The generalized Van Vleck second order multireference perturbation theory (GVVPT2) method was used to investigate the low-lying electronic states of Ni$_2$. Because the nickel atom has an excitation energy of only 0.025 eV to its first excited state (the least in the first row of transition elements), Ni$_2$ has a particularly large number of low-lying states. Full potential energy curves (PECs) of more than a dozen low-lying electronic states of Ni$_2$, resulting from the atomic combinations $^3F_4 + ^3F_4$ and $^3D_3 + ^3D_3$, were computed. In agreement with previous theoretical studies, we found the lowest lying states of Ni$_2$ to correlate with the $^3D_3 + ^3D_3$ dissociation limit, and the holes in the d-subshells were in the subspace of delta orbitals (i.e., the so-dubbed δδ-states). In particular, the ground state was determined as $X_1^1\Gamma_g$ and had spectroscopic constants: bond length ($R_e$) = 2.26 Å, harmonic frequency ($\omega_e$) = 276.0 cm$^{-1}$, and binding energy ($D_e$) = 1.75 eV; whereas the $1^1\Sigma_g^+$ excited state (with spectroscopic constants: $R_e = 2.26$ Å, $\omega_e = 276.8$ cm$^{-1}$, and $D_e = 1.75$) of the $^3D_3 + ^3D_3$ dissociation channel lay at only 16.4 cm$^{-1}$ (0.002 eV) above the ground state at the equilibrium geometry. Inclusion of scalar relativistic effects through the spin-free exact two component (sf-X2C) method reduced the bond lengths of both of these two states to 2.20 Å, and increased their binding energies to 1.95 eV and harmonic frequencies to 296.0 cm$^{-1}$ for $X_1^1\Gamma_g$ and 297.0 cm$^{-1}$ for $1^1\Sigma_g^+$. These values are in good agreement with experimental values of $R_e = 2.1545 \pm 0.0004$ Å, $\omega_e = 280 \pm 20$ cm$^{-1}$, and $D_0 = 2.042 \pm 0.002$ eV for the ground state. All states considered within the $^3F_4 + ^3F_4$ dissociation channel proved to be energetically high-lying and van der Waals-like in nature. In contrast to most previous theoretical studies of Ni$_2$, full PECs of all considered electronic states of the molecule were produced.

Keywords: nickel dimer, metal dimers, multireference perturbation theory, generalized Van Vleck perturbation theory, electronic structure calculations

INTRODUCTION

Since Ni$_2$ has few holes in otherwise complete subshells, one might expect theoretical studies of Ni$_2$ to be less complicated than for other first row transition metal dimers, like Cr$_2$ where one has many more possibilities of distributing 12 electrons in 12 valence orbitals. Reported information on Ni$_2$, however, proves the contrary. For example, the exact symmetry of the ground electronic state of Ni$_2$ is still debated: Different studies have reported different space and spin symmetries for the molecule’s ground term.

Experimental data on Ni$_2$ is sparse and the true ground state of the molecule is not unequivocally accepted. From the analysis of electronic absorption bands of Ni$_2$ in the visible spectral region in argon matrices, De Vore et al. (De Vore et al., 1975) determined $\omega_e = 192$ cm$^{-1}$, whereas a frequency...
of 380.9 cm\(^{-1}\) was found in solid argon matrix (Ahmed and Nixon, 1979). The latter result was later criticized by Rasansen et al. (Rasansen et al., 1987) in photoelectron spectroscopic studies of Ni\(_2^+\), \(\omega_c = 280 \pm 20\) cm\(^{-1}\) was determined for the lowest electronic state of Ni\(_2^+\) (Ho et al., 1993). Second and third law analyses of information derived from a combination of Knudsen effusion and mass-spectrometric techniques led to a binding energy of \(D_0 = 2.03 \pm 0.30\) eV (second law result) and \(D_0 = 2.36 \pm 0.22\) eV (third law result) for ground state Ni\(_2^+\) (Kant, 1964).

By using time-delayed resonant two-photon ionization, Morse et al. (Morse et al., 1984) determined \(D_0 = 2.068 \pm 0.010\) eV and \(R_c = 2.200 \pm 0.007\) Å for the lowest state of Ni\(_2^+\), but assigned as either \(^3\Sigma_u^+\) or \(^1\Gamma_g^+\). Also from two-photon ionization studies on supersonic jet-cooled Ni\(_2^+\) in argon carrier gas, Pinegar et al. (Pinegar et al., 1995) determined \(D_0 = 2.042 \pm 0.002\) eV and \(R_c = 2.1545 \pm 0.0004\) Å for the lowest state of Ni\(_2^+\) but were unable to ascertain the symmetry of this state.

Theoretical studies of the electronic states of Ni\(_2^+\) are complicated by the fact that the first excited state of the Ni atom, \(^3\Delta_3\) (3d\(^8\)4s\(^2\)) is only 0.025 eV above the \(^3\Sigma_u^+\) (3d\(^8\)4s\(^2\)) ground atomic state, which is the least excitation energy of any of the first row of transition elements (Harrison, 2000; Kramida et al., 2013). This low promotion energy supports the existence of several low-lying molecular states of the Ni\(_2^+\) molecule resulting from the \(^3\Sigma_u^+\) (3d\(^8\)4s\(^2\)) ground state of Ni\(_2^+\). In particular, the lowest states of the Ni\(_2^+\) molecule can be expected to correlate with the \(^3\Sigma_u^+\) (3d\(^8\)4s\(^2\)) ground state of Ni\(_2^+\), and provides insight into necessary levels of experimental and theoretical approaches. The \(^3\Sigma_u^+\) (3d\(^8\)4s\(^2\)) \(\rightarrow\) \(^3\Delta_3\) (3d\(^8\)4s\(^2\)) excitation energy has been determined by at least one experimental study (Moore, 1952) to be negative (-0.029 eV). This negative value was supported by ab initio wave function and density functional theory (DFT) calculations (Bauschlicher et al., 1982; Raghavachari and Trucks, 1989; Russo et al., 1994). A more recent study, (Schultz et al., 2005) that employed several functionals at all five rungs of Jacob's ladder of DFT functionals, predicted the ground state configuration of the Ni atom as 3d\(^8\)s\(^1\) (\(^3\)D\(_3\)) with most of the functionals when using a triple-ζ quality basis set. On the other hand, multireference studies (Andersson and Roos, 1992; Murphy and Messmer, 1992) predicted a 3d\(^8\)s\(^1\) (\(^3\)F\(_4\)) ground state configuration for the Ni atom. Illustrating additional complexity, Upton and Goddard (Upton and Goddard III, 1978) found that averaging over J components (where J is the sum of spin and orbital angular momenta of the atom) of each state places the \(^1\Sigma_u^+\) (3d\(^8\)4s\(^2\)) state lower energetically than the \(^3\Sigma_u^+\) (3d\(^8\)4s\(^2\)) state.

One of the earliest theoretical studies (Cooper et al., 1972) on Ni\(_2^+\) employed the extended Hückel molecular orbital method and found a \(^1\Sigma_g^+\) ground state with \(R_c = 2.21\) Å, \(\omega_c = 370\) cm\(^{-1}\), and \(D_c = 2.45\) eV, with dominant configuration 3d\(^8\)g\(^2\) 3d\(^4\)u\(^4\) 3d\(^5\)g\(^2\) 3d\(^2\)u\(^2\) 3d\(^2\)g\(^2\) 4s\(^0\)g\(^2\); whereas the generalized valence bond (GVB) method (Melius et al., 1976) predicted a \(^1\Sigma_g^+\) ground state for Ni\(_2^+\), but with configuration 3d\(^8\)g\(^4\) 3d\(^4\)u\(^2\) 3d\(^4\)u\(^4\) 3d\(^2\)g\(^2\) 3d\(^2\)u\(^2\) 4s\(^0\)g\(^2\); whereas the generalized valence bond (GVB) method (Melius et al., 1976) predicted a \(^1\Sigma_u^+\) ground state for Ni\(_2^+\), and provides insight into necessary levels of experimental and theoretical approaches. The \(^3\Sigma_u^+\) (3d\(^8\)4s\(^2\)) ground state configuration for the Ni atom. Illustrating additional complexity, Upton and Goddard (Upton and Goddard III, 1978) found that averaging over J components (where J is the sum of spin and orbital angular momenta of the atom) of each state places the \(^1\Sigma_u^+\) (3d\(^8\)4s\(^2\)) state lower energetically than the \(^3\Sigma_u^+\) (3d\(^8\)4s\(^2\)) state.

Using an effective core potential basis set specifically optimized for the Ni atom in the \(^3\Sigma_u^+\) state within the generalized valence bond (GVB) method, Noell et al. (Noell et al., 1980) found the splitting of the six \(\delta\delta\)-hole states of Ni\(_2^+\) to be quite small (\(\leq 0.1\) eV), with the lowest states being \(^1\Sigma_g^+\) and \(^1\Sigma_u^+\). Inclusion of polarization configurations involving single and double excitations to the virtual space (POLSDCI) placed the triplet states (\(^1\Sigma_g^+\), \(^3\Sigma_g^+\), \(^3\Sigma_u^+\)) approximately 0.07 eV below the singlets. At the singles and doubles CI (SDCI) level of theory, these authors found the energy splitting of the six lowest \(\delta\delta\)-hole states of Ni\(_2^+\) to be less than 0.009 eV, with an average bond length of 2.26 Å and binding energy of 1.88 eV.

With a basis set similar to that used by Noell et al. (Noell et al., 1980) a contemporaneous restricted Hartree-Fock (RHF) and CI with single and double excitations (CISD) study predicted a \(^1\Sigma_u^+\) ground state for Ni\(_2^+\), with spectroscopic data: \(R_c = 2.33\) Å, \(\omega_c = 211\) cm\(^{-1}\), and \(D_c = 1.43\) eV (Basch et al., 1980). Calculations by these authors at the same levels of theory using an all electron basis set corroborated the prediction of the ground state symmetry as \(^1\Sigma_u^+\). On the other hand, a local spin density
method (Harris and Jones, 1979) predicted a $3\Sigma^-$ ground state with $R_e = 2.18 \text{ Å}$, $\omega_e = 320 \text{ cm}^{-1}$, and $D_e = 2.70 \text{ eV}$. A slightly earlier CASSCF/CASPT2 study (Pou-Amérgio et al., 1994) that used an atomic natural orbital (ANO) type contraction of the (21s15p10d6f4g) primitive basis to (6s5p4d3f2g) for calculations without correlation of the semi-core 3s3p electrons, and a (10s9p8d3f2g) contracted basis for calculations involving the correlation of 3s3p electrons, likewise found the six lowest $\delta\delta$-hole states of Ni$_2$ to lie within a particularly narrow energy gap (0.04 eV) with the triplet states higher in energy than the singlets. However, after inclusion of scalar relativistic effects, the ground term was predicted as $1\Gamma_g$ with the $3\Sigma^+$ term lying only 0.01 eV higher at the equilibrium geometry. Correlating the 3s3p electrons in these calculations predicted the $1\Gamma_g$ and $3\Sigma^+$ states to be degenerate to the reported accuracy, with slightly improved spectroscopic constants relative to reference experimental values [i.e., $R_e = 2.23$ Å, $D_e = 2.06$ eV; and $\omega_e = 293$ cm$^{-1}$ for $1\Gamma_g$ versus $\omega_e = 294$ cm$^{-1}$ for $3\Sigma^+$] compared with experimental values of $R_e = 2.1545 \pm 0.0004$ Å, (Pinegar et al., 1995) $D_e = 2.042 \pm 0.002$ eV, (Pinegar et al., 1995) and $\omega_e = 280 \pm 20$ cm$^{-1}$ (Ho et al., 1993).

DFT studies of Ni$_2$ have also been inconclusive. Yanagisawa et al. (Yanagisawa et al., 2000) used various DFT functionals to study the $2\Sigma^+$ and $2\Sigma^-$ states of Ni$_2$ and found B3LYP (Becke, 1993) to predict the $2\Sigma^-$ state to lie lower than $2\Sigma^+$ whereas the rest of the functionals predicted the latter state to lie lower at the equilibrium geometry. However, the $2\Sigma^+$ state that they found had a configuration that corresponded to the $\pi\pi$-hole manifold rather than the $\delta\delta$. Gutsев et al. (Gutsев and Bauschlicher, 2003) also found a $2\Sigma^-$ ground state, with the same configuration as did Yanagisawa et al. (Yanagisawa et al., 2000) when using a variety of hybrid functionals. Contrarily, Diaconu et al. (Diaconu et al., 2004) found a singlet $\delta\delta$-hole ground state (with a mixture of $1\Gamma_g$ and $3\Sigma^+$) for Ni$_2$ when using B3LYP with the (14s11p6d3f)/[8s6p4d1f] basis set, whereas use of the Stuttgart RSC ECP basis set (Dolg et al., 1987) with the same functional gave a triplet $\delta\delta$-hole (with a mixture of $2\Sigma^+$ and $1\Gamma_g$ symmetries) that lay 0.001 eV lower than the singlet $\delta\delta$-hole state at the equilibrium geometry. Using functionals at all levels of Jacob’s ladder of DFT functionals, Schultz et al. (Schultz et al., 2005) also found different functionals to predict different ground state symmetries for Ni$_2$, with all local spin density approximation (LSDA) functionals predicting a $3\Sigma^-$ ground state and all generalized gradient approximation (GGA) and meta GGA functionals predicting a $1\Pi_u$ ground state; whereas hybrid GGA and hybrid meta GGA functionals found either $2\Sigma^+$ or $2\Sigma^-$ to lie lowest energetically. Du et al. (Du et al., 2008) used various functionals to study the low-lying states of Ni$_2$. Their results that agreed best with experiment were obtained when using BLYP, which predicted a triplet $\delta\delta$-hole (3d$^{3dz}_2$, 3d$^{4sp}_a$, 3d$^{3sp}_y$, $\delta^+_1$, $\delta^+_2$) ground state. The space symmetry of this state was not reported. With the B3P86 functional, (Perdew, 1986; Becke, 1993) a quintet ground state was predicted for Ni$_2$ (Shi-Ying and Zheng-He, 2008) although the space symmetry was not reported. The Perdew-Burke-Ernzerhof (PBE) exchange correlation functional (Perdew et al., 1996) predicted a $3\Sigma^-$ ground state for Ni$_2$, (Kamal et al., 2012) with spectroscopic constants $R_e = 2.93$ Å, $D_e = 3.09$ eV, and $\omega_e = 334.08$ cm$^{-1}$, which showed significant deviations from experimental values.

Some of the most recent wave function based calculations on Ni$_2$ include those due to Dong et al. (Dong et al., 2013) using the symmetry-adapted-cluster configuration interaction (SAC-Cl) method (Nakatsuji, 1979) and Cheskidov et al. (Cheskidov et al., 2012) using the average coupled pair functional (ACPF), (Gdanitz and Ahlrichs, 1988) average quadratic coupled cluster (AQCC), (Szalay and Bartlett, 1993) internally contracted single and double multireference configuration interaction (MRCl or MRCI with Davidson corrections, i.e., MRCI + Q), (Werner and Knowles, 1990) and N-electron valence state second-order perturbation theory (NEVPT2) (Angeli et al., 2001) methods. The study by Dong et al. (Dong et al., 2013) predicted a $1\Sigma^+$ ground state (with $R_e = 2.56$ Å) for Ni$_2$ in D$_{2h}$ symmetry which corresponds to $2\Sigma^+$, $3\Delta_u$ or $3\Gamma_u$ in D$_{coh}$. The study by Cheskidov et al. (Cheskidov et al., 2012) used the Dunning-type quadruple-ζ quality basis set, cc-pVQZ-DK ([25s18p11d3f2g1h]/[8s7p6d3f2g1h]), (Balabanov and Peterson, 2005) and found the $1\Gamma_g$ and $1\Sigma^+$ $\delta\delta$-hole states to be quasidegenerate for all five methods with the $3\Sigma^-$ state lying lower when using AQCC, MRCI + Q, and MRCI methods and the two states fully degenerate (to the reported accuracy level) at the ACPF and NEVPT2 levels. At the ACPF level, the predicted ground state was instead $1\Sigma_u^-$; inclusion of spin-orbit relativistic corrections within ACPF calculations led to an $0^+$ ground state ($1\Sigma_u^- + 3\Sigma^-\delta\delta$-hole states), whereas the $0^-$ term ($1\Sigma_u^- + 3\Sigma^+\delta\delta$-hole states) lay at only 0.009 ± 0.004 eV above the predicted ground state.

The above synopsis of previous work on Ni$_2$ shows the difficulties involved in studying not only the spectroscopic constants, but even the ordering of the low-lying electronic states of Ni$_2$. Although wave function methods generally support $\delta\delta$-hole states ($1\Gamma_g$, $1\Sigma^+_u$, $3\Sigma^-$, $1\Gamma_u$, $3\Sigma^+$) as lying lowest energetically, the methods predict different ground state symmetries with some finding all six states to be degenerate. Similarly, experimental spectroscopic data have been obtained but most of the studies could not ascertain the ground state symmetry of the molecule. Our current study exploits the ability of the GVPT2 method (Khait et al., 2002; Jiang et al., 2009) to describe well full PECs of ground- and excited-electronic states of complicated transition element dimers, such as has already been demonstrated on other problematic transition metal molecules [e.g., Cr$_2$ and Y$_2$ (Tamukong et al., 2012; Tamukong et al., 2014)]. It should be noted that of all previous theoretical work described above on electronic states of Ni$_2$, only six of the articles reported full PECs of the states they investigated. Consequently, where other data is available, this study also provides further assessment of the capabilities of the GVPT2 method for difficult transition metal dimers, including the bond breaking regions. We have constructed full PECs of 21 states of Ni$_2$. All (nonrelativistic) calculations used the Dunning-type cc-pVTZ basis set (Balabanov and Peterson, 2005), and calculations were performed using D$_{2h}$ symmetry. Furthermore, low-lying $1\Gamma_g$ and $1\Sigma^+$ states were further studied with scalar relativistic effects included in GVPT2 (Tamukong et al., 2014) through the spin-free exact two component (sf-X2C) method (Liu, 2010; Cheng and Gauss, 2011; Li et al., 2012; Li et al., 2013). Relativistic
calculations used the cc-pVTZ-DK basis set (Balabanov and Peterson, 2005). The rest of the paper is organized as follows: Methods section briefly reviews key features of GVVPT2 and the spin-free exact two component (sf-X2C) methods, and describes computational details; the results are presented and discussed in Results and Discussion section; while conclusions are drawn in Conclusion section.

**METHODS**

**GVVPT2**

The GVVPT2 method for electron correlation in molecules has been thoroughly described elsewhere, (Khait et al., 2002; Jiang et al., 2009) as has its application to some challenging systems (Mbote et al., 2010; Khait et al., 2012; Tamukong et al., 2012; Mokambe et al., 2013; Tamukong et al., 2014). Here, salient features of the GVVPT2 method relevant to the present study are reviewed. In GVVPT, the total Hilbert space of many-electron functions [e.g., configuration state functions (CSFs)] with appropriate molecular space and spin symmetry ($L$) is partitioned into a model space ($L_M$), and an external space ($L_Q$) whose electronic configurations are derived from configurations generated from the model space by single and double electron excitations into virtual orbitals, $L = L_M @ L_Q$. The model space is further partitioned into a primary subspace, spanned by a set of reference functions that are linear combinations of CSFs (typically the lowest MCSCF or CASSCF states), and a secondary subspace. States within the primary subspace are then perturbatively corrected through primary-secondary (P–Q) interactions whereas the secondary subspace serves as a buffer energetically separating the primary and external subspaces. This energy buffer circumvents most intruder state problems that plague many multireference perturbation theory techniques. An effective Hamiltonian matrix ($H^{\text{eff}}_{LM}$) is constructed with the same dimension as the model space, and its diagonalization includes both perturbatively corrected primary and unperturbed secondary subspace states. To guarantee continuity and smoothness of CSF responses (and ultimately PECs) even in situations of quasidegeneracies between primary and external states, GVVPT2 uses a continuously varying nonlinear denominator shift that arises from a resolvent that is both degeneracy-corrected and contains a hyperbolic tangent function as a switching function from nondegenerate to degenerate regimes (Khait et al., 2002). This resolvent can be written

$$X_{pq} = \frac{\tanh(\Delta)}{\Delta} H_{pq} + \frac{\tanh(\Delta)}{\Delta} \sum_{m \in L_M} H_{qm} C_{pq}$$ (1a)

$$\Delta_i = \frac{1}{2} \left( \epsilon_i - \epsilon_i^{(0)} \right) + \frac{1}{2} \sqrt{\left( \epsilon_i - \epsilon_i^{(0)} \right)^2 + 4 \sum_{q \in \epsilon} H_{pq}^2}$$ (1b)

where the $C_{pq}$ denote components of eigenvectors of the unperturbed model Hamiltonian; $\epsilon_i^{(0)}$ is the reference Møller-Plesset-type energy while $\epsilon_i$ is the state-specific zeroth-order energy of external CSF $q$. As with all studies of specific molecules with GVVPT2 since ca. 2005, semicanonical orbitals from the MCSCF are used. The mathematical robustness of GVVPT2 allows it to support both complete and incomplete model spaces. By construction, GVVPT2 is subspace-specific (N.B. excited states of the same symmetry as lower-lying states can be calculated) and is spin-adapted.

**Spin-Free Exact Two Component Method**

Matrix formulations of two-component relativistic methods have had significant successes in molecular electronic structure calculations, following Dyall’s seminal Normalized Elimination of Small Component (NESC) paper (Dyall, 1997) in 1997. For a summary of development of matrix two-component methods, we refer the reader to Ref. (Liu, 2014). In this work, we adopt the spin-free version of exact two component (sf-X2C) (Liu, 2010; Cheng and Gauss, 2011; Li et al., 2012; Li et al., 2013) that was previously used with GVVPT2 (Tamukong et al., 2014). The following Hamiltonian, written in second quantization form, incorporates scalar relativistic effects through the sf-X2C approach

$$H = \sum_{pq} \left[ h_{pq}^{X2C} a_{pq}^\dagger a_{pq} + \frac{1}{2} \sum_{pqrs} (pr|qs) a_{pq}^\dagger a_{rs}^\dagger a_{rs} a_{pq} \right]$$ (2)

where the first term is the one-electron spin-free part of the exact two-component (X2C) Hamiltonian, while the second is the unmodified Coulombic two-electron term. The sf-X2C Hamiltonian for positive energy states derives from a modified Dirac Hamiltonian, $h^D$ which is decomposed into spin-free (sf) and spin-dependent (sd) parts.

$$h^D = h^D_{\text{sf}} + h^D_{\text{sd}} = \left( \begin{array}{cc} V & T \\ T & \frac{\alpha^2}{4} W_{\text{sf}} - T \end{array} \right) + \left( \begin{array}{cc} 0 & 0 \\ 0 & \frac{\alpha^2}{4} W_{\text{sd}} \end{array} \right)$$ (3)

where $V$ is the matrix representation of the external nuclear attraction potential operator; $T$ is the matrix representation of the kinetic energy operator; $\alpha$ is the fine-structure constant; while $W$ is the matrix representation of the operator

$$W = \left( \vec{\sigma} \cdot \vec{p} \right) V \left( \vec{\sigma} \cdot \vec{p} \right) = \vec{p} \cdot V \vec{p} + i \vec{\sigma} \cdot \left( \vec{p} \times V \vec{p} \right) = W_{\text{sd}} + W_{\text{sf}}$$ (4)

The spin-free (sf) part of $W$, that is $W_{\text{sf}}$, describes scalar relativistic effects whereas the spin-dependent (sd) part, $W_{\text{sd}}$, incorporates spin-orbit coupling effects.

**Computational Details**

Unperturbed wavefunctions for GVVPT2 calculations were obtained from multiconfigurational self-consistent field (MCSCF) reference functions, using the local code “undmol.” The macroconfiguration approach (Khait et al., 2004) was used in all MCSCF and GVVPT2 calculations. In the macroconfiguration scheme, active orbitals are partitioned into orbital groups based on physical and mathematical intuition, such as orbital type or energy, and electrons are assigned to active orbital groups. Each
generates a unique set of configurations, and hence configuration state functions (CSFs) that are orthogonal to those of all other \(\kappa(n)\). Additionally, the macroconfiguration approach permits a large number of noninteracting electronic configuration pairs to be efficiently screened by recognizing that all matrix elements resulting from configurations that differ by more than two electrons must be identically zero. The macroconfiguration formalism also provides an efficient way of generating excited configurations.

In all calculations, the active space consisted of 3d and 4s-derived molecular orbitals (MOs) of \(\text{Ni}_2\) (Figure 1) shows representative 3d and 4s-derived MOs that were used to constitute the active spaces in this study). Depending on the specific state being investigated, some of the 3d-derived MOs and/or 4s-derived MOs were restricted to be doubly occupied in the MCSCF calculations, but were included with the 3s- and 3p-derived MOs in the active core and correlated at the GVVPT2 level of theory. For example, in all MCSCF calculations of \(\delta\delta\)–hole states the 3\(\delta\sigma\) and 3\(\delta\pi\) electrons were kept doubly occupied in MCSCF calculations of \(\pi\pi\)–hole states while only the 3\(\delta\sigma\) electrons were kept doubly occupied in MCSCF calculations of \(\sigma\delta\)–hole states, whereas the 4\(\sigma\), or 4\(\sigma\) + 3\(\delta\sigma\), or 4\(\sigma\) + 3\(\delta\pi\) orbitals were kept doubly occupied in MCSCF calculations of states within the \(3\Sigma^+\) and \(3\Sigma^+\) atomic couplings. In the present study, we indicate the positions of holes within the subspace of active 3d–derived MOs by specifying the active orbital types that qualitatively describe where holes exist (e.g., \(\delta\delta\), \(\delta\pi\), \(\pi\pi\), \(\pi\sigma\), \(\sigma\delta\), \(\sigma\pi\)) as did Shim et al. (Shim et al., 1979) and Noel et al. (Noell et al., 1980)

All \(\delta\delta\)–states were computed using a single reference macroconfiguration,

\[
\kappa_i(n) = \left(3d\delta^1_13d\delta^1_23d\delta^1_33d\delta^1_4\right)\left(4s\sigma^1_44s\sigma^1_2\right) \quad (5)
\]

where the superscripts denote the number of electrons in each orbital group. The semi-core 3s3p electrons were correlated together with those derived from 3d\(g\), 3d\(u\), and 3d\(g\) at the GVVPT2 level. For four of the computed \(\delta\delta\)–states, additional calculations were also performed in which the 3s3p were kept doubly occupied throughout (i.e., at both the MCSCF and GVVPT2 levels). When using the cc-pVTZ basis set, (Balabanov and Peterson, 2005) reference \(\kappa_i(n)\) generated 8 model and 27,891,120 total CSFs (in \(D_{2h}\) symmetry) for the \(1^2\Sigma^+_u\) and \(1^1\Sigma^+_u\) states; 8 model and 15,290,666 total space CSFs for the \(1^1\Sigma^+_u\), \(1^1\Sigma^+_g\), and \(1^1\Sigma^+_u\) states); 10 model and 27,982,592 all space CSFs for the \(1^1\Sigma^+_g\) and \(1^1\Sigma^+_u\) states; and 12 model versus 15,270,687 all space CSFs for the \(X^1\Gamma_g\) and \(1^1\Sigma^+_g\) states. Without correlating the 3s3p electrons at the GVVPT2 level, the dimensions were: 12 model space CSFs versus 3,593,707 total CSFs for the \(X^1\Gamma_g\) and \(1^1\Sigma^+_g\) states; and 8 model versus 6,434,550
all space CSFs for the $1^3\Sigma_u^+$ and $1^1\Gamma_u$ states. Relativistic calculations on the $X \ 1^1\Gamma_g$ and $1 \ 1^3\Sigma_u^+$ states utilized the same reference macroconfiguration, $\kappa_1(n)$. A $\delta\delta \ 3\Gamma_u$ state was computed with 4 active electrons in 4 orbitals using reference

$$\kappa_1(n) = \left(3d\delta_3 \cdot 3d\delta_3 \cdot 3d\delta_3 \cdot 3d\delta_3\right)^6\left(4s\sigma_4 \cdot 4s\sigma_4\right)^2$$

which gave rise to 4 model space and 7,518,688 all space CSFs, using the cc-pVTZ basis set. The $\pi\pi$–states were computed using reference

$$\kappa_2(n) = \left(3d\pi_3 \cdot 3d\pi_3 \cdot 3d\pi_3 \cdot 3d\pi_3\right)^6\left(4s\sigma_4 \cdot 4s\sigma_4\right)^2$$

which is similar to $\kappa_1(n)$ but with delta replaced with pi orbitals. This macroconfiguration gave rise to 12 model space and 7,518,688 all space CSFs, which is similar to $\kappa_1(n)$ but with delta replaced with pi orbitals. This macroconfiguration gave rise to 12 model space and 7,518,688 all space CSFs, when using the cc-pVTZ basis set.

$$\kappa_3(n) = \left(3d\delta_3 \cdot 3d\pi_3 \cdot 3d\pi_3 \cdot 3d\delta_3\right)^6\left(3d\pi_3 \cdot 3d\pi_3 \cdot 3d\pi_3 \cdot 3d\pi_3\right)^6$$

In these calculations, the 3s, 3p, 3d2, and 4s electrons were kept doubly occupied at the MCSCF level but correlated at the GVVPT2 level. Reference $\kappa_3(n)$ resulted in 40 model versus 20 model and 50,736,846 all space CSFs for the $1^3\Phi_g$ and $1^3\Pi_u$ states, using the closed-shell Hartree–Fock (HF) reference. At the GVVPT2 level, 3s, 3p, and all 3d and/or 4s electrons were correlated, whether they were or were not at the MCSCF level. For comparison purposes, a few of the GVVPT2 calculations were performed without correlating the 3s and 3p electrons. Calculations that accounted for scalar relativistic effects employed the sf-X2C method described above. Finally, to aid in interpretation, the effective bond order (EBO) was computed, and used the following expression

$$\eta = \frac{\sum_i c_i^2}{\sum c_i^2}$$

where $\eta$ is the EBO, $\chi_i$ is the EBO for the $i$th CSF, while $c_i^2$ is its corresponding weight. For each CSF used to estimate EBO, $\chi_i$ was determined as

$$\chi_i = \frac{1}{2} (n_b - n_{ab})$$

where $n_b$ and $n_{ab}$ are the numbers of bonding and antibonding electrons, respectively. Vibrational frequencies were obtained by 3-point finite differencing near the minima of the curves.

**RESULTS AND DISCUSSION**

Where indicated, the letter “R” in parentheses following a molecular term denotes that scalar relativistic effects were included in the calculations, while the expression “no 3s3p” in parentheses after a molecular term symbol denotes that 3s and 3p electrons were not correlated in GVVPT2 calculations.

**The $\delta\delta$–Hole States**

PECs of the $\delta\delta$–hole states are shown in Figure 2 and the data describing them are in Table 1. In agreement with results from other high level ab initio methods, the lowest states of Ni$_2$ were found to be $\delta\delta$–hole states of the $3\Sigma_d$ (3d$^9$4s$^1$) + $3\Sigma_d$ (3d$^8$4s$^2$) manifold. In particular, the ground state was found to be $X \ 1^1\Gamma_g$, with the $1^1\Sigma_g^+$ state lying only 16.40 cm$^{-1}$ (0.0028 eV) higher at the equilibrium geometry. After including scalar relativistic effects, the energy gap between these states slightly increased to 23.39 cm$^{-1}$ at equilibrium, with the $X \ 1^1\Gamma_g$ term having spectroscopic constants: $R_e = 2.20$ Å, $D_e = 1.95$ eV, and $\omega_c = 296$ cm$^{-1}$. These results are in good agreement with experimental
data ($R_e = 2.1545 \pm 0.0004$ Å, Cooper et al., 1972) $D_e = 2.042 \pm 0.002$ eV (Cooper et al., 1972) and $\omega_e = 280 \pm 20$ cm$^{-1}$) (Rösch and Rhodin 1974) and with the relativistic CASSCF/CASPT2 results of Pou-Amérgo et al. (Pou-Amérgo et al., 1994) who also found the lowest $^1\Gamma_g$ and $^1\Sigma_g^+$ terms to be quasidegenerate (with $R_e = 2.23$ Å, $D_e = 2.06$ eV, and $\omega_e = 293$ cm$^{-1}$ for the $^1\Gamma_g$ term). These results are also in good agreement with the time-delayed resonant two-photon ionization study of Morse and co-workers (Pinegar et al., 1995) that predicted either a $^3\Gamma_u$ or $^1\Sigma_g$ state as the ground state of Ni$_2$ and the scalar relativistic calculations of Cheskidov et al. (Cheskidov et al., 2012) who found the lowest $^1\Gamma_g$ and $^1\Sigma_g^+$ terms to be degenerate at the ACPF and NEVPT2 levels of theory and the

![Figure 2](image-url) PECs of low-lying electronic states of Ni$_2$ computed at the GVVPT2 level of theory using the cc-pVTZ basis set. All energies are plotted relative to the lowest energy value of the ground X $^1\Gamma_g$ term. For all states, the holes are in the 3d delta orbitals ($\delta\delta$–holes) except for $^1\Delta_g$ and $^2\Sigma_g^+$ states which are $\pi\pi$–hole states.

**TABLE 1** Equilibrium bond lengths, $R_e$ (Å), binding energies, $D_e$ (eV), harmonic frequencies, $\omega_e$ (cm$^{-1}$), and adiabatic transition energies, $T_e$ (cm$^{-1}$), of electronic states of Ni$_2$ calculated at the GVVPT2 level of theory using the cc-pVTZ basis set (or cc-pVTZ-DK for scalar relativistic calculations).

$^b$Ref. (Rösch and Rhodin, 1974).
\( \Sigma^+ \) term to lie very slightly lower than the \( \Gamma_g \) at the AQCC, MRCI, and MRCI + Q levels of theory. At 2.25 Å, we found the EBO to be 0.963 and 0.960 for the \( \Gamma_g \) and \( \Sigma^+ \) states, respectively (using the largest dozen CSFs). In relativistic GVVPT2 calculations, these EBOs increased slightly to 0.975 for \( \Gamma_g \) and 0.972 for \( \Sigma^+ \) at this geometry.

The major configurations describing the X \( \Gamma_g \) and \( \Sigma^+ \) states involved two holes in the same \( \delta \)-type; i.e.,

\[
0.445 \times (3d_{xy}\delta_{u}^{2} - 3d_{x^2-y^2}\delta_{g}^{2}) \quad 4s\sigma_{g}^{2} + 3d_{xy}\delta_{g}^{2} \quad 3d_{x^2-y^2}\delta_{g}^{2} \quad 3d_{x^2-y^2}\delta_{u}^{2}
\]

FIGURE 3 | PECs of low-lying \( \delta \)-hole electronic states of Ni\(_2\) computed at the GVVPT2 level of theory, with and without the correlation of 3s3p semi-core electrons, using the cc-pVTZ basis set. All energies are plotted relative to the lowest energy value of the ground X \( \Gamma_g \) term.

FIGURE 4 | PECs of the lowest-lying \( \delta \)-hole X \( \Gamma_g \) and \( \Sigma^+ \) states of Ni\(_2\) computed at the GVVPT2 level of theory, with and without scalar relativity included, using the cc-pVTZ (or cc-pVTZ-DK) basis set. 4s\sigma_u^2) and 0.077 \times (3d_{xy}\delta^2 3d_{xy}\delta_u - 2 3d_{x^2-y^2}\delta_u^2 4s\sigma_u^2 - 3d_{xy}\delta_u^2 3d_{x^2-y^2}\delta_u 2 3d_{x^2-y^2}\delta_u^2 4s\sigma_u^2 - 3d_{xy}\delta_u^2 3d_{x^2-y^2}\delta_u 2 3d_{x^2-y^2}\delta_u 4s\sigma_u^2), where coefficients are amplitudes and each term within parentheses denotes active orbitals of each leading CSF of the GVVPT2 wavefunction.

The semi-core 3s3p electrons were found to be important in the description of low-lying states of Ni₂. The inclusion of 3s3p electron correlation at the GVVPT2 level increased the binding energies by 0.09 eV for X₁Γ₁g 0.10 eV for 1Σ⁺u¹, and 0.09 eV for 1Σ⁺u² and 1Γ₁u states in non-relativistic calculations. As can be seen in Figure 3 and Table 1, the results of the 3s3p electrons on the equilibrium bond lengths and harmonic frequencies for these states are minimal whereas inclusion of such core-valence correlation raises, for example, the binding energy of X₁Γ₁g from 1.66 to 1.75 eV compared to a reference D₀ value of 2.042 ± 0.002 eV (Cooper et al., 1972). Scalar relativistic effects shortened the bond length of X₁Γ₁g by 0.06 Å and further increased the bond energy by 0.20 to 1.95 eV which agreed even better with the reference experimental values (see Figure 4 and Table 1). The 3s3p electrons did not have any effect on the EBOs of X₁Γ₁g and 1Σ⁺u¹; the EBOs were determined as 0.962 and 0.959 at 2.27 Å for X₁Γ₁g and 1Σ⁺u¹, respectively, when the 3s3p electrons were not correlated compared to 0.963 vs. 0.960 when the semi-core electrons (3s3p) were correlated. Note the quasidegeneracy in the X₁Γ₁g states was reported (Cheskidov et al., 2012) as lying 1238 cm⁻¹ above the ground state at equilibrium. The present results suggest that the 3d6 orbitals are indeed split in the bonding interaction. Since they are nondegenerate, the Aufbau principle suggests that energetically low-lying orbitals (the bonding 3d6 orbitals) be occupied before higher ones. Moreover, Hund’s rule suggests that orbitals with similar energies (in this case, 3dδπ⁺ orbitals) be singly occupied before electron pairing occurs. This seems to bring qualitative understanding into why the 13Γ₁g, 13Σ⁺u, and 11Γ₁u states in which the 3dδxy and 3dδx^2-y^2 are singly occupied lie energetically lower than the 21Γ₁u state for which the 3dδxy and 3dδx^2-y^2 are singly occupied.

The δπ-Hole and ππ-Hole States

The PECs of the computed ππ-hole states (1Δπg and 2Σ⁺u²) are shown in Figure 2, while those for the δπ-hole states (1Φp, 1Πp, 1Πu, and 1Φu) are shown in Figure 5 and compared with the ground state PEC. The data describing these curves are in Table 2. GVVPT2 predicted the ππ-hole states to lie higher in energy than the δπ-hole states, in agreement with previous studies (Ahmed and Nixon, 1979; Rasen et al., 1987; Russo et al., 1994). For all four δπ-hole states studied, the major CSFs involved a doubly occupied 4σg bonding orbital. Thus, the main configurations of the 1Φp and 1Πu states involved an unpaired spin-increasing electron in the 3dδ π subspace and an unpaired spin-decreasing electron in the 3dσ subspace, e.g., 3dδπ⁺ 3dδπ² 3dδπ⁻ 3dδπ⁺↑ 3dδπ⁻ 3dσu₂ 3dσu⁻↑ 3dσu₂ 3dσu⁻↑ 3dσu₂ 3dσu⁻↑ 3dσu₂ 3dσu⁻↑ 4σg², whereas the major configurations of the 1Πp and 1Πu states were similar to those of the corresponding singlet states but with two unpaired spin-increasing electrons: one in each of the 3dδ π and 3dσ subspaces, e.g., 3dδπ⁺ 3dδπ² 3dδπ⁻ 3dδπ⁺↑ 3dσu₂ 3dσu⁻↑ 3dσu₂ 3dσu⁻↑ 3dσu₂ 3dσu⁻↑ 3dσu₂ 3dσu⁻↑ 4σg².

At the equilibrium geometries, the EBOs were 0.930 for the singlet 1Φp and 1Ππg states and 0.933 for the 1Πp and 1Φg states. GVVPT2 predicted the four δπ-hole states to lie energetically in the order 1Φp < 1Πu < 1Πp < 1Φg, in agreement with the Ref. (Cheskidov et al., 2012) study at the scalar relativistic ACPE, AQCC, MRCI, and MRCI + Q levels of theory. However, our calculations found all three states considered in Ref. (Cheskidov et al., 2012) (i.e., 1Πp, 1Πu, and 1Φg) to lie some 500 cm⁻¹ closer to the ground state; e.g., at the scalar relativistic MRCI + Q level, the 1Φg state was reported (Cheskidov et al., 2012) as lying 1238 cm⁻¹ above the ground state at 2.5 Å while non-relativistic GVVPT2 calculations predicted this state to lie 546.76 cm⁻¹ above the ground state at equilibrium. Based on our observation that including scalar relativistic effects increased the energy gap between the 13Γ₁g and X₁Γ₁g states, it is likely that including
such effects in GVVPT2 calculations on the δπ–hole states might lead to increases in corresponding adiabatic transition energies. It is not anticipated, however, that such effects would lead to any change in the energy ordering of the states.

Although lying higher in energy than the δπ–hole states, the ππ–hole states were found to have slightly shorter bond lengths and larger bond strengths than the δπ–hole states. The 11Δg state was 0.06 Å shorter while the 21Σg+ state was 0.01 Å shorter in bond length than the δπ–hole states. At 2.24 Å, the EBOs of 11Δg and 21Σg+ were 1.108 and 1.084 respectively (computed with a dozen CSFs); these were slightly higher than the EBOs of all computed δδ–hole and δπ–hole Ni2 states. Near equilibrium, the major configurations of these ππ–hole states involved a doubly occupied 4sσg bonding orbital and a configuration of the 3dπ subspace that had the two π–holes in the same π–orbital; e.g., 3dπu2 3dπg2 3dπu2 3dπg0 4sσg2.

### States of the 3F4 + 3F4 and 3F4 + 3D3 Manifolds

Figure 6 contains PECs of states belonging to the 3F4 + 3F4 manifold. The data describing these curves are in Table 2. Irrespective of how the model space was partitioned into macroconfigurations [i.e., κn(n)], all such states were found to be van der Waals-like with interaction energies ≤0.04 eV. For example, near the equilibrium geometry (i.e., 3.77 Å), the 21Γg and 31Σg+ states had EBO of only 0.005, while the 15Φu and 15Πu states had EBOs of 0.003 and 0.00, respectively, at 3.84 Å. These latter quintet states were computed using reference κ7(n) and found to have the lowest total energies among the computed states of the 3F4 + 3F4 manifold; the 15Φu state is 3.312 cm⁻¹ less stable than the 15Φu state at equilibrium. The rest of the PECs in Figure 6 were plotted relative to the 15Φu PEC.

Lastly, the 11Δg and 21Δg states of the 3F4 + 3D3 manifold were investigated, at short bond lengths only, using reference

### Table 2

| Molecular term | Re (Å) | De (eV) | ωe (cm⁻¹) | Te (cm⁻¹) |

| States computed with κ14(n) | 15Δg | 2.22 | 249.1 | 5123.66 |
| States computed with κ15(n) | 25Δg | 2.54 | 150.1 | 9018.57 |
macroconfiguration $\kappa_8(n)$. The data for these states are included in Table 2. Whereas the $^3\text{F}_4$ (3d$^8$4s$^2$) $^3\text{F}_4$ (3d$^8$4s$^2$) states are van der Waals-like, the short bond length (2.22 Å) and high frequency (249.1 cm$^{-1}$) of the $^1\Delta_g$ state is suggestive of significant bonding interaction. At 2.22 Å, the major configuration for this state was $3d^{2}\delta_g^2 3d\pi^2 \delta_u^1 3d\pi_u^2 3d\pi^4 \delta_u^1 4s\sigma_g^2 4s\sigma_u^1$, contributing 50% by weight to the total wave function. At this geometry, the EBO was found to be 1.186. However, one should approach these results for $^3\text{F}_4 + ^3\text{D}_3$ derived states with some caution, as the macroconfiguration used cannot describe their dissociation limits.

CONCLUSION

The GVVPT2 method was used to study low-lying electronic states of Ni$_2$. The results indicate, in general, that bonding in these states involves predominantly the doubly occupied 4s$\sigma_g$ bonding orbital with the 3d–3d electrons pairwise spin coupled (e.g., consistent with antiferromagnetism). This statement is corroborated by EBOs that were found to be approximately 1.0 for most states studied and, moreover, states that did not allow this type of interaction [e.g., belonging to the $^3\text{F}_4$ (3d$^4$4s$^2$) $^3\text{F}_4$ (3d$^4$4s$^2$) manifold] were found to be bound only by weak polarization forces with bond orders close to zero. For computed states of the $^3\text{D}_3$ (3d$^4$4s$^1$) $^3\text{D}_1$ (3d$^4$4s$^1$) dissociation limit, all major configurations involved a doubly occupied 4s$\sigma_g$ bonding orbital and a vacant 4s$\sigma_u^*$ antibonding orbital. The energy ordering of the computed states of the $^3\text{D}_3$ (3d$^4$4s$^1$) $^3\text{D}_1$ (3d$^4$4s$^1$) manifold is in agreement with previous studies that found the $\delta\delta$–hole states to lie lowest in energy followed by the $\delta\pi$–hole and then the $\pi\pi$–hole states (Rasanen et al., 1987). For the investigated $\delta\delta$–hole states, the singlets were more stable than the triplet states at the GVVPT2 level of theory. As expected, based on previous GVVPT2 studies of transition metal dimers, all computed PECs are smooth and without unphysical artifacts (e.g., wiggles).

The ground state of Ni$_2$ was predicted as $X^1\Gamma_g$ in agreement with previous results from other high level ab initio methods (Cheskidov et al., 2012; Pou-Amérigo et al., 1994). The determined equilibrium spectroscopic constants of the $X^1\Gamma_g$ state, using a cc-pVTZ (or cc-pVTZ-DK) basis, were within the uncertainties of experimental results. The lowest $^1\Sigma_g^+$ state was found to be only 0.002 eV (16.40 cm$^{-1}$) higher than the ground state at the equilibrium geometry. Core-valence correlation was found to be important in the description of low-lying states of Ni$_2$ where the inclusion of 3s3p electron correlation at the GVVPT2 level was shown to improve harmonic frequencies and bond energies (e.g., by an increase of 7.5 cm$^{-1}$ in frequency and 0.09 eV in bond energy when 3s3p electron correlation was included in GVVPT2 calculations of the $X^1\Gamma_g$ state). Scalar relativistic effects were also shown to be important, especially for dissociation energy, where spectroscopic constants from relativistic calculations were predicted to agree better with reference data (e.g., a decrease of 0.06 Å in bond length, increase of 0.20 eV in bond energy, and an increase of 20.0 cm$^{-1}$ in harmonic frequency when including scalar relativistic effects in calculations of the $X^1\Gamma_g$ state). In our previous study (Tamukong et al., 2014) on electronic states of Y$_2$, Mn$_2$, and Tc$_2$, we did not find scalar relativistic effects to be as important for the Mn$_2$ molecule as they have proven to be in the present study. The inclusion of spin-orbit coupling effects was previously found (Cheskidov et al., 2012; Rasanen et al., 1987; Pou-Amérigo et al., 1994) to mix the low-lying states of Ni$_2$.
leading to a $^1g_3^1\Sigma_g^+(\delta \delta) + ^3\Sigma_g^-(\delta \delta)$ ground state. Since the two curves are close and nearly parallel for all internuclear separations in our study, we expect that including such effects after our scalar relativistic GVVPT2 treatment should lead to a similar mixing of states (i.e., and without change in spectroscopic constants).

The states investigated within the $^3\Sigma_g$ (3d$^4$4s$^2$) + $^3\Sigma_g$ (3d$^4$4s$^1$) manifold suggested significant bonding interaction, giving large harmonic frequencies and short bond lengths in comparison with states correlating with the $^3\Pi_g$ (3d$^4$4s$^2$) + $^3\Pi_g$ (3d$^4$4s$^1$) dissociation limit. Further work on Ni$_2$ should explore the $^3\Sigma_g$ (3d$^4$4s$^2$) + $^3\Sigma_g$ (3d$^4$4s$^1$) manifold more thoroughly, including possible expansion of the active space. It should be noted, however, that in the present study, we did not observe any significant electron excitations from the valence orbitals to 4p-dominated virtual orbitals. Also, while spin-free relativistic effects are noticeable (especially for bond dissociation energies), the parallelity and small energy separations for states in these manifolds are very similar to those in the $^3\Sigma_u$ (3d$^4$4s$^2$) + $^3\Sigma_u$ (3d$^4$4s$^1$) dissociation channel and, again, we do not expect that spin-dependent relativistic effects would change PECs appreciably, although current capabilities of our GVVPT2 code did not let us explore this.

In summary, the present study showed that Ni$_2$ does not form strong bonds with atomic configurations in which the 4s subshell is fully filled. This observation is consistent with other studies, by us and by others, of transition elements of the first row. Bonding in these systems is generally favored by atomic configurations that involve at least one of the participating atoms in an excited state (3d$^n$4s$^2$). For example, in our previous study (Tamukong et al., 2012) of the low-lying electronic states of Sc$_2$, Cr$_3$, and Mn$_2$, the lowest states of Sc$_2$ were shown to correlate with the $^2\Sigma_g^+$ (3d$^4$4s$^2$) + $^4\Sigma_g^-$ (3d$^4$4s$^1$) dissociation asymptote, while those of Cr$_2$ correlated with the $^2\Sigma_g^+$ (3d$^4$4s$^2$) + $^4\Sigma_g^-$ (3d$^4$4s$^1$) dissociation limit. However, bonding in transition metal dimers is subtle and the most stable states of Mn$_2$ were obtained from weakly coupled $^3\Sigma_g$ (3d$^4$4s$^2$) + $^3\Sigma_g$ (3d$^4$4s$^1$) ground state Mn atoms, similar to the $^2\Sigma_g^+$ (3d$^4$4s$^2$) + $^2\Sigma_g^+$ (3d$^4$4s$^1$) coupling of ground state Ni atoms. Our results provide further evidence that GVVPT2, with sf-X2C treatment of relativistic effects, predict electronic excitation and bond energy trends in the first row transition metals consistent with experiment and the highest level $ab$ initio calculations. In the present case, the quasidegeneracy of the $^3\Sigma_g$ and $^3\Sigma_u$ states of the Ni atom demonstrates that GVVPT2 can successfully be used for a system with an extraordinarily dense manifold of states, which generally requires computationally intensive variational treatments.

**DATA AVAILABILITY STATEMENT**

The raw data supporting the conclusions of this article will be made available by the authors, without undue reservation.

**AUTHOR CONTRIBUTIONS**

MH and PT contributed to conception and design of the study. PT performed numerical calculations. MH and PT interpreted data and organized presentation. PT wrote the first draft of the manuscript. All authors contributed to manuscript revision, read, and approved the submitted version.

**FUNDING**

The authors gratefully acknowledge the National Science Foundation (Grant No. EPS 0814442) for the financial support under which the project was started, and to North Dakota EPSCoR for support in later stages.
