranded oligonucleotides were annealed and ligated into the pENTR/U6 vector according to the manufacturer’s instructions (Invitrogen). The shRNA constructs were transferred to the final pLenti4/BlockIT-DEST expression vector by recombination using LR Clonase (Invitrogen) and were validated by sequencing. The final plasmids were prepared with EndoFree Plasmid Maxi Kit (Qiagen, Hilden, Germany). For viral production and cell infection, Invitrogen’s ViralPower lentiviral system was used. The pLenti4/BlockIT-U6-shRNA plasmid was transfected into 293FT cells and viral supernatant was collected after 48 h. hMSC were incubated with the virus-containing supernatant for 24 h in the presence of 8 μg/ml polybrene (Sigma) and were selected with 50 μg/ml Zeocin (Invitrogen) for 10 days. As the three different donor-derived cells represented equivalent hMSC populations (Supplementary Figure 1), we designated hMSC XI as the main donor. hMSC XI was infected independently three times and used in all experiments. The additional two donors, hMSC XIII and hMSC XV, were infected once and were used only in the major experiments to confirm that the observed phenotype is not donor-specific.

**Semi-quantitative and real-time PCR.** Total RNA was extracted with RNeasy Mini Kit (Qiagen). For cDNA synthesis, 1 μg total RNA and AMV First-Strand cDNA Synthesis Kit (Invitrogen) were used. RT-PCR was performed with Taq DNA Polymerase (Invitrogen) in MGRResearch instrument (Bio-Rad, Munich, Germany). Primer pairs and PCR conditions are listed in Supplementary Table 3. For quantitative RT-PCR, LightCycler Fast Start DNA Master SYBR Green kit (Roche, Munich, Germany) and primer kits for α2, α11 and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) (Search-LC, Heidelberg, Germany) were used. The quantitative RT-PCR was performed with LightCycler1.5 instrument (Roche) equipped with LightCycler5.5 software. Crossing points for each sample were determined by the second derivative maximum method and relative quantification was performed using the comparative ΔΔCt method according to the manufacturer’s protocol. The relative gene expression was calculated as a ratio to GAPDH. All PCR results have been reproduced minimum three times. For PCR analysis of IFN-related gene expression, a positive control was prepared by incubating hMSC with 2 × 10^6 U/ml IFN-γ (Cat. No. CYT-26766, Dianova, Germany) for 72 h at 37 °C as demonstrated in Croitoru-Lamoury et al.

**Western blot analysis.** Adherent cells were directly lysed in 1x Laemmli buffer (200 mM Tris-HCl pH 6.8, 40% glycerol, 10% sodium dodecyl sulfate (SDS), 30% 2-mercaptoethanol, 0.02% bromphenolblue and 0.2 M dithiothreitol). The lysates were homogenized, denatured at 99 °C for 5 min and centrifuged at 4 °C for 10 min. Equal volumes of the protein lysates were loaded on 8% or 15% SDS-PAGE gels and transferred onto polyvinylidene fluoride membranes. For blocking, 5% skim milk (Merck, Darmstadt, Germany) in Tris-buffered saline buffer (0.05% Tween20) was used. The following primary anti-human antibodies were applied: integrins α2 and β1 (both R&D Systems, Minneapolis, MN, USA), integrin α2 (BD Biosciences), Bax (Biolegend, San Diego, CA, USA), phospho-FAK (Invitrogen), total FAK, total and phospho-ERK1/2, and total and phospho-Akt (all Cell Signaling, Danvers, MA, USA). In the western blot analysis, β-actin (Santa Cruz Biotechnology, Santa Cruz,
Roles of collagen I-binding integrins in hMSC

C Popov et al

CA, USA) was used as a loading control allowing for a simultaneous detection with the integrins on the same protein membrane. The antibodies were diluted in the blocking solution and incubated overnight at 4 °C. Secondary horseradish peroxidase-conjugated antibodies (Rockland, Gilbertsville, PA, USA or Santa Cruz) were applied for 1 h at room temperature. Electrochemiluminescence solution (GE Healthcare, Waukesha, WI, USA) and Lumi-detection films (Roche) were used for protein visualization. Band intensities were quantified with ImageProPlus4 software program (Media Cybernetics, Bethesda, MA, USA).

Immunocytochemistry and cytochemistry. hMSC were cultured on 30 µg/ml collagen I-coated glass slides (BD Biosciences) for 48 h. The cells were fixed with methanol or acetone/methanol, treated with Image-iT FX signal enhancer (Invitrogen), and blocked with 10% BSA. Primary antibodies against integrins α1 (R&D Systems), α2 (AbD Serotec, Oxford, UK) and α1117 were applied overnight at 4 °C. Next, secondary Alexa Flour 488-conjugated antibodies and 4',6-diamidino-2-phenylindole were used (all Invitrogen). For apoptosis analysis, the fluorescent JC-1 dye (Invitrogen) was implicated. shRNA-transduced hMSC (2 × 106 cells/cm²) were cultured on collagen I-coated glass slides for 24 h. On the basis of Kennea et al.,38 to create a positive control for apoptosis, hMSC were treated with 1 µg/ml FAS antibody (BD Biosciences) for 2 h at 37 °C, followed by overnight incubation with 1 µg/ml donkey anti-mouse IgG (Santa Cruz). Next, the cells were incubated with 3 µg/ml JC-1 and 1 µg/ml 2,5-Bi1H-benzimidazole (both Invitrogen) solved in complete growth medium for 30 min at 37 °C/5% CO2. Photomicrographs were taken with Axiozoom MRF camera (Carl Zeiss, Jena, Germany) on Axioscope 2 or Axiovert100 microscope (Carl Zeiss), Staining procedures were reproduced at least twice with hMSC XI and hMSC XIII.

Proliferation analyses. Long-term cell growth was examined by calculating hMSC cumulative population doubling (PD) and PD time according to Docheva et al.29 50% phase analysis was performed with the Cell Proliferation ELISA, BrDU (colorimetric) kit (Roche) as described in Böker et al.4 Briefly, 96-well dishes were coated with 10 µg/ml collagen I (BD Biosciences), fibronectin, laminin I and PLL (all R&D Systems) and seeded with 3 × 103 hMSC per well. After 12 h media supplemented with 10% FCS, BrDU was added. BrDU incorporation was measured after 24 h using microplate reader (Mirotek, Overath, Germany) at 450 nm with 690 nm reference wavelength. Three independent experiments were performed in triplicate. For assessment of cell numbers after shRNA transduction, hMSC XI and XV were plated in six-well dishes and microscopically photographed every 24 h for a period of 14 days. Then, two different areas per well (each 1.1 cm²) were used for automated cell counting by ImageJ software program (http://rsb.info.nih.gov/ij).

Adhesion assay. Cell adhesion assay was performed as described in Docheva et al.39 Briefly, 96-well plates were coated with 10 µg/ml collagen I, fibronectin, laminin I and blocked with 5% milk/PBS (biotin). hMSC were plated in triplicate (3 × 103 cells per well) and incubated for various time periods (15–120 min) at 37 °C, then non-adherent cells were removed by PBS washing. Cell adhesion was colorimetrically estimated using p-nitrophenyl N-acetyl-beta-o-glucosaminide (Sigma-Aldrich, Munich, Germany) as a substrate. Absorbance was measured at 405 nm on microtitre-plate reader (Mirotek). The percentage of adherent cells was calculated to a maximum reference (suppression of 3 × 105 cells).

Live cell imaging. Time lapse experiments were performed with an automated Axiovert100 inverted microscope system (Carl Zeiss) equipped with controlled biochamber (Pecon, Erbach, Germany). hMSC (2 × 105 cells per well) were plated on collagen I-coated six-well dishes. For spreading analysis, cells were imaged immediately after plating with 20 frames/h for 3 h using 20 objective and AxioCam MRF camera (Carl Zeiss). For migration analysis, cells were imaged 3 h after plating for 18 h with 4 frames/h. Three independent movies were produced and approximately 30 cells per type were evaluated. hMSC XI, from two independent viral infections, were used for the time lapse-based experiments. The obtained data were processed with AxioVision LE (Carl Zeiss) and ImageJ software programs.

Osteogenic differentiation. OS was performed as described previously in Böker et al.4 Briefly, hMSC were plated in six-well dishes in a density of 3.5 × 103 cells/cm². Osteogenic media was applied for 21 days and was changed twice weekly. The osteogenic differentiation was evaluated by AR staining, which visualizes calcium-rich deposits produced by the cells. AR staining and quantification were performed with Osteogenic Quantification kit (Millipore, Billerica, MA, USA) according to the manufacturer’s instructions. First, pictures were taken on Axiovert100 microscope with AxioCam ICc3 color camera (Carl Zeiss) and next, AR was extracted with 10% acetic acid and neutralized with 10% NH4OH. Optical density measurements were taken at 405 nm on microtitre-plate reader (Mirotek). The AR amount was calculated against an AR standard curve. The experiment was repeated three times.

Statistics. Statistical evaluation was performed using the GraphPrism software (GraphPad, La Jolla, CA, USA). All quantitative data were acquired from two or three independent experiments, each performed with duplicates or triplicates. Graphs and bar charts show mean values and S.D. Unpaired t-test was used for two group analysis and Dunnet’s one-way ANOVA was applied for multi group statistical testing. A P-value < 0.05 was considered statistically significant.

Conflict of Interest

The authors declare no conflict of interest.
