From inherent structures to pure states: some simple remarks and examples.

Giulio Biroli and Rémi Monasson  
Laboratoire de Physique Théorique de l’Ecole Normale Supérieure*,  
24 rue Lhomond, 75231 Paris cedex 05, France.

The notions of pure states and inherent structures, i.e. stable configurations against 1-spin flip are discussed. We explain why these different concepts accidentally coincide in mean-field models with infinite connectivity and present an exactly solvable one dimensional model where they do not. At zero temperature pure states are to some extent related to k-spin flip stable configurations with \( k \to \infty \) after the thermodynamical limit has been taken. This relationship is supported by an explicit analysis of the TAP equations and calculation of the number of pure states and k-spin flips stable configurations in a mean-field model with finite couplings. Finally we discuss the relevance of the concepts of pure states and inherent structures in finite dimensional glassy systems.

I. INTRODUCTION

In a series of seminal papers, Kirkpatrick, Thirumalai and Wolynes (KTW) suggested ten years ago that (discontinuous) mean-field spin glasses could serve as a paradigm for vitreous systems \( \Box \). The major success of KTW theory lies in its ability to predict the existence of both low (Kauzmann) and high (dynamical freezing) temperature critical points and thus to describe in a unified framework the thermodynamical and dynamical signatures of the glassy transition \( \Box \). This achievement relies on a simple but rich picture of glassy pure states (PS), that is local minima in the free-energy landscape, and of the dynamical evolution taking place in the latter. To what extent KTW mean-field picture applies to real systems is a crucial issue \( \Box \).

An apparently related approach based on the investigation of the potential energy landscape and of its local minima called inherent structures (IS) had been already proposed at the beginning of the eighties by Stillinger and Weber in the context of liquid theory \( \Box \). IS present a considerable advantage with respect to PS: they are well defined and free of any mean-field hallmark. Recently, numerical studies proposing that some understanding of the glass transition could be gained from the analysis of potential energy landscapes \( \Box \) strengthened the feeling that Stillinger and Weber’s analysis and KTW theory were basically the same description of glassy systems. This point of view was later supported by the equivalence of IS and PS in some mean-field spin-glasses, e.g. Sherrington-Kirkpatrick (SK) or p-spins models \( \Box \) and by analytical works \( \Box \).

In this letter, we present some arguments to clarify the relationship between IS and PS. We present some one dimensional models for which IS can be exactly computed and do not coincide with PS. We show in addition that the degeneracy between IS and PS in infinitely-connected models is due to the vanishing of the interactions in the thermodynamical limit and is lifted by the introduction of finite couplings. Focusing on the TAP equations “defining” IS and the number of the latters, we show that zero temperature PS are related to extended IS, that is configurations stable with respect to an arbitrary large number \( k \) of spin flips (and not only to a single one as usual IS) \( \Box \).

II. DEFINITIONS AND NOTATIONS

We consider a model including \( N \) Ising spins \( S_i \). A configuration of spins will be said \( k \)-stable if its energy cannot be decreased by flipping any subset of \( k \) (or less than \( k \)) spins. Let us call \( s_k(e) \) the logarithm (divided by \( N \)) of the number of \( k \)-stable configurations with energy density \( e - e_{GS} \) with respect to the ground state energy density \( e_{GS} \) when \( N \to \infty \). IS correspond to 1-stable configurations and \( s_1(e) \) is usually called configurational entropy. We have of course \( s_{k+1}(e) \leq s_k(e) \) and \( s_k(e) = -\infty \) for \( e < e_{GS} \).

The notion of PS is much trickier. In mean-field systems PS are usually defined through TAP equations \( \Box \) for the local magnetisations \( m_i \). TAP solutions are exponentially numerous in the volume \( N \) and can be accounted for through the so-called complexity \( \sigma(f) \), that is the normalised logarithm of PS having free-energy densities \( f \). We shall focus in the following on the zero temperature limit of the complexity \( \sigma(e) \) and compare it to \( s_k(e) \).

We shall denote hereafter the maximum over \( e \) of \( s_k(e) \) (respectively \( \sigma(e) \)) by \( s_k \) (resp. \( \sigma \)).

*Unité Mixte de Recherche du Centre National de la Recherche Scientifique et de l’Ecole Normale Supérieure.
III. ONE DIMENSIONAL DISORDERED CHAIN

We first consider a Ising chain with disordered nearest neighbour couplings $L_i$ and no external field [11]. The $L_i$s are independent random variables drawn from an even distribution $P(L)$. No phase transition can take place at finite temperature: there is only one paramagnetic PS [11]. Therefore, the zero temperature limit of the complexity simply reads $\sigma(e) = 0$ if $e = e_{GS}$, $\sigma(e) = -\infty$ if $e \neq e_{GS}$ where the ground state energy density equals $e_{GS} = -\int dLP(L)|L|$. Ettelaie and Moore have calculated $s_1(e)$ [12]. We extend their approach to obtain $s_k(e)$ using the following observation by Li: a necessary and sufficient condition for a configuration to be $k$-stable is that each frustrated bond be $k$-weak, i.e. smaller in magnitude than the $2k$ nearest bonds ($k$ on the left, $k$ on the right) on the chain [13]. The typical and self-averaging $s_k(e)$ thus reads

$$s_k(e) = \lim_{N \to \infty} \frac{1}{N} \ln \left( \sum_{\{\tau_{\ell} = 0,1\}} \delta \left( e - e_{GS} - \frac{2}{N} \sum_{\ell=1}^{N_k} |L_{\ell}| \tau_{\ell} \right) \right),$$

where $N_k$ is the number of $k$-weak bonds on the chain and $\tau_{\ell}$ equals 1 if the $\ell^{th}$ $k$-weak bond is frustrated, 0 otherwise. Using an integral representation of the delta function in (1), the $\tau_{\ell}$’s may be traced over and one finds

$$s_k(e) = \lim_{N \to \infty} \frac{1}{N} \ln \left\{ \int_{-\infty}^{+\infty} \frac{du}{2\pi N i} \exp \left( u(e - e_{GS}) - 2 \int_{0}^{+\infty} dL \ P_k(L) \ln(1+e^{2Lu}) \right) \right\}.$$

where $P_k(L) = P(L)(2\int_{|L|}^{\infty} dL' \ P(L'))^{2k}$ denotes the probability that a bond is $k$-weak and has value $L$. The integral over $u$ can be evaluated by the method of steepest descent. In fig.1, $s_k(e)$ is plotted for a Gaussian $P(L)$ (with variance unity) and for different values of $k$. At fixed $k$, $s_k(e)$ is symmetric around its maximum located in $e_k = e_{GS} + \int dLP_k(L)|L|$, $s_k = \ln 2/(2k + 1)$. Note that the height of the maximum $s_k$, related to the total number of $k$-stable configurations is independent of $P$ as found by Li [13]. On the left boundary, all curves exhibit an infinite slope when $e \to e_{GS}$. More precisely, $s_k(e_{GS} + \varepsilon) \propto -\varepsilon \ln \varepsilon$ if the support of $P(L)$ does not contain $L = 0$ and $s_k(e_{GS} + \varepsilon) \propto \varepsilon^{(\alpha+1)/(\alpha+2)}$ if $P(L) \propto L^\alpha$ when $L \to 0$ (with $\alpha > -2$ to make $e_{GS}$ finite).

![FIG. 1. Logarithm of the number of $k$-stable configurations $s_k(e)$ as a function of the excess of energy density $e - e_{GS}$ for a Gaussian coupling distribution $P(L)$ (with variance unity and zero mean). From top to bottom: $k = 1, 2, 3, 4, 5$.](image)

The above model is a clear example of a system with many IS and at the same time a single PS. More precisely, the zero temperature limit of the complexity $\sigma(e)$ (related to PS) is not equal to the configurational entropy $s_1(e)$ counting IS but to $s_\infty(e)$. Before exposing why $s_1$ and $\sigma$ accidentally coincide in infinitely connected spin-glasses, let us briefly see to what extent the above results apply to generic finite dimensional systems.

IV. GENERAL REMARKS FOR FINITE DIMENSIONAL SYSTEMS

The main features of $s_k(e)$ can be found by some general arguments which apply to any finite dimensional system. The behaviour of $s_1(e_{GS} + \varepsilon)$ at small $\varepsilon$ has been predicted in [4,17] and depends only on the lowest-lying excitations
of the system. In addition, the scaling of the right-edge energy $2e_k - e_{GS}$ at which $s_k(e)$ vanishes can be understood by a simple energy balance argument. Flipping a cluster of $k$ spins among a configuration with energy density $e$, one may gain a bulk energy $E_b(k) \sim -k(e - e_{GS})$ and loose at least some surface energy $E_s(k)$. As a consequence, $k$-stable configurations with energy densities higher than $e_{GS} + E_s(k)/k$ should not exist. For 1-D Ising disordered chain, $E_s(k)$ is equal to the average magnitude of the smallest bond among $k$ ones and can be easily computed. As expected $E_s(k)/k \sim e_k - e_{GS}$ for large $k$. Let us emphasise that the previous argument implies that there cannot be infinite stable configurations (after the thermodynamical limit has been taken) with energy densities differing from the ground state one: $s_{\infty}(e \neq e_{GS}) = -\infty$.

**V. MEAN-FIELD SPIN-GLASSES WITH INFINITE CONNECTIVITY**

It is well known that the zero temperature limit of the complexity equals the configurational entropy in infinite connectivity spin-glasses [10]. For instance in the case of the SK model,

$$\sigma^{SK} = s_1^{SK} = \max z \left\{ -\frac{z^2}{2} + \ln 2 \int_{-z}^{+\infty} Dy \right\} \simeq 0.1992$$

(3)

with $Dy = e^{-y^2/2}/\sqrt{2\pi}$ dy [17][18]. The equivalence between TAP solutions at zero temperature and 1-stable configurations (IS) is a straightforward consequence of the vanishing of couplings in the thermodynamical limit. The scaling of the couplings $J_{ij}$ with size $N$ ensures that the excitation energy $\Delta E_i$, corresponding to flipping spin $i$ remains finite in the thermodynamical limit, e.g. $J_{ij} = O(1/\sqrt{N})$ for the SK model. As a consequence the excitation energy $\Delta E_{ij} = \Delta E_i + \Delta E_j - 2J_{ij}S_iS_j$ corresponding to flipping both spins $i$ and $j$ reduces to $\Delta E_i + \Delta E_j$ in the large $N$ limit. For infinite connectivity models IS are also $k$-stable configurations for every finite $k$. Therefore, $s_k(e)$ does not depend on $k$ and $s_1 = \ldots = s_{\infty} = \sigma$.

**VI. TAP SOLUTIONS AT ZERO TEMPERATURE ARE $\infty$-STABLE CONFIGURATIONS**

We now show that in presence of finite couplings, the degeneracy between all $s_k$s is lifted since $k$-stable configurations are not necessarily $k + 1$-stable. In addition, we show that zero temperature TAP solution are $\infty$-stable and not only 1-stable. To do so, let us first recall how TAP equations can be derived for a one dimensional spin glass [19]. We call $l_i$ and $r_i$ respectively the effective magnetic fields due to all the spins on the left and on the right of $i$ and $h_i$ the external magnetic field acting on $S_i$. It is easy to write the equation verified by $m_i$ in terms of $l_{i-1}$ and $r_{i-1}$,

$$m_i = \tanh[\beta h_i + \tanh^{-1}(\tanh(\beta l_{i-1})\tanh(\beta J_{i-1})) + \tanh^{-1}(\tanh(\beta r_{i+1})\tanh(\beta J_i))].$$

(4)

This is the equation verified by the local magnetisation of a spin $S_i$ interacting with two spins $S_{i-1}$, $S_{i+1}$ on which the magnetic fields $l_{i-1}$ and $r_{i+1}$ act. Focusing on two neighbouring spins the equations verified by the two local magnetisations are:

$$m_i = \frac{\tanh(\beta l_i) + \tanh(\beta J_i)\tanh(\beta r_{i+1})}{1 + \tanh(\beta l_i)\tanh(\beta J_i)\tanh(\beta r_{i+1})}$$

(5)

$$m_{i+1} = \frac{\tanh(\beta r_{i+1}) + \tanh(\beta J_{i+1})\tanh(\beta l_i)}{1 + \tanh(\beta r_{i+1})\tanh(\beta J_{i+1})\tanh(\beta l_i)}$$

(6)

These equations give $m_i$ and $m_{i+1}$ as a function of $l_i$ and $r_{i+1}$. Inverting (3), (4) one obtains $l_i$ and $r_{i+1}$ as functions of $m_i$ and $m_{i+1}$. Plugging $l_{i-1} = l_{i-1}(m_{i-1}, m_i)$ and $r_{i+1} = r_{i+1}(m_i, m_{i+1})$ into (3) the TAP equations for the local magnetisations are established [10].

To prove that TAP solutions are mapped into ground states in the zero temperature limit let us focus on $k$ contiguous spins on the chain. The TAP equations on these $k$ spins are by construction the equations verified by the local magnetisations of the system of $k$ spins, as if it were isolated from the rest of the chain and there were magnetic fields $l_{i-1}$, $r_{i+1}$ acting on the leftmost and rightmost spins respectively. As a consequence in the zero temperature limit, the $k$ local magnetisations tend towards the configuration of $k$ spins which realizes the global minimum of the isolated system of $k$ spins for any value of $l_{i-1}$ and $r_{i+1}$. As $k$ can be made arbitrarily large once $N$ has been sent to infinity, the configurations corresponding to the zero temperature limit of TAP solutions are $\infty$-stable. The argument can be straightforwardly extended to Ising spin glasses on Cayley trees or on random graphs.
VII. CALCULATION FOR A MEAN-FIELD MODEL WITH FINITE COUPLINGS

The results of the previous sections suggest that in finite connectivity models \( s_k \) is a non trivial function of \( k \) which tends towards the zero temperature limit of the complexity \( \sigma \) for large values of \( k \). To corroborate this point, it is interesting to study a model whose complexity \( \sigma \) is non zero. Consider the Hamiltonian \( H = - \sum_{i<j} J_{ij} S_i S_j - \sum_{i=1}^N L_i S_i S_{i+1} \). The first term is the usual SK Hamiltonian: couplings \( J_{ij} \) are independent Gaussian random variables of zero mean and variance \( J^2/N \). The one dimensional Hamiltonian involves disordered interactions \( L_i \) which are independent random variables vanishing with probability \( 1 - \alpha \) and distributed according to an even distribution law \( P(L) \) with probability \( \alpha \). This system smoothly interpolates between the SK model (\( \alpha = 0 \)) and the one dimensional spin glass (\( J = 0 \)). We calculate below the departures of \( \sigma \) and \( s_k \) from their common value in the SK model to the first order in \( \alpha \) only to avoid useless tedious calculations.

To compute the complexity two approaches can be used. The first one consists in making the (annealed) sum over all locally stable TAP solutions [21]. The other method relies on the computation of the logarithm of the (average) \( n^{th} \) power of the partition function using Bray and Moore replica symmetry breaking scheme [22]. As \( n \) goes to zero, the annealed complexity is recovered [21]. Calculations are sketched in Appendix A and B and provide the same average complexity \( \sigma(\alpha) = \sigma^SK + \alpha \gamma^{(1)} + O(\alpha^2) \) where

\[
\gamma^{(1)} = -1 + \frac{\int_{-\infty}^{+\infty} dLP(L) \int_{-\infty}^{+\infty} D y_1 D y_2 \theta(y_1 + y_2 + 2z^*)}{\left( \int_{-\infty}^{+\infty} D y \right)^2}.
\]  

and \( z^* \approx 0.506 \) is the maximum of (3). \( \theta \) denotes the Heaviside function.

We now turn to the computation of \( s_k \). The excitation energy corresponding to \( k \) spin flips depends on the SK couplings and the initial configuration through the variables \( x_i = \sum_j (x_{ij}) J_{ij} S_j \) only. For large \( N \), the \( x_i \)'s become independent of the spin configuration \( \{S_i\} \) and can be written as \( x_i = y_i + z \), where \( y_i \) and \( z \) are independent Gaussian random variables of zero means and variances \( J^2 \) and \( J^2/N \) respectively [22]. The annealed configurational entropy is defined through

\[
e^{-N s_1} = \left( \prod_{\{S_i\}} \theta \left( L_{i-1} S_{i-1} S_i + L_i S_i S_{i+1} + y_i + z \right) \right) \quad \{L,y,z\}.
\]

Once the average \( \langle \cdot \rangle \) over disorder has been carried out, spins may be traced over and (8) may be evaluated for large \( N \) by the method of steepest descent. We find \( s_1(\alpha) = \sigma^{SK} + \alpha c_1^{(1)} + O(\alpha^2) \) with

\[
c_1^{(1)} = -1 + \frac{\int_{-\infty}^{+\infty} dLP(L) \int_{-\infty}^{+\infty} D y_1 D y_2}{\left( \int_{-\infty}^{+\infty} D y \right)^2}.
\]

giving \( s_1 > \sigma \) as expected, compare [7] and [8] [23]. Repeating the same calculation for \( k(\geq 2) \)-stable configurations, we have found that they are equally numerous to the first order in \( \alpha \): \( s_k(\alpha) = \sigma^{SK} + \alpha c_k^{(1)} + O(\alpha^2) \) with \( c_k^{(1)} = \gamma^{(1)} \) for any \( k \geq 2 \). This result extends to higher orders in \( \alpha \) as follows. Let us call \( c_k^{(n)} \) the coefficient of \( \alpha^n \) in \( s_k \). Contributions to \( c_k^{(n)} \) come from disordered lattices of \( L \) bonds involving clusters of at most \( n + 1 \) contiguous spins along the chain. Clearly, spin configurations on such lattices that are \( n + 1 \)-stable are for ever stable. Therefore, \( c_1^{(n)} > c_2^{(n)} > \ldots > c_{n+1}^{(n)} = c_k^{(n)} \) for any \( k \geq n + 1 \). We have in particular explicitly checked that \( c_2^{(2)} > c_3^{(2)} \).

As a conclusion, we have found a mean-field model with non zero complexity \( \sigma \) and \( s_1 > \sigma \). We have checked that \( \sigma \) coincides with \( s_{\infty} \) to the first order in the density of \( O(1) \) couplings.

VIII. CONCLUSION

The above examples have shown the differences between IS and PS even in mean-field models provided that finite couplings are present. Our results could also be extended to models with continuous degrees of freedom, e.g. systems of \( N \) interacting particles [13]. In this case IS are configurations stable against infinitesimal moves of any subset of the \( N \) particles, that is local minima of the potential energy. \( k \)-stable local minima can be defined as IS stable against finite moves of any subset of \( k \) (or less than \( k \)) particles. \( \infty \)-stable minima gather all configurations that can be reached from each other by crossing finite barriers and are related to PS.
From the equilibrium point of view, PS and thus complexity are the only relevant concepts. The decomposition of the partition function put forward by Stillinger based on IS though mathematically exact does not seem to be thermodynamically founded \([14]\). However, usual nucleation arguments imply that no PS with free-energy \(f \neq f_{eq}\) can live forever, that is \(\sigma(f \neq f_{eq}) = -\infty\). We thus face the following alternative. Either nucleation arguments break down for some reason and finite-dimensional glassy systems with full curves for \(\sigma(f)\) may exist \([23]\). Or they hold and the KTW entropy crisis scenario cannot be extended to realistic systems without taking into account the notion of life time for PS (as was already emphasized in \([11]\)). IS, besides their phenomenological interest can be seen as a very valuable step in that direction.

Acknowledgements: We are very grateful to Marc Mézard for very interesting and motivating discussions.

IX. APPENDIX A

To first order in \(\alpha\) spin \(i\) has at most one neighbour \(v = i \pm 1\) along the chain of \(L\) bonds. As a consequence the TAP equations can be written as

\[
m_i = \frac{t_i + t_v \tanh(\beta L)}{1 + t_i t_v \tanh(\beta L)}, \quad \tanh^{-1}(t_i) = \beta \sum_{j \neq i} J_{ij} m_j - \beta^2 J^2 (1 - q) m_i \tag{10},
\]

where \(q = 1/N \sum_{i=1}^{N} m_i^2\). To compute the annealed complexity we sum over all solutions of equations \([17]\) following \([17]\). Introducing auxiliary variables one can perform the average over \(J_{ij}\) and using the same notation as \([17]\), we find

\[
s = \text{extr}_{\eta, \lambda, \Delta} \left\{ -\lambda q - \Delta (1 - q) - \Delta^2 / 2 \beta^2 J^2 + \right.
\]

\[
\frac{1}{N} \ln \left\{ \sum_{x < 0} \exp \left( -\frac{(\tanh^{-1} t_i - \Delta m_i)^2}{2 \beta^2 J^2 q} + \lambda m_i^2 \right) \right\} \tag{12}.
\]

Performing the average on \(L_i\) at the first order in \(\alpha\) and taking the zero temperature limit we obtain the expression of \(\gamma\).

X. APPENDIX B

To compute the \(n^{th}\) moment of the partition function, we use the replica trick and obtain \(n\) coupled chains. Defining the overlap \(q^{ab}\) between replicas \(a\) and \(b\) and the \(2^n \times 2^n\) transfer matrix,

\[
\mathcal{M}(\vec{S}, \vec{T}) = \left\{ 1 - \alpha + \int dLP(L) \exp \left[ \beta L \sum_a S_a^a T^a \right] \right\} \exp \left[ \frac{\beta^2 J^2}{2} \sum_{a < b} q^{ab} (S_a^a S_b^b + T^a T^b) \right], \tag{13}
\]

the complexity may be computed within Bray and Moore two-group Ansatz \([20]\): \(\sigma = \text{extr}_{\{q\}} \left[ - (\beta J)^2 \sum_{a < b} (q^{ab})^2 / 2 + \ln \Lambda(\{q\}) \right]\) where \(\Lambda(\{q\})\) is the largest eigenvalue of \(\mathcal{M}\). The saddle-point equation for \(\{q\}\) read \(q^{ab} = \sum_a S^a S^b [\Psi(\vec{S})]^2\).

The normalised ground state wave function \(\Psi\) obeys the two group symmetry with breakpoint \(m\) \([21]\). \(\Psi\) depends on \(\vec{S} = (S^1, \ldots, S^n)\) through \(S_- = \sum_{a < m} S^a\) and \(S_+ = \sum_{a > m} S^a\) only and can be written as \(\Psi(S_-, S_+) = e \int \rho(h_0, h_1) \rho(h_0, h_1) \exp(\beta h_0 (S_+ + S_-) + h_1 (S_+ - S_-)) \) where \(e\) is a normalisation factor. In the zero temperature limit, the effective fields \(h_0, h_1\) are both of order one and the overlaps \(q^{ab}\) read \(q_1 = A - z/(\beta m J), q_2 = A - w/(\beta m J)^2, q_3 = A + z/(\beta m J), A \to 1\) with the notations of \([20]\). The eigenvalue equation for \(\Lambda, \Psi\) provides a linear equation for the effective field distribution

\[
\lambda \rho(h_0, h_1) = \int dLP(L) \left\{ (1 - \alpha) \delta(L) + \alpha P(L) \right\} \int DuDv \int dh_0 dh_1 \exp \left[ h_1^t \omega_L(h_0) \right] \delta \left( h_0 - \varphi_L(h_0) \right) \delta \left( h_1 - h_1^t \eta L(h_0) \right), \tag{14}
\]

where \(\lambda = \Lambda \exp(\beta J m z)\). \(\omega_L(x)\) (respectively \(\varphi_L(x), \eta_L(x)\)) equals \(-1\) (resp. \(-L, 0\)) if \(x < -|L|\); \(0\) (resp. \(x \text{ sign}(L), \text{ sign}(L)\)) if \(-|L| < x < |L|\) and \(1\) (resp. \(L, 0\)) if \(x > |L|\). The complexity \(\sigma\) is found through maximising \(-z^2 / 2 - w + \ldots\)
$\ln \lambda(z, w)$ over $z, w$ and can in principle be computed for any $\alpha$. The small $\alpha$ expansion of $\sigma$ is computed from the expansion of $\rho$ around the SK distribution $\rho^{SK}(h_0, h_1) = \delta(h_0)\delta(h_1)$ using (14).
