NEW CONNECTION METHOD
ACROSS MORE GENERAL TURNING POINTS

BY J. F. PAINTER AND R. E. MEYER

The basic oscillator or Schrödinger equation
\[ e^2 \frac{d^2 w}{dz^2} + q(z) w = 0, \quad \epsilon \downarrow 0, \]
with \( q(z) \) analytic, except for a root or singular point at \( z = 0 \), poses a well-known connection problem. WKBJ or L-G approximations
\[ w \sim A q^{-\nu/2} \exp(\xi/\epsilon) + B q^{-\nu/2} \exp(-\xi/\epsilon), \]
\[ \frac{dw}{dz} \sim (iq^{1/2}/\epsilon)[A \exp(i\xi/\epsilon) - B \exp(-i\xi/\epsilon)] \]
with
\[ \xi = \int_0^z q(s) \, ds \]
and constants \( A, B \) are valid in suitable regions, but not in a neighborhood of the transition point. The constants \( A_\rho, B_\rho \) in (2) valid to the left of such a point generally differ from those, \( A_\rho, B_\rho \), valid to the right. Langer [1] found one constant pair in terms of the other for the class of “fractional turning points” at which \( z^{-\nu} q(z) \) is analytic for real \( \nu > -1 \). But, if branch points, even of infinite order, be thus admitted, why not logarithms of \( z \) and still other branch points?

The reason lies in his “central connection” method by uniform approximation even near \( z = 0 \). For fractional turning points such approximands to \( w(z) \) are furnished by Bessel functions, but for logarithmic turning points they are necessarily less tractable. Uniform approximation, however, is not a prerequisite for connection, nor is it needed for the most important physical applications, e.g., in scattering.

A new method will now be summarized which solves the problem for a more general class of equations (1) characterized (a precise statement is found in the Appendix) by
\[ \varphi(\xi) := \frac{1}{2} q^{-2} dq/dz = \xi^{-1}(\gamma + o(1)) \quad \text{as} \quad \xi \to 0 \]
with real \( \gamma < \frac{1}{2} \). This includes the fractional turning points, where \( \gamma = \frac{1}{2} \nu/(1 + \nu) \) \((\leq \frac{1}{2} \text{ since } \nu > -1\)) and also logarithmic turning points, where \( q(z) \sim z^\nu (\log z)^\mu \).
with real \( \mu \) and \( \gamma \) has the same value, but the \( o(1) \) term in (4) is more disagreeable, and also a great many more general branch points of \( q(z) \).

The connection problem has many related versions; for definiteness, the branch cut will be taken along the negative real \( \xi \)-axis (Figure 1) and connection, attempted from \( \xi = -1 \) on the left to \( \xi = 1 \) on the right. For the term in (2) dominant above the real axis, a simple asymptotic argument [2] then gives \( B_\tau = B_\tau + o(1) \), the difficulty lies in finding \( A_\tau \). Let \( A(\xi), B(\xi) \) denote the functions for which (2) is an identity, not an asymptotic relation; then (1) can be cast as an integral equation

\[
A(\xi) = A_\tau + B_\tau (\xi, \xi) e^{-\rho \xi} + \int_{\xi}^{\xi} A(s) j(\xi, s) \varphi(s) ds
\]

with \( \xi \) any negative number and

\[
\rho = 2i/e, \quad j(\xi, s) = e^{\rho s} \int_{\xi}^{s} e^{-\rho t} \varphi(t) dt, \quad A_\tau = A(\xi), \quad B_\tau = B(\xi).
\]

It is studied first on a semicircle \( ||| = \delta(\epsilon) \) (Figure 1), so that \( \xi = -\delta, \xi = \delta \) and

\[
\delta(\epsilon) \to 0, \quad \epsilon/\delta(\epsilon) \to 0 \quad \text{as} \quad \epsilon \to 0.
\]

This involves a drastic departure from the key requirement of turning point theory [3] to specify integrals only along “progressive paths” along which the exponentials in the integrands vary monotonely in magnitude. In the new method, non-monotone and wild variation of the exponentials is central, a price paid for gains in flexibility.

By careful choice of the paths of integration, the kernel \( j(\xi, s) \) can be approximated [4] for \( \xi \) and \( s \) on the arc emphasized in Figure 1 (where \( \theta_0 > 0 \).
and independent of $e$) by an incomplete gamma function, whence in turn,

$$ f(\xi, s) e^{-ps} = [\gamma + o(1)] \left( e^{-ps} - e^{-p\xi/p} \right) $$

on that arc. Related estimates for other $\xi$, $s$ on the semicircle [4] complement (6), and by splitting off a volatile exponential factor, the integral operator in (5) may be made to contract—only a disappointing bound $|A(\xi)| \leq \text{const.}$ times $\exp(2\delta/e)$ is so obtainable for $\xi$ on the semicircle.

Now, for $\varphi(\xi) = \gamma/\xi$ exactly, because $q(z) = z^\gamma$ exactly, (1) is solved in terms of Hankel functions by

$$ w = \xi^\lambda H^{(i)}_\lambda(\xi/e), \quad \lambda = \frac{1}{2} - \gamma, \quad i = 1 \text{ or } 2, \quad (7) $$

whence $A(\xi)$ can be calculated for this special case; call this function $A^\gamma(\xi)$. Then (5) can be cast as an integral equation for $A(\xi) - A^\gamma(\xi)$, and a contraction argument yields [4] $A(\xi) - A^\gamma(\xi) \to 0$ as $e \to 0$ uniformly on the entire semicircle $|\xi| = \delta(e)$ (Figure 1) provided $\delta(e)$ be chosen so that

$$ (e/5) [\delta(\delta) - \gamma] \exp(2\delta/e) \to 0 \quad \text{as } e \to 0. $$

The known connection formula for (7) is thereby extended to $A$:

$$ A(\delta(e)) = A(-\delta(e)) - 2iB(-\delta(e))\sin(\gamma\pi) + o(1). \quad (9) $$

Unfortunately, this requires a $\delta(e)$ so close to $e$ that the extension from $\xi = \delta$ to $\xi = 1$ (and $-\delta$ to $-1$) necessary for practical usefulness of connection, remains a real problem. For (5) on the real axis, a contraction argument [4] shows $A(\xi)$ to be approximately constant over intervals of sufficiently short length (dependent on $\epsilon$ and $\delta$). They are generally too short to reach from $\delta(e)$ to $1$, but a finite chain of them [4] does yield the desired extension, provided (4) is slightly strengthened to

$$ \xi \varphi(\xi) = \gamma + o(\log \log \ldots \log \xi)^{-1} \quad \text{as } \xi \to 0 \quad (8) $$

which still admits logarithmic turning points and many more. Then

$$ A(1) = A(-1) - 2iB(-1)\sin(\gamma\pi) + o(1), \quad (9) $$

$$ B(1) = B(-1) + o(1) $$

as $\epsilon \to 0$. Much in contrast to the uniform approximation to the solution of (1), the first approximation to connection is thus the same for our generalized turning points as for Langer’s fractional ones—and for Bessel functions.

**Appendix.** A precise statement of the assumptions assuring (9) is that $q(z)$ in (1) is analytic and nonzero on an open, connected and simply connected set $R_z$ of complex numbers and also at every point of $\partial R_z$, except for $z = 0$. At $z = 0$, $q(z)$ is absolutely integrable so that $\xi$ can be defined by (3). The image $R_{\xi} = \xi(R_z)$ contains a fixed rectangular neighborhood of the branch point, except
for the cut. On $R_{\xi}$, $\varphi(\xi)$ is of exponential order as $|\xi| \to -\infty$, and (8) holds with real constant $\gamma < \frac{1}{2}$ and some finite iterate of the logarithm.
