Abstract

Storage oil breakdown plays an important role in the life cycle of many plants by providing the carbon skeletons that support seedling growth immediately following germination. 1-Butanol, a specific inhibitor of phospholipase D (PLD)-dependent production of the signalling molecule phosphatidic acid (PA), inhibited Arabidopsis seed germination. N-Acylethanolamines (NAEs), which have been shown to inhibit PLD activity, have no effect on seed germination. However, mobilization profile of triacylglycerols (TAG) that induced by each compound has not been reported. To gain deeper insights into the mode of mobilization of TAG during NAE 12:0 or 1-butanol treatment, we conducted a detailed comparative analysis of the effect of NAE 12:0, DMSO, 1-butanol and tert-butanol on Arabidopsis seed germination and fatty acid composition, tert-butanol and DMSO served as the corresponding controls treatment respectively. Our data show that 1-butanol, but not the inactive tert-butanol isomer, inhibited Arabidopsis seed germination, which is accompanied by a with retardation of the mobilization of triacylglycerols (TAG). In contrast, NAE 12:0 did not affect mobilization of TAG, nor did it significantly delay seed germination as monitored by radicle and cotyledon emergence. 1-Butanol induced RNA degradation in seeds and seedlings. We speculate that the large-scale degradation of RNA under the induction of 1-butanol may lead to abnormal gene expression in genes necessary for seed germination, including the genes needed for the mobilization of oil bodies, and thus cause a delay of seed germination. To the best of our knowledge, we report for the first time that 1-butanol delays the mobilization of TAG.

1. Introduction

Plant synthesize fatty acids and store them as triacylglycerols (TAG) in seeds which subsequently utilize TAGs during seed germination and early seedling development for energy before seedlings are fully established and photosynthetically sustainable (Murphy, 1993; Quettier and Eastmond, 2009). In plant cells, TAGs are stored in a specialized intracellular organelle-like structure called oleosomes, or oil bodies, that are surrounded by a monolayer of phospholipids containing embedded proteins that stabilize their structures (Murphy, 1993). Mobilization of TAGs is initiated by the activity of seedling-specific TAG lipases which liberate fatty acids from TAG molecules. The free fatty acids can then be converted to acetyl-CoA units, which are the precursors of sugar synthesis, via the β-oxidation cycle in the peroxisome (Bradford, 1997; Kepczynski and Kepczynska, 1997). More than 200 unique fatty acids have been identified in plant species (Kelly, Quettier et al., 2011). These fatty acids are classified according to chain length, number of carbon atoms, type and arrangement of unsaturated bonds, and presence of functional groups (Badami and Patil, 1980; Quettier and Eastmond, 2009). This huge structural diversity means that seed oils often consist of a wide range of TAG species with different fatty acid combinations (Fatima, Snyder et al., 2012). Depending on the rate of water uptake, the time course of germination and subsequent growth is divided into three phases. In phase I, which is also called imbibition, water uptake is rapid; in phase II, water uptake is much slower and reaches a plateau; in phase III, water uptake increases (Bewley, 1997; Weitbrecht, Muller...
et al., 2011). During the germination process, membrane reorganization is an important event (Verkleij, Demaagd et al., 1982; Ishibashi, Koda et al., 2013). During phase III, phosphatidyglycerol (PG) levels increase after seeds have germinated for one to three days at 25 °C; at the same time, both monogalactosyldiacylglycerol (MGDG) and digalactosyldiacylglycerol (DGDG) levels increase considerably. Taken together, these changes in phospholipids levels indicate that plastid biogenesis is achieved during this phase of germination. During this same phase, phosphatidic acid (PA) has been found to have the same level as in the membranes of non-germination cells. In contrast, phosphatidylinositol (PI) levels increase first day after the beginning of imbibition and subsequently decrease to background levels by day 3 (Yu, Li et al., 2015). The hydrolysis of PC and PE which are catalyzed by PLD to lysophosphatidylethanolamine (lysoPC) disturbs the membrane structure, inducing the release of TAG from oil bodies, which is used as the source of energy for germination (Parthibane, Iyappan et al., 2012).

1-Butanol specifically stimulates PLD and functions as a transphosphatidylolation substrate; tert-butanol, however, does not have the same effect (Munnik, Arisz et al., 1995). N-Acylethanolamines (NAEs) are fatty acid amides that are derived from an N-acylated phosphatidylethanolamine precursor, a minor membrane lipid constituent of plant and animal cells (Hayes, Stupak et al., 2013). Although these fatty acid amides have been identified and quantified in plant tissues, their significance and precise function in plant cells remains to be elucidated. NAE 12:0, a naturally occurring NAE in plants is a specific inhibitor of PLDα1 activity (Motes, Pechter et al., 2005; Jia, Tao et al., 2013). Seed germination is regulated by numerous chemicals derived from a multitude of metabolic pathways (Motes, Pechter et al., 2005; Zheng, Jia et al., 2012; Blancaflor, Kilaru et al., 2014). NAE 12:0 has a profound influence on Arabidopsis root cell development and early seedling growth. 1-Butanol, an antagonist of PLD-dependent PA production, was reported to induce defects in Arabidopsis by seedling development that were somewhat similar to effects induced by elevated levels of NAE. However, although 1-butanol and NAE 12:0 inhibit Arabidopsis seedling development, the severity, quality, and concentrations needed to invoke distinct cellular and developmental effects have been shown to be different between the two compounds. For example, 1-butanol, but not the inactive tert-butanol isomer, has been shown to inhibit Arabidopsis seed germination (Gardner et al., 2003). In contrast, NAE 12:0 up to 500 μM did not significantly delay seed germination as monitored by radicle and cotyledon emergence (Gardner, Collings et al., 2003; Motes, Pechter et al., 2005).

Seed storage oil metabolism is important for germination or seedling establishment in Arabidopsis (Quettier and Eastmond, 2009). Since NAE and 1-butanol appear to modulate PLD activity in vitro, and induce different effects on seed germination (Dhonukshe, Laxalt et al., 2003; Motes, Pechter et al., 2005), both compounds may induce different processes of TAG metabolism. To gain deeper insights into the mode of mobilization of TAG during NAE 12:0 or 1-butanol treatment, we conducted a detailed comparative analysis of the effect of NAE 12:0, DMSO, 1-butanol, and tert-butanol on Arabidopsis seed germination and fatty acid composition. Our data show that NAE and 1-butanol invoke different effects on mobilization of TAG and fatty acid composition as well as seed germination. 1-butanol induced the degradation of RNA in seeds and seedlings. Based on this result, we speculate that the large-scale degradation of RNA under the induction of 1-butanol may lead to a lack of normal expression of most of the genes needed for seed germination, including the genes needed for the mobilization of oil bodies, thus causing the delay of seed germination. To the best of our knowledge, we report for the first time that 1-butanol delays the mobilization of TAG.

2. Materials and methods

2.1. Plant materials and growth conditions

Seeds of Arabidopsis thaliana L. Heynh (ecotype Columbia) were sterilized for 2 min in 95% ethanol, 2 min in 5% bleach and then rinsed three times in sterile deionized water. The Arabidopsis seedlings used to detect the oil bodies with confocal laser scanning microscopy were planted in growth media consisting of MS salts supplemented with micronutrients, 0.05% morpholineethanesulfonic acid, 0.01% myo-inositol and 0.004 M each of pyridoxine, nicotinic acid, and thiamine. After adjusting the pH to 5.7, the media containing growth media supplemented with NAE 12:0, 1-butanol, tert-butanol, and the equivalent volume of dimethyl sulfoxide (DMSO) (used as a solvent for NAE) was poured onto plates (9 × 9 cm). For seed germination assays and fatty acid assays, seeds were planted in plates on filter paper floated on either sterile deionized water or water supplemented with NAE 12:0, 1-butanol, tert-butanol, or the equivalent volume of DMSO. DMSO and tert-butanol served as controls treatments (Blancaflor, Hou et al., 2003; Gardiner, Collings et al., 2003). After planting, plates were wrapped in aluminum foil and incubated at 48 h at 4 °C. The aluminum foil was then removed and plates were transferred to a room with a photoperiod of 12 h light (120 mol/s m²) and 12 h dark. Phenotype at 1, 3, and 5 days after removal from cold was observed using an Olympus SZ 61 stereomicroscope.

2.2. Confocal microscopy

To visually detect neutral lipids, seedlings (aged 1, 3–5 days) grown under 12-h-light/12-h-dark cycles were infiltrated with an aqueous solution of Nile Red (Sigma) (Siloto, Findlay et al., 2006). Images were obtained with a 100 × oil objective by confocal laser scanning microscopy using an Olympus FV 1000 system equipped with argon as an excitation source. Fluorescence was excited at 515 nm and collected with a 539–653 nm filter.

2.3. Lipid extraction and fatty acid methyl ester preparation

Approximately 50 mg of seeds of each sample (n = four independent replicates) were placed in a hexane-washed, hand-held, group-glass homogenizer and boiled in 1 mL of isopropanol (80 °C) for 10 min. The seeds were then cooled on ice for 5 min. Thereafter, 1 mL of hexane and 2 mL of 3:2 hexane/isopropanol (H/P) was added and the seeds were homogenized until completely pulverized. An additional 2 mL of 3:2 H/P was added and grinding continued. The homogenate was transferred to a screw-capped glass tube, and 2 mL of 3.3% (W/V) Na2SO4 was added, capped, and shaken for 2 min. The tubes were spun at 555 g for 2 min, and the upper organic phase was transferred to a new hexane-washed screw-capped tube. The aqueous phase was re-extracted with 4 mL of 7:2 H/P, capped, and shaken for 2 min. The tubes were spun again at 555 g for 2 min, and the upper organic phase added with the first extracted organic phase. The combined organic phases were evaporated to dryness in a heating block (37 °C) under a gentle N2 stream. To isolate fatty acid methyl esters (FAMES), 1.2 mL of HCl-methanol (1.5 M HCl in methanol made fresh) was added to the dried lipid and incubated at 100 °C for 1 h. Then, 1 mL of double distilled water was added to quench the transesterification reaction. The FAMES were then extracted with 2 mL of hexane. The samples were centrifuged as above and the upper organic phase
containing the FAMEs transferred to a clean hexane-washed test tube. The aqueous phase was re-extracted with an additional 2 mL of hexane and centrifuged and the resulting upper phase transferred and combined with the previously collected organic phase. The combined organic phases containing the FAMEs were then dried down completely in 1 mL of hexane and transferred to gas chromatography vials and capped.

2.4. Data analysis

Statistical analysis was performed using Origin 7.0 (Origin Lab Corporation, Northampton, MA, USA). For all quantitative measurements in this study, five replicates from each sampling time were analysed. The data were subjected to one-way ANOVA analysis of variance with SPSS 16.0.

3. Results

3.1. 1-Butanol, but not NAE12:0, retains oil bodies

Oil bodies have been shown to release TAG to supply energy for seed germination and seedling establishment (Quettier and Eastmond, 2009). To visualize oil bodies in Arabidopsis seedlings, we stained Arabidopsis seeds germinated on wet filters containing 1-butanol, NAE 12:0, or their corresponding controls (DMSO and tert-butanol) with Nile Red during seedling growth from days 1–5 after imbibition (Fig. 1A). Confocal laser microscopy revealed the presence of red-stained spherical inclusions in seeds, which represent oil body accumulation. The oil bodies of seeds planted in NAE 12:0 were not significantly different from the oil bodies of seeds planted in plates water, DMSO, or tert-butanol. The number of oil bodies had substantially declined by day 2 and very few were...
evident by day 4 or 5 (Fig. 1A). In seeds treated with 1-butanol, oil bodies did not show any obvious change until day 4, and oil bodies were no longer evident by day 5, although by that point the radicle had emerged and the chloroplast had been formed (Fig. 1B, C). These results indicate that the NAE 12:0 did not affect the metabolism of oil bodies nor affect seed germination. Furthermore, these results suggest that the inhibition of seed germination by 1-butanol might be related to the inhibition of oil body metabolism.

3.2. Total TAG accumulates in Arabidopsis seedlings treated with 1-butanol

In plant seeds, TAG is the major storage lipid in oil bodies and functions as a critical energy reserve during germination and seedling establishment (Bradford, 1997). The differential accumulation of oil bodies by 1-butanol-treated seedlings prompted us to investigate whether oil body accumulation coincided with changes in TAG content. We used gas chromatography-mass spectrometry (GC-MS) to analyze TAG content in dry seeds and seedlings treated with 1-butanol, NAE 12:0, tert-butanol, and water. One day after germination, no significant change in TAG content of seedlings incubated in the four treatments were detected relative to the content in dry seeds. At day 3, the TAG content of seedlings treated with water, DMSO, NAE 12:0, and tert-butanol decreased significantly in comparison to that at day 1, while the TAG content of seedlings from the four treatment did not show obvious differences. Compared to dry seeds, TAG content five days after imbibition decreased in seedlings treated with water (28.49%), NAE 12:0 (31.59%), DMSO (27.26%), and tert-butanol (27.54%). In contrast, after 1-butanol incubation for 1 and 3 days, TAG content of decreased to 58.47% in comparison to that of dry seeds (Fig. 2). TAG degradation may provide energy for post-germinative growth. These results indicate that TAG content coincided with that of oil bodies detected by confocal laser scanning microscopy.

3.3. NAE12:0, tert-butanol, and DMSO had no effect on fatty acid degradation

Oil breakdown is initiated during lipolysis when TAG in oil bodies is hydrolyzed to free fatty acids (FA) and glycerol (Quettier and Eastmond, 2009; Fatima, Snyder et al., 2012). We identified changes in FA content were identified among dry seeds and seedlings exposed to water, DMSO, NAE 12:0, 1-butanol and tert-butanol (Fig. 3).

The total FA content of seedlings exposed to water, NAE and DMSO increased at day 1 in comparison to dry seeds, and then declined rapidly at day 3, and day 5, and declined to 12.01%, 19.69%, and 18.54%, respectively. These results indicate that during the early stages of germination, the FAs released from stored TAGs to provide carbon and metabolic energy for seedling development. Meanwhile, there were no obvious differences detected in the FA content of seedlings incubated in water, NAE, or DMSO. In 1- and 3-day-old seedlings, the total FAs content of seedlings exposed to 1-butanol showed a slight increase in contrast to dry seeds, whereas the content of FAs clearly increased at day 5, especially molecular species 16:0, 18:2, 18:3, 20:1 (ω-9) (Fig. 4). When compared with 1-butanol of the same concentration, the tert-butanol seedlings did not show considerable differences in overall fatty acid profiles in TAG with water treatment. These results indicated that 1-butanol delayed seed germination at the same time at FA degradation delayed (See Fig. 5).

3.4. Fatty acid composition of TAGs in seedlings exposed to 1-butanol remained unchanged during germination

Previously studies have shown that in seed oil, linoleic acid (18:2) and α-linolenic acid (18:3) accounted for roughly equal proportions of the total composition, at 28.32–29.98% and 29.68–32.46%, respectively. Eicosenoic acid (20:1ω-7) content was 17.47%–18.01%, followed by palmitic acid (16:0) at 8.46–8.76%. Oleic acid (18:1), palmitoleic acid (16:1), stearic acid (18:0), eicosenoic acid’s isomer (20:1ω-9), 16:3, 20:2 and 22:1 were each present at < 4% of the total fatty acids (Fatima, Snyder et al., 2012).

We next asked whether 1-butanol and NAE12:0 exert differential effects on fatty acid composition. There was little variation...
among the seedlings incubated in water, DMSO, NAE12:0, or tert-butanol in the fatty acid compositions of the seed oils. Compared to dry seeds, all fatty acid species in seeds incubated in water, DMSO, NAE12:0, tert-butanol for 1 and 3 days remained unchanged; fatty acid molecular species palmitic acid (16:0), 16:3 and 18:3 increased, and molecular species 18:2, 20:0, and 20:1 (ω-9) decreased at day 5. In comparison to seedlings exposed to water, seedlings incubated in 1-butanol showed no obvious change over the 5-day observation period. These results suggest that the stage of seed germination is a main controlling factor in fatty acid composition.

4. Discussion

NAE and 1-butanol appear to modulate PLD activity in vitro and induce somewhat similar effects on seedling development (Austin-Brown and Chapman, 2002). NAE 12:0 and 1-butanol have been shown to have different effect on hypocotyl length, cotyledon area, first true leaf formation, and pattern of root swelling. NAE 12:0 is a more potent regulator of cellular organization, which in contrast to 1-butanol, translates into more profound effects on seedling morphology at micromolar concentrations. The differential effects
of 1-butanol and NAE 12:0 on seedling morphology and cellular architecture are due in part to the differential modulation of specific PLD isoforms (Blancaflor, Hou et al., 2003; Gardiner, Collings et al., 2003; Motes, Pechter et al., 2005). 1-Butanol has been used by many researchers as a nonselective “inhibitor” of PLD action, because it blocks the transphosphatidylolation reaction catalyzed by all PLD isoforms. NAE on the other hand is more specific, potently inhibiting PLD2, but not the PLD β, γ, or δ isoforms (Austin-Brown and Chapman, 2002; Dhonukshe, Laxalt et al., 2003; Jia, Tao et al., 2013; Yu, Li et al., 2015; Chen, Yu et al., 2017). Given previous reports, although both NAE 12:0 and 1-butanol were known as antagonist of PLD activity, there were distinct effects on seed germination. Because NAEs are abundant in desiccated seeds and are rapidly hydrolyzed during seed imbibition and germination (Chapman, 2004), it is not surprising that NAE 12:0 does not inhibit seed germination. The lowest concentration of 1-butanol that has been found to induce a delay in seed germination is 0.025% (Austin-Brown and Chapman, 2002; Motes, Pechter et al., 2005).

When seeds germinate, the TAGs are degraded in order to produce a carbon sources that will fuel the embryo’s post-germinative growth and allow it to become a photosynthetically active seedling with a root system and leaves (Quettier and Eastmond, 2009). In the present study, we show that 1-butanol, but not the inactive tert-butanol isomer, inhibited Arabidopsis seed germination, and that inhibition is accompanied by a retardation in the mobilization of TAG (Figs. 1–3). In contrast, NAE 12:0 did not affect mobilization of TAG, nor did it significantly delay seed germination as monitored by radicle and cotyledon emergence. In ungerminated seeds, oil bodies are composed of TAGs which are surrounded by a monolayer of phospholipids containing two kinds of embedded proteins, oleosin and calceolin. The analysis of changes in oil bodies and in the composition of oil storage at different germinating stages showed that oil degradation is progressive. The first step is the loss of oil body membrane integrity. There may be two reactions at the same time or one after the other, causing the disintegration of the oil body membrane. First, the cytoplasmic domain of oleosin, which is used as the structural protein of the oil body membrane, is hydrolyzed (Yang, Yu et al., 2011; Parthibane, Iyappan et al., 2012; Shrestha, Callahan et al., 2016); second, phospholipid of the oil body membrane are degraded, which may require PLD. After the disintegration of the oil body membrane, the TAG is exposed to TAG lipase and releases fatty acids (Quettier and Eastmond, 2009; Parthibane, Iyappan et al., 2012). At the early stage of seed germination, a series of newly synthesized proteins (at least 3 new proteins, lipoxigenase, phospholipase and TAG lipase) can be detected on the phospholipid monolayer when the oil body begins to degrade (Hilhorst and Toorop, 1997; Hsiao, Haslam et al., 2014). The newly synthesized proteins begin mobilization of the stored TAG. Mobilization of TAG is initiated by the activity of seedling-specific TAG lipases which liberate fatty acids from TAG molecules. 1-Butanol has been reported as an antagonist of PLD-dependent phosphatidic acid production, and NAE has been shown to inhibit PLD activity. The inhibition of PLD-mediated PA formation through application of 1-butanol or NAE alleviates imbibitional chilling injury in cucumber and pea seeds (Yu, Li et al., 2015) and increases desiccation tolerance in recalcitrant seeds. However, the specific and functional reorganization of lipid composition during germination occur on cell membranes (Chen, Yu et al., 2017). Furthermore, when PLDδ1 and δ are suppressed, the germination level remained unchanged relative to wild type Arabidopsis. These findings indicated that the retardation of mobilization by 1-butanol is not relative to the inhibition of PLD activity. Based on these results, we propose that 1-butanol inhibition of the mobilization of TAGs may affect activity of the TAG lipases. In recent years, a number of lipases have been cloned and characterized from plants, such as AtDADI (Yu, Zhu et al., 2006), SDP1, SDP 2, and SDP 3 (Cotter, Teaster et al., 2011; Yang, Yu et al., 2011; Shrestha, Callahan et al., 2016; Lunn, Wallis et al., 2017). We attempted to determine the expression pattern of these genes in seeds or seedlings incubated in 1-butanol, NAE, DMSO, tert-butanol, and water; however, RNA of the seeds incubated in 1-butanol is extremely degraded, therefore it was not possible to extract intact RNA that could be used for downstream gene expression detection. Based on this experimental result, we speculate that the large-scale degradation of RNA after 1-butanol treatment may lead to the lack of normal expression of most of the necessary genes for seed germination, including the genes needed for the mobilization of oil bodies, thus causing the delay of seed germination. Therefore, other techniques may be needed to verify the effect of 1-butanol on the expression of genes involved in seed germination.
