ABSTRACT
High-resolution cosmological hydrodynamic simulations are currently limited to relatively small volumes due to their computational expense. However, much larger volumes are required to probe rare, overdense environments, and measure clustering statistics of the large scale structure. Typically, zoom simulations of individual regions are used to study rare environments, and semi-analytic models and halo occupation models applied to dark matter only (DMO) simulations are used to study the Universe in the large-volume regime. We propose a new approach, using a machine learning framework to explore the halo-galaxy relationship in the periodic EAGLE simulations, and zoom C-EAGLE simulations of galaxy clusters. We train a tree based machine learning method to predict the baryonic properties of galaxies based on their host dark matter halo properties. The trained model successfully reproduces a number of key distribution functions for an infinitesimal fraction of the computational cost of a full hydrodynamic simulation. By training on both periodic simulations as well as zooms of overdense environments, we learn the bias of galaxy evolution in differing environments. This allows us to apply the trained model to a larger DMO volume than would be possible if we only trained on a periodic simulation. We demonstrate this application using the (800 Mpc)³ P-Millennium simulation, and present predictions for key baryonic distribution functions and clustering statistics from the EAGLE model in this large volume.

Key words: galaxies: abundances – galaxies: luminosity function, mass function – software: simulations

1 INTRODUCTION
Cosmological hydrodynamic simulations self-consistently model the evolution of baryonic and cold dark matter, and the subsequent hierarchical assembly of galaxies in a ΛCDM universe (Benson 2010; Somerville & Davé 2015). A number of projects, such as EAGLE (Schaye et al. 2015), Illustris (Vogelsberger et al. 2014), Illustris-TNG (Pillepich et al. 2018), Mufasa (Davé et al. 2016) and Simba (Davé et al. 2019) have had reasonable success at reproducing key galaxy distribution functions in the low-redshift Universe, such as the galaxy stellar mass function. They are typically run within large periodic volumes, ∼100 Mpc on a side, and have mass resolutions of order ∼10⁸ M⊙. This is sufficient to resolve the internal structure of galaxies, but still coarse enough to necessitate the use of subgrid models for small-scale stellar and black hole processes.

It is currently computationally infeasible to run simulations at this resolution in substantially larger volumes1. This is an issue for certain science questions, since the volumes typically simulated (∼(100 Mpc)³) do not contain large numbers of rare, overdense environments, as well as galaxies with unusual growth histories (e.g. star bursts). For example, EAGLE contains only seven clusters at z = 0, and these are all relatively low mass (M_{200,crit}/M_⊙ < 10¹⁴.5). In order to simulate rare environments, that are not represented in smaller scale periodic volumes, another approach is to use ‘zoom’ simulations (Katz & White 1993; Tormen et al. 1997). These use initial conditions selected from a much larger dark matter only (DMO) simulation, of order ∼(1 Gpc)³ in volume, and then resimulate a smaller region from this volume with full hydrodynamics. Large scale tidal forces are preserved by simulating the rest

1 The BlueTides simulation (Feng et al. 2016) is one of the largest high-resolution hydrodynamic simulations, with a volume 400 h⁻¹ Mpc on a side, but was only run to z = 7.
of the volume with low resolution dark matter only particles. This approach has been used successfully to simulate cluster environments with the EAGLE code (Barnes et al. 2017b; Bahé et al. 2017).

However, since zooms only simulate a small region of interest they have a number of drawbacks compared to periodic simulations. They cannot be used to predict mean distribution functions directly, since they are, by construction, biased regions. One means of circumventing this limitation is to use multiple zoom simulations of differing environments, and weight the relative abundance of each simulation based on its relative total matter overdensity. This technique was first demonstrated with the GIMIC simulations (Crain et al. 2009), and recently used in the FLARES simulations to make predictions for the abundance of galaxies during the epoch of reionisation (Lovell et al. 2021; Vijayan et al. 2021). Another drawback is that zooms cannot be used to self-consistently predict aspects of the large scale structure, such as the clustering of galaxies, since they are by construction non-representative, small volume regions of the Universe. Large periodic volumes are the only means of studying these kinds of spatial statistics (e.g. the BAHAMAS project; McCarthy et al. 2017), but these large volumes cannot currently be simulated at the high resolution necessary to model internal galaxy structures. This limits what can be achieved with high-resolution hydrodynamic simulations.

N-body DMO simulations predict the distribution of matter as a result of gravitational interactions only, and are therefore significantly cheaper computationally than simulations including the gas hydrodynamics. They are therefore less demanding to run accurately in large volumes, allowing them to be used to explore the large scale structure (LSS). There are also a number of approaches to modelling galaxy evolution that are relatively simpler than running a full hydro simulation, using semi-analytic or phenomenological models to populate haloes in DMO simulations. The host halo has a significant impact on the properties of a galaxy; haloes are the cradles within which galaxies form, and continue to influence the evolution of a galaxy throughout its lifetime (Wechsler & Tinker 2018). Understanding the relationship between galaxy properties and the properties of their host haloes is an important factor in understanding galaxy formation and evolution, and in the subsequent building of these kinds of galaxy evolution models.

Semi Analytic Models (SAMs) explicitly assume a close relationship between a galaxy and its host-halo. They treat the complicated physics of galaxy formation with approximate, physically-motivated analytical models, applied ex post facto to N-body dark matter only simulations (for a review, see Baugh 2006). The halo properties, and their merging history, provide the input parameters for such models, which have successfully reproduced a number of distribution functions simultaneously (e.g. Gonzalez-Perez et al. 2014; Henriques et al. 2015, 2020). Subhalo Abundance Matching (SHAM) models also rely explicitly on the galaxy-halo relationship, populating dark matter haloes from simulations with rank ordered galaxies from observations. Such models have been used to constrain the stellar mass - halo mass relation (e.g. Behroozi et al. 2010; Moster et al. 2010, 2013; Legrand et al. 2019), though it has been noted that the efficacy of such methods is highly dependent on the observational selection function (Stiskalek et al. 2021). Both these approaches are capable of modelling galaxy evolution over very large volumes, allowing predictions for the clustering of galaxies as well as their evolution in rare, overdense environments. They have also been used in combination with hydrodynamic simulations in order to highlight potential issues (e.g. for satellites where mergers lead to mass loss; Simha et al. 2012), and SAMs have even been explicitly calibrated to reproduce hydrodynamic simulations (Neistein et al. 2012; Mitchell & Schaye 2021), allowing an investigation into the effects of changes to specific coefficients in the model.

Machine learning methods continue to grow in popularity in all areas of astronomy (see Ball & Brunner 2010; Fluke & Jacobs 2020), and a number of recent papers have explored how they can be used in combination with simulations to emulate galaxy properties, analogous to a SHAM or SAM model. In a pioneering paper, Xu et al. (2013) used the Millennium simulation, coupled with a SAM, to predict the number of galaxies in a given halo using support vector machines and k-nearest neighbour algorithms. Later, Kandar et al. (2016a) showed how tree based methods can be trained to learn additional properties of the the baryon-halo relationship directly from an existing SAM. They used dark matter properties from each halo as features, and baryonic properties as predictors, and trained the machine to learn the mapping between the two. They then followed this up by applying the same technique to the ILLUSTRIS hydrodynamic simulation (Kandar et al. 2016b). Agarwal et al. (2018) presented a similar model applied to the MUFASA simulation. Using the more recent ILLUSTRIS-TNG simulation, Jo & Kim (2019) presented a similar model, and then applied this trained model to the much larger DMO MultiDark-Planck simulation. A novel addition to their model was historical halo features (extracted from the halo merger tree), which allowed the model to broadly reproduce key distribution functions, though we note that they do not present tests in the high halo mass regime (>10^{14} M_{\odot}). Sullivan et al. (2018) used artificial neural networks to better predict the baryon fraction of haloes at high-redshift using both dark matter and baryonic properties from their RAMSES-RT radiative transfer simulations. Most recently, a number of hybrid approaches have been presented: Moews et al. (2020) combined the results of an equilibrium model with machine learning on the SIMBA simulations, and Hearin et al. (2020) combined empirical modelling with simulation outputs from a SAM to populate large DMO volumes with galaxies. Icaza-Lizaoela et al. (2021) demonstrated, using a sparse regression approach, that halo angular momentum has little impact on the stellar-halo mass relation. Finally, a number of approaches have demonstrated predictions for baryonic properties of the cosmic web not necessarily linked to discrete subhaloes (e.g. Sinigaglia et al. 2020).

In this paper we build on these previous works, by combining the results of both periodic and zoom cosmological simulations from the EAGLE project to train a machine learning model to learn the relationship between galaxy baryonic properties and their host dark matter haloes. Our approach is unique in two ways. Firstly, we match subhaloes from each hydrodynamic simulation with those in a DMO counterpart (simulated from the same initial conditions), in order to avoid the effect of baryons on the host dark matter halo (Schaller et al. 2015). This allows the model to be directly applied to an independent DMO simulation, without leading to biases in the predictions due to differences in the dark matter features.
Secondly, we address the issue of generalization error. Machine learning methods are a powerful set of techniques for making predictions on data that look similar to the data on which they are trained, but fail when presented with new data that lies outside of the bounds of the original training data. This presents a problem for models trained on smaller periodic volumes, since such volumes will not contain the massive clusters present in larger DMO simulations, and hence any model trained on these volumes won’t provide good predictions for galaxies in overdense environments. We avoid this by including clusters from the C-EAGLE project (C-EAGLE; Barnes et al. 2017b; Bahé et al. 2017) in our training set. This allows us to apply the trained model to the much larger volume (800 Mpc)$^3$ P-MILLENNIUM simulation (Baugh et al. 2019), and predict distribution functions of key baryonic properties within this enormous volume, extending the dynamic range, as well as allowing predictions of clustering statistics on larger scales / for higher mass haloes. The method is shown diagrammatically in Figure 1.

Whilst often negatively perceived as a ‘black box’, many machine learning methods in fact provide a wealth of insights into the form of their predictive model, and the weight given to their input parameters. This presents an opportunity to learn, in an unbiased manner, what parameters best explain the galaxy-halo connection. We train the model with a range of dark matter properties, and explore the relative predictive power of each one on the baryonic properties. Hydrodynamic simulations represent the cutting edge of cosmological modelling; machine learning methods could provide a practical way of extracting quantitative information on the modelled relationships. All of these insights can be used to inform future analytic, semi-analytic and hydrodynamic model development.

This paper is laid out as follows. In Section 2 we present the simulations used to train the model, as well as our algorithm for matching subhaloes between the hydro and DMO runs. Section 3 details the machine learning methods used, as well as our choice of features and predictors. Section 4 details our results on test sets, including the effect of including density information. Section 5 presents our results on independent DMO simulations, including the P-Millennium simulation, and Section 6 shows our feature exploration analysis. Finally, in Section 7 we discuss our results and summarise our conclusions. Throughout, we assume a (flat) Planck year 1 cosmology ($\Omega_m = 0.307$, $\Omega_\Lambda = 0.693$, $h = 0.6777$, Planck Collaboration et al. 2014) and a Chabrier stellar initial mass function (IMF; Chabrier 2003)

## 2 SIMULATIONS

### 2.1 The EAGLE & C-EAGLE simulations

The EAGLE project is a suite of cosmological hydrodynamic simulations (Schaye et al. 2015; Crain et al. 2015) employing subgrid models for feedback from stars and AGN. EAGLE has been shown to accurately reproduce many observed relations, including the galaxy stellar mass function, galaxy sizes, quenched fractions, gas content and black hole masses (Trayford et al. 2015, 2017; Lagos et al. 2015; Bahé et al. 2016; Crain et al. 2017; Furlong et al. 2017; McAlpine et al. 2017) at a range of redshifts (e.g. Furlong et al. 2015). A number of different resolutions and volumes make up the EAGLE simulation suite. In this work we use the ‘fiducial’ resolution simulations, with gas particle mass $m_g = 1.8 \times 10^6 ~M_\odot$, dark matter particle mass $9.7 \times 10^6 ~M_\odot$, and a physical softening length of 0.7 kpc. Haloes in the simulation are identified first through a Friends-Of-Friends (FOF) halo finder, and then split into child self-bound objects with SUBFIND (Dolag et al. 2009). Cluster-Eagle (or C-EAGLE, Barnes et al. 2017b; Bahé et al. 2017), uses the EAGLE model to simulate cluster environments using the ‘zoom’ re-simulation technique (Katz & White 1993; Tormen et al. 1997). 30 clusters at $z = 0$ (shown in Figure 1), with a range of halo masses ($14 < \log_{10}(M_{200}/M_\odot) < 15.5$), are selected from a (3.2 Gpc)$^3$ ‘parent’ DMO simulation (Barnes et al. 2017a). The clusters are resimulated at an identical resolution to the fiducial periodic EAGLE simulation. Full details on the selected clusters is provided in Barnes et al. (2017b).

C-EAGLE uses the AGNdT9 calibration of the EAGLE model (Schaye et al. 2015), which, compared to the fiducial Reference model, uses a higher value for $C_{\text{esc}}$, which controls the sensitivity of the BH accretion rate to the angular momentum of the gas, and a higher gas temperature increase from AGN feedback, $\Delta T$. A larger $\Delta T$ leads to fewer, more energetic feedback events, whereas a lower $\Delta T$ leads to more continual heating. Schaye et al. (2015) show that AGNdT9 predicts X-ray luminosities and hot gas fractions in galaxy groups in better agreement with observational constraints, though with some discrepancies on cluster scales (Barnes et al. 2017b).

Table 2.1 details the simulations used in this work, and any combinations. L100Ref is a (100 Mpc)$^3$ periodic volume (shown in Figure 1) run with the Reference model parameters; the hydro simulation contains $1504^3$ dark matter and $1504^3$ gas particles. L050AGN is a smaller, (50 Mpc)$^3$ periodic volume (shown in Figure 1) run at the same resolution as L100Ref but with the AGNdT9 model parameters; it contains $752^3$ dark matter and $752^3$ gas particles. L050AGN+ZoomAGN is a combination of L050AGN with the zoom cluster regions from C-EAGLE. We also match with DMO counterparts to each of these simulations, run using the same initial conditions; the match is described in Section 2.2. We use the snapshot corresponding to $z = 0.101$ in all simulations.

Throughout the rest of this text, whenever we refer to a model we are referring to a machine learning model (unless otherwise stated) trained on the matched hydro-DMO simulations indicated in the name. The simulations are all referred to explicitly as simulations to distinguish them from the machine learning models.

### 2.2 Matching between hydrodynamic and dark matter only simulations

Including baryons can lead to significant alterations to the underlying dark matter haloes (Weinberg et al. 2008). For example, Schaller et al. (2015) demonstrate that, in the EAGLE simulation, the halo centres are more ‘cuspy’ in the presence of stars. In order to apply our trained model to DMO simulations it is necessary to avoid these effects, as they will bias any predictions based on the dark matter features. We achieve this by matching subhaloes in each hydrodynamic simulation to their counterparts in DMO simulations, and use the properties of the matched haloes in the DMO simulation as our
Figure 1. Diagram showing the simulations (approximately to scale) used throughout this work, and the features and predictors used for training the machine learning model. At the top are the C-EAGLE zoom simulations; each image shows the distribution of dark matter (left) in the DMO simulations, and the gas (right) in the full hydro simulation, centred on the centre of potential of the most massive FOF group in each simulation, within a radius $r = 15 \times R_{200}$. Below these are the cubic periodic L100Ref and L050AGN simulations, again showing the dark matter (left) and gas (right). In the centre are tables detailing the features from the DMO simulations (left) and the predictors from the hydro simulations (right). At the bottom is a cropped image of the dark matter distribution in the P-Millennium simulation, to which the trained machine learning model is applied to predict the baryonic properties of its haloes.
we can use a similar threshold in any target DMO simulation. By using a threshold dependent only on the DMO properties with masses above this threshold (see Section 3.3 for details).

We hence choose to train our model only on subhaloes from each DMO simulation set in Table 2.1. More than 95% of subhaloes with masses in the test set, (8) the value of the viscosity parameter, and (9) the value of the $\Delta T$ parameter.

Table 1. Details on each simulation set. The columns provide (1) the name or description of the simulation set, (2) the prefix used throughout this paper, (3) the total volume, (4) the number of subhaloes with mass $>10^{10} M_\odot$, (5) the number of those haloes matched between the hydro and DMO simulations (see Section 2.2), (6) the number of subhaloes in the training set, (7) the number of subhaloes in the test set, (8) the value of the viscosity parameter, and (9) the value of the $\Delta T$ parameter.

| Simulation          | Prefix    | Volume (Mpc$^3$) | $N_{\text{halo}}(>10^{10} M_\odot)$ | $N_{\text{matched}}$ | $N_{\text{train}}$ | $N_{\text{test}}$ | $C_{\text{visc}}$ | $\Delta T$ |
|---------------------|-----------|-----------------|-----------------------------------|----------------------|-------------------|-------------------|-----------------|----------|
| Reference L0100N1504| L100Ref   | $10^3$          | 88173                             | 86861                | 69615             | 17246             | $2\pi \times 10^3$ | $10^3$   |
| AGNdT9 L0050N0752   | L050AGN   | $50^3$          | 11423                             | 11265                | 9031              | 2231              | $2\pi \times 10^2$ | $10^3$   |
| C-EAGLE             | ZoomAGN   | 202.7$^3$       | 373275                            | 364408               | -                 | -                 | $2\pi \times 10^2$ | $10^3$   |
| C-EAGLE + L050AGN   | L050AGN+ZoomAGN | 203.7$^3$ | 384968                            | 375673               | 300770            | 74903             | $2\pi \times 10^2$ | $10^3$   |

Figure 2. Fraction of subhaloes from each DMO simulation matched with a counterpart in the hydro simulation, binned by total subhalo mass. L050AGN and L100Ref are shown in blue and orange, respectively, and each zoom from ZoomAGN is shown as a black dashed line.

features. The galaxy properties that a given halo would have if hydrodynamics had been included are then predicted. Each DMO simulation is run from the same initial conditions, but is not split into baryonic and dark-matter species. Aside from this, all cosmological and numerical parameters are identical.

We perform the match using the approach of Schaller et al. (2015). We first find the 50 most bound dark matter particles in a subhalo in the hydro simulation, and search for haloes in the DMO simulation that have 50% or more of these same particles (matched on particle ID). We then perform the same match in reverse (subhaloes in the DMO matched with subhaloes in the hydro simulation). Those haloes that match bijectively are linked.

Figure 2 shows the fraction of haloes matched from the DMO simulation at a given DMO halo mass for the two periodic simulations (L100Ref and L050AGN) as well as each of the C-EAGLE clusters. We also detail the total number of haloes and the number of matched haloes for each simulation set in Table 2.1. More than 95% of subhaloes with $M_{\text{subhalo}} > 10^{10} M_\odot$ are matched bijectively across all simulations. We hence choose to train our model only on subhaloes with masses above this threshold (see Section 3.3 for details).

By using a threshold dependent only on the DMO properties we can use a similar threshold in any target DMO simulation (subject to the existing resolution constraints of that simulation).

It is noticeable that there are a larger fraction of subhaloes at the high-mass end ($M_{\text{subhalo}} / M_\odot > 5 \times 10^{12}$) that are not matched, in both the periodic and zoom simulations. We looked at these cases individually, and found, where a single halo was identified in the DMO simulation, the halo finder splits this halo into multiple individual haloes in the baryonic simulation. Missing these haloes reduces the size of our training set, which is particularly disappointing at the high-mass end where the number of haloes is already low, however we do not expect this to lead to biases in our predictions due to the already heterogenous nature of our training set.

2.3 The P-MILLENNIUM simulation

P-MILLENNIUM is a large DMO simulation (800 cMpc on a side; particle mass $1.06 \times 10^8 M_\odot$) using the same Planck Collaboration et al. (2014) cosmology as EAGLE. Baugh et al. (2019) first presented the simulation, and demonstrated its use as a parent volume for the GALFORM model, in order to predict the atomic hydrogen content of galaxies. Safonova et al. (2020) also used P-MILLENNIUM as a parent simulation for a SHAM model, generating mock catalogues. P-MILLENNIUM uses the same FOF and Subfind structure finders as the EAGLE simulation project, which means the features can be used directly for any model trained on EAGLE. We present our predictions using P-MILLENNIUM in Section 5.

3 MACHINE LEARNING METHODS

3.1 Extremely Randomised Trees

We used the SCIPIT-LEARN (Pedregosa et al. 2011) implementation of Extremely Randomised Trees (ERT; Geurts et al. 2006), a tree based ensemble method. ERT is demonstrably effective in this domain compared to other popular machine learning methods (Kamdar et al. 2016a; Jo & Kim 2019).
To understand what makes ERT such an effective learner, first consider a single decision tree. Decision trees are typically constructed top down, numerically evaluating all splits for each feature using a cost function. The best split (lowest cost) is chosen at each level. Some of the issues seen with Decision Trees, particularly overfitting, can be alleviated by ensembling many different trees trained on subsets of the data. Random Forests extend this idea by, at each split, randomly limiting the feature space from which splits can be made (within individual trees not all of the data is used, but over the whole ensemble it is). This increases the variance by stopping strong features from dominating each tree. ERT also introduces another layer of randomness; each split is chosen at random from the range of values available for each feature. Bad splits are still rejected, but the extra layer of randomness encourages exploration of the full feature space, creating more ‘weak’ learners for use in the ensemble. At each iteration, only the best split from the subset of features is chosen, and the iterative procedure continues until a leaf node condition is reached.

Within ERT the mean squared error (MSE) is used to evaluate each split. To quantify the effective fit of each model, and to discriminate between models, we used both MSE and the Pearson correlation coefficient ($\rho$), defined below:

$$
\rho = \frac{\text{cov}(X_{\text{predicted}},X_{\text{test}})}{\sigma_{X_{\text{predicted}}} \sigma_{X_{\text{test}}}} .
$$

3.2 Features & Predictors

We chose our features from the properties of the DMO haloes and their host FOF haloes. Some features are expected to be of greater importance for predicting certain baryonic properties; we explore this in Section 6. The selected subhalo features are as follows: total subhalo mass ($M_{\text{sub}}$), half mass radius ($R_{1/2}$), peculiar velocity ($v$), maximum circular velocity ($v_{\text{max}}$), radius of maximum circular velocity ($R_{\text{max}}$), potential energy ($E_{\text{p}}$), FOF group mass ($M_{\text{cent}}$), and finally a boolean feature that specifies whether the subhalo is a satellite or a central.

Since we wish to evaluate the impact of environment we also include additional features to quantify this. As a simple measure of environment we calculated the density of dark matter within spheres centred on a given subhalo in the DMO simulation. We ran a periodic KD-tree search for neighbouring particles, then calculated the density on different scales, $R = [1, 2, 4, 8] \, \text{Mpc}$, to quantify both the small and large scale environment. We indicate in the text where these additional features are included in a given training set.

More dark matter features are available in the subfind catalogues, and additional features could be calculated from the particle information (such as the large scale tidal torque), but we limited our chosen features to those above as they are present in both the EAGLE and P-MILLENIUM catalogues. Combinations of features may also lead to better predictive accuracy; we will explore this systematically in future work.

We predict six baryonic properties: the stellar mass, gas mass, black hole mass, stellar velocity dispersion, star formation rate and stellar metallicity. The stellar mass and gas mass are taken from the central 30 kpc of each subhalo to allow better comparison with observations. We transform all of these predictors into log space, which has been shown to improve the prediction accuracy due to the typically large dynamic range of cosmological properties (Jo & Kim 2019). If the value is zero, we set it to some small value, determined by the resolution limit where appropriate,

$$
\frac{M_i}{M_{\odot}} \geq 1 \times 10^5 \quad M_{\text{gas}}/M_{\odot} \geq 5 \times 10^5 \quad M_{\bullet}/M_{\odot} \geq 2 \times 10^4 \\
\text{SFR}/M_{\odot} \, \text{yr}^{-1} \geq 1 \times 10^{-4} \quad Z_{*} \geq 5 \times 10^{-7} \quad v_{*,\text{disp}}/\text{km s}^{-1} \geq 3 .
$$

3.3 Training

We train our model on all haloes with a dark matter mass (as measured in the DMO simulation) $M_{\text{sub}}/M_{\odot} \geq 1 \times 10^{10}$. The completeness of our selection with respect to stellar mass is shown in detail in Appendix A. By applying our selection to the dark matter properties we can use the same thresholds when applying the model to independent dark matter only simulations. We split our data into training and test sets, 80-20% respectively. All hyperparameter optimisation, parameter scaling, and training is done on the training set, and only final model assessment is performed on the test set. For each feature set, the hyperparameters of the ERT instance are chosen through an exhaustive grid search. For each set of hyperparameters, $k$-fold cross validation is performed (Stone 1974) with $k = 10$ folds, and the coefficient of determination, $R^2$, is used to discriminate,

$$
R^2 = 1 - \frac{\sum_i (X_{i,\text{test}} - X_{i,\text{predicted}})^2}{\sum_i (X_{i,\text{test}} - X_{\text{mean,train}})^2} .
$$

We standardise all of our features and predictors by subtracting the mean and scaling to unit variance.

4 PREDICTING BARYONIC PROPERTIES FROM DARK MATTER PROPERTIES

We first present results for the LO50AGN+ZoomAGN model, with the fiducial feature set (excluding environmental features). Figure 3 shows the predicted against the true value for the six baryonic properties in the test set. Figures 4, 5 & 6 compare the predicted and true distribution of these properties in the test set as violin plots\(^2\). Together, these figures show how accurately the model predictions are, and how well the cosmic distribution is reproduced. We also quote the fraction of galaxies where the predicted value is within 0.2 dex of the true value; for the stellar velocity dispersion this is as high as 97%, but even for the gas mass, which has the lowest prediction accuracy, this is still close to two thirds of the sample (65%). This is comparable to the accuracy achieved in Neistein et al. (2012) in their SAM trained on a hydro simulation, though we push our predictions to lower stellar masses.

To qualitatively demonstrate the accuracy of the ERT

\(^2\) Bin width of the kernel density estimate is calculated using Scott’s rule (Scott 1979).
model, we compare to predictions utilising a single feature (subhalo mass or $V_{\text{max}}$), analogous to a SHAM approach. For this single feature we fit an isotonic regression model\(^3\) between the feature and each predictor (for the whole dataset, not just training). This model ensures monotonicity, and broadly fits each predictor well considering the simplicity of the model. We again quote the fraction of galaxies where the predicted value from this simple relation is within 0.2 dex of the true value. The ERT model shows greater accuracy for all predictors compared to the Isotonic model, whether subhalo mass or $V_{\text{max}}$ are used. This is particularly the case for the gas mass (49\% where $V_{\text{max}}$ is used, compared to 65\% for the ERT model). Full details on the Isotonic fits, and comparison to the predicted GSMF and projected correlation function, are provided in Appendix B.

The model is able to accurately predict both the stellar mass and stellar velocity dispersion remarkably well, however there is more structure in the joint plots for other properties. Predictions for the stellar metallicity show a greater spread than the other values, perhaps unsurprisingly due to its known complex dependence on the star formation history, however the violin plot shows that the overall distribution is recovered. Black hole masses in EAGLE are dominated by newly formed black holes at the seed mass ($10^5 M_\odot$), as more haloes reach the mass-threshold for black hole seeding. The model is able to capture these, and does a reasonable job of predicting the masses of more massive black holes.

The relations for the total gas mass and SFR are more complicated. There are a large number of galaxies with zero star formation, and the right panel of Figure 5 shows that the model predicts a range of SFRs for these galaxies, though the majority are limited to $<3 \times 10^{-3} M_\odot \text{yr}^{-1}$. To see how well the model predicts the distribution of star forming galaxies, we show in the middle panel of Figure 5 the distribution of SFR ignoring quiescent galaxies. It is clear that the model underpredicts the SFR for most galaxies. This may be due to the quiescent galaxies biasing the predictions for other haloes, as well as ERT predicting a smooth distribution of SFRs when a discontinuous distribution would be more appropriate. The SFR is also known to be more strongly dependent on the assembly history; including features that encode this may lead to better predictions, which we discuss in Section 7.

Figure 6 shows that, as for the SFR, there is a reasonably tight relation for the total gas mass, except where galaxies have zero gas mass. These galaxies make up a large proportion of all subhaloes, and the model fails to predict low gas masses for these galaxies, instead predicting a wider range of gas masses, as can be seen in the right panel of Figure 6. This suggests that the physics that causes the evacuation of gas from low mass haloes is not encoded in the provided dark matter parameters. However, the overall distribution, when renormalised, better reproduces that seen in the test set compared to the SFR.

\(^3\) see here for details on the Isotonic regression model employed.
To demonstrate the impact of adding the C-EAGLE clusters to our training set, we compare the prediction accuracy against models trained only on the periodic volumes. Figure 7 shows the Pearson correlation coefficient for the L100Ref, L050AGN and L050AGN+zoom models. Adding the zoom regions leads to a large increase in the training set size, but this has no significant positive effect on the predictive accuracy for any of the features. In fact, for the gas mass, black hole mass and stellar metallicity the predictive accuracy is actually worse. This may be due to the unique impact of the cluster environment on these three particular baryonic properties of galaxies, for example through the effect of ram pressure stripping and fly-by interactions. So while there is more data for the machine to learn from, the relationship represented is more complicated than that present in the periodic volumes, and therefore more difficult to predict. We stress that in order to make predictions for larger boxes, it is essential to include these environments in the training set, and that a lower predictive accuracy compared to the periodic volumes is not necessarily indicative of a poorer model.

This does not suggest that adding more data does not improve the predictive accuracy - $\rho_{\text{pearson}}$ calculated for L100Ref is higher than than for L050AGN for all baryonic properties, showing the advantage of a larger training set size where the underlying distribution of galaxy properties is broadly similar.

4.1 The effect of including local density in the feature set

We add four features for the local density calculated within spheres with radii $R = [1, 2, 4, 8]$ Mpc. Figure 7 also shows the impact of including these additional features on the predictive accuracy for the L050AGN, L100Ref and L050AGN+zoom simulation sets. Including density information has a minor positive impact on the predictive accuracy of all features for almost all simulation sets, though the quantitative impact is
small in most cases. The largest impact is seen for the gas mass, with an increase in \(\rho_{\text{Pearson}}\) of approximately +0.05 for the periodic simulation sets, and +0.07 for the L050AGN+Zoom simulation set. This fits with the hypothesis suggested above that environmental effects operating in clusters lead to poor predictions for the gas mass when environmental features are not included. Such features are important for accurately predicting specific baryonic properties.

In summary, our model is capable of predicting a range of baryonic properties with reasonable accuracy, and successfully reproduces their cosmic distributions. We now show how the model can be applied to independent, larger DMO volumes, and the impact of including the zoom regions on the predicted relations.

5 APPLICATION TO DMO SIMULATIONS

A key aim of the model is to produce predictions for distribution functions and clustering statistics for much larger volumes than can be achieved using periodic hydrodynamic simulations. To this end we test how well our model produces the two-point galaxy correlation function (2PCF), galaxy stellar mass function (GSMF), star-forming sequence, stellar mass – metallicity relation and the stellar mass – black hole relation in independent DMO volumes, including the (800Mpc\(^3\)) P-Millennium simulation.

5.1 The Two-Point Galaxy Correlation Function

Galaxy clustering measurements provide a powerful means of testing gravity and cosmological parameters, including the contribution of dark energy, as well as the impact of galaxy bias on galaxy formation and evolution. One of the key statistics for measuring clustering is the spherically averaged two-point correlation function (2PCF) (Peebles 1980), defined as

\[
\xi(r) = \frac{1}{\langle n \rangle} \frac{dP}{dV} - 1, \quad (3)
\]

where \(\langle n \rangle\) is the mean comoving number density of galaxies, and \(dP/dV\) is the probability of finding a galaxy in volume \(dV\) at comoving distance \(r\) from another galaxy. For redshift surveys, where the line-of-sight distance is inaccessible, this is often split into projected and line-of-sight distance components, which can be used to estimate the projected correlation function (Davis & Peebles 1983),

\[
w_p(r_p) = 2 \int_0^{r_{\text{max}}} \xi(r_p, \pi) d\pi, \quad (4)
\]

where \(r_{\text{max}}\) is the maximum distance along the line-of-sight. Since \(w_p(r_p)\) is robust against redshift space distortion effects it is better suited for comparisons with simulations.

Simulation studies of galaxy clustering are typically carried out on large scales with DMO simulations or relatively lower resolution hydrodynamical simulations (e.g. BAHAMAS; McCarthy et al. 2017), and on smaller scales using high-resolution hydrodynamical simulations, which can resolve the baryonic feedback effects on haloes (see van Daalen et al. 2014). We here see how well our machine learning model can provide predictions on both large and small scales simultaneously by applying the model to the large-volume P-Millennium simulation. We estimate errors on our clustering statistics using jackknife resampling of each simulation volume (for details, see Artale et al. 2017).

Figure 8 shows the projected 2PCF measured on the L100Ref simulation, the L050AGN+Zoom model applied to the P-Millennium simulation, and compared to observational results from GAMA (Farrow et al. 2015) in different stellar mass bins. As shown in Artale et al. (2017), the L100Ref simulation is in good agreement with the observational constraints on small scales up to stellar masses of \(10^{11} M_\odot\). However, on larger scales \((r_p > 3h^{-1}\text{Mpc})\) there is a deficit in the normalisation, attributed to finite-volume effects; the smaller periodic boxes do not sample the largest modes in the power spectrum. There are also too few galaxies above a stellar mass of \(10^{11} M_\odot\) in L100Ref to obtain robust clustering statistics.

The L050AGN+Zoom model, applied to the much larger volume P-Millennium simulation, shows no such deficit at the largest scales. We are in fact able to make predictions out to scales of \(100h^{-1}\text{Mpc}\), a factor of ten larger than achievable with the periodic simulations. The model is also able to make predictions for the clustering of the most massive galaxies, \(> 10^{11} M_\odot\), since there are sufficient numbers of these galaxies to produce reliable statistics.
Figure 8. Projected correlation function in bins of stellar mass; the mass range is indicated in each column. The results from L100Ref are shown in blue, and the L050AGN+Zoom machine learning model predictions on P-Millennium are shown in orange. Observational results from GAMA (Farrow et al. 2015) are shown in grey. Errors are estimated using jacknife resampling of each simulation volume.

There is, however, a small deficit in the normalisation at the smallest scales in the lower mass bins for the L050AGN+Zoom model (outside the estimated errors). This may be due to a number of effects, one being the lower resolution of the P-Millennium simulation, which may lead to sub-structures on small scales being smoothed out. To test the impact of this we applied the L050AGN+Zoom model to the DMO 100Mpc box (using the same initial conditions as the L100Ref simulation), which has a mass resolution $\sim 10 \times$ higher. This is shown in Figure 8; at the largest scales the model shows the same deficit as the L100Ref simulation, due to the smaller box size. However, at small scales there is the same deficit as in the L050AGN+Zoom model applied to P-Millennium. This confirms that it is not resolution effects leading to the lower amplitude.

An alternative explanation is the well known effect of baryons on their host dark matter haloes (e.g. Velliscig et al. 2015; Schaller et al. 2015). This may not only affect the masses of haloes, but also their mass distribution, changing the substructure on small scales, and hence the clustering measurement (van Daalen et al. 2014; Hellwing et al. 2016). To test whether this is causing the lower normalisation at small scales, we extract a catalogue of features from the full hydro simulation (L100Ref) and use these as inputs to the L050AGN+Zoom model. We emphasise that these ‘halo’ features contain the contribution from both baryons and dark matter, but are otherwise identical to the features from a DMO simulation. The predicted clustering for this hybrid model application is shown in the second panel of Figure 8; the normalisation matches that of the L100Ref simulation, confirming that it is indeed baryonic effects causing the lower normalisation on small scales. We stress that this is not strictly a fair use of the machine learning model, as it was trained on haloes from a DMO simulation, and as such the predictions should be taken with some caution. However, we argue this is a relatively ‘clean’ test of the impact of baryons on the halo, and the knock on effect on the clustering.

Other effects may also contribute to the deficit, such as differences in the parameters of the halo finder between DMO and hydro simulations, and for different resolution simulations. However, it seems clear that baryonic effects on haloes...
Mapping baryons onto dark matter haloes

5.2 The Galaxy Stellar Mass Function

The left panel of Figure 9 shows the L050AGN model run on the L100Ref DMO simulation. We compare to the GSMF from the hydrodynamic L100Ref simulation, and it is clear that the high mass end of the GSMF is not reproduced. Whilst there are parameter differences between the models, it is not expected that the AGNdT9 model would fail to produce any $10^{12} M_\odot$ galaxies in a $(100 \text{ Mpc})^3$ volume. In fact, the predictions broadly follow the model used for training, L050AGN, though underestimate the abundance of galaxies at the high-mass end ($> 10^{11} M_\odot$). This additional underestimate is likely the result of a lack of training data at the high-mass end, due to the low number of high-mass galaxies in the L050AGN volume.

However, if we use the L050AGN+Zoom model we get much better agreement with the L100Ref simulation at the high-mass end. This demonstrates the effect of including the C-EAGLE zoom regions; the model is able to learn the baryonic properties of galaxies in the cluster regions, which are not present in L050AGN. Predictions at lower stellar masses are also consistent with both L100Ref and L050AGN down to $\sim 10^8 M_\odot$, the approximate resolution limit of the original simulations (Schaye et al. 2015), and where our predictions are approximately complete (see Appendix A).

We now turn our attention to the much larger P-Millennium DMO simulation. The right panel of Figure 9 shows predictions for the L050AGN and L050AGN+Zoom models on this volume, and whilst the former still completely misses the high mass end, the model including zooms is able to predict stellar masses out to $\sim 10^{12} M_\odot$. This extends the dynamic range of the GSMF beyond that accessible to the L100Ref hydrodynamic simulation, and improves the statistics significantly. This is a significant achievement of the model – it is able to successfully extend the predictive range beyond that achievable with periodic hydrodynamic simulations. At lower stellar masses the predictions are consistent with both L100Ref and L050AGN. The predictions at the high mass end are also in broad agreement with the observational constraints from Baldry et al. (2012).

The P-Millennium simulation is lower resolution than those used for training, which may impact the predicted properties of galaxies, particularly those close to the resolution limit. To test the impact of resolution, we applied the L050AGN+Zoom model to a lower resolution $(100 \text{ Mpc})^3$ DMO run, with 8 times...
fewer particles. The predictions for the GSMF were identical, which confirms that differing resolution has no impact on the predicted properties; as long as the haloes are resolved, the halo features used for prediction are robust.

5.3 The black hole – stellar mass relation

We have demonstrated how the model is able to predict stellar masses with high accuracy, and produce a GSMF for the P-MILLENNIUM simulation volume. We now explore other key baryonic distribution functions. Figure 10 shows the black hole – stellar mass relation, the stellar mass – metallicity relation, and the star-forming sequence. Each panel shows the relation in the L100Ref, L050AGN & L050AGN+Zoom simulations, as well as the predicted relation for our L050AGN+Zoom model, with fiducial feature set, run on the P-MILLENNIUM simulation.

The black hole – stellar mass relation shows a rapid increase in the stellar mass above $M_\star \sim 10^{10} M_\odot$, though the exact mass at which the relation turns upwards is dependent on the simulation. In L050AGN+Zoom the increase is at a higher mass compared to the two periodic simulations. This is not due to any parameter differences, since L050AGN has identical parameters, but may be due to the cluster environment delaying black hole accretion by starving the central regions of a galaxy of gas. Though van Son et al. (2019) note an excess of ‘black hole monster galaxies’ in cluster environments due to tidal stripping, this is a sub-dominant population compared to the main relation, so it does not increase the normalisation of the black hole – stellar mass relation in these environments. The model predictions lie between the periodic and zoom relations, which is perhaps expected since both environments are providing training data from which the machine is making its predictions. Overall the relation is predicted remarkably well, and the predictions extend the dynamic range to higher stellar and black hole masses than those achievable in L100Ref & L050AGN. At these higher masses the model is in good agreement with the observational results of McConnell & Ma (2013), though the scatter at fixed stellar mass is still underpredicted (as seen in Schaye et al. 2015).

5.4 The stellar mass – metallicity relation

Predictions from the model for the stellar mass – metallicity relation show similar behaviour. The model predictions lie between the relations from the periodic and zoom simulation sets at high stellar masses ($M_\star / M_\odot > 10^{10}$), but closely follow the predictions below this, except at the very lowest stellar masses.

The scatter in both these relations is much tighter for the model predictions than in the original simulation sets. This is a reflection of the deterministic nature of the machine learning prediction, combined with the relatively limited feature set, which has been discussed in a number of previous works (e.g. Kamdar et al. 2016b; Moews et al. 2020). Historical halo features, such as the formation and assembly time, may help to increase the diversity of baryonic properties at fixed stellar mass. However, the predictions still lie within the uncertainties on observational constraints from Gallazzi et al. (2005) at all stellar masses.

5.5 The star forming sequence

Finally, the right panel of Figure 10 shows the star-forming sequence, excluding passive galaxies ($sSFR < 10^{-11} \text{yr}^{-1}$). As shown in Figure 5 the model tends to underpredict SFRs of star forming galaxies, and this is reflected in the star-forming
sequence, where the normalisation at $M_*/M_\odot = 10^{11}$ is lower than that in the original simulation sets, by up to -0.8 dex compared to L050AGN+Zoom. The scatter at fixed stellar mass is comparable to the simulation sets ($\pm 0.25$ dex), though this may be partly due to truly quiescent galaxies in the simulation sets that have residual star formation when predicted in the model. In general, however, the star forming sequence is broadly reproduced, is in good agreement both above and below the characteristic mass, and lies within the uncertainties on observational constraints from Bauer et al. (2013).

Figure 11. Matrix showing the relative importance (0 → 1, low to high importance) of each feature (y-axis) for each predictor quantity (x-axis), for the L050AGN+Zoom model. The importance is normalised by the maximum for each predictor.

6 FEATURE EXPLORATION

Feature importance in ERT can be evaluated from the relative position of a given feature in the tree; the closer to the root node in the ensemble of trees, the higher the importance. In order to evaluate the feature importance for each predictor, we re-train the model on each predictor individually. Figure 11 shows a matrix of each predictor against each feature, coloured by their relative importance. The order of relative importance is generally the same for all predictors. $V_{\text{max}}$ is by far the most important feature; Kamdar et al. (2016b) attributed a similarly high importance for $V_{\text{max}}$ in their machine learning model trained on Illustris. A number of other studies have highlighted the importance of $V_{\text{max}}$ for predicting baryonic properties. (Matthee et al. 2017) showed that, in EAGLE, $V_{\text{max}}$ is a key predictor of the stellar mass, more so than the halo mass, Chaves-Montero et al. (2016) use a subhalo abundance matching technique to test the recovery of the clustering of galaxies in EAGLE and find a similarly strong dependence on $V_{\text{max}}$. The circumgalactic medium mass fraction, at fixed halo mass, has also been shown to correlate strongly with $V_{\text{max}}$ (when parametrised as a ratio with the virial circular velocity, closely related to the halo binding energy), in both EAGLE and Illustris (Davies et al. 2018, 2020; Oppenheimer et al. 2019); the authors of these studies argue that a high $V_{\text{max}}$ corresponds to an early collapse time for a halo, which leads to greater black hole growth, which in turn ejects more of the circumgalactic medium mass. This has a big impact on the latter baryonic properties of the galaxy, such as its star formation history and morphology. This explains the strong importance of $V_{\text{max}}$ in our feature set for the majority of our baryonic predictors.

Interestingly, for the gas mass, the half-mass radius is instead the most important feature. $V_{\text{max}}$ is still of high importance, but at a similar level to the subhalo mass and total halo mass ($M_{\text{crit,200}}$). This suggests that the size of the underlying dark matter halo is closely related to its current gas mass. A similarly strong correlation between (HI) gas mass and size has been found observationally, though with the stellar component rather than dark matter (Catinella et al. 2012).

The peculiar velocity is the least important feature for all predictors, as expected. Interestingly, features that encode the local halo environment, such as $M_{\text{crit,200}}$ and its status as a satellite or central, are also two of the least important features. This suggests that the properties of the subhalo itself mostly determine the baryonic properties, however this does not necessarily mean that ‘nature’ rather than ‘nurture’ is the dominant evolutionary process. Instead, other subhalo features may encode environmental information, e.g. satellites are clear outliers in the $M_{\text{crit,200}} - M_{\text{subhalo}}$ plane.

We also evaluated the effect of including local density features, $\rho(R)$. Figure 12 shows the feature importance for all predictors, in the L050AGN and L050AGN+Zoom machine learning models. None of these local features dominates the
feature importance, but the density on intermediate scales ($R = [2.4 \text{ Mpc}]$) has a higher importance than on the smallest and largest scales ($R = [1, 8 \text{ Mpc}]$, respectively). The order of feature importance is otherwise mostly preserved.

7 DISCUSSION & CONCLUSIONS

We have demonstrated the effectiveness of machine learning methods in modelling the complex relationships between galaxies and their host haloes by training a machine learning model to directly learn this mapping. By combining hydro and DMO simulations we avoid baryonic effects on haloes that would bias predictions. And by using a training set consisting of both periodic and zoom simulations of galaxy clusters, we include rare environments that may not be present in typical periodic simulations, allowing the model to be applied to much larger volume dark matter-only simulations, increasing the dynamic range, and allowing the evaluation of clustering statistics over much larger scales. Our conclusions are as follows:

- The model successfully predicts the stellar mass, stellar velocity dispersion and black hole mass, and provides reasonable predictions for the star formation rate, stellar metallicity and total gas mass. Even where the stellar metallicity shows some dispersion in the prediction, the overall distribution is recovered.
- Star formation rates and gas masses are biased low due to the effect of quiescent, gas poor galaxies, and some suggestions for improving this are put forward, including the use of historical halo features.
- Adding features representing the local density leads to a negligible increase in the predictive accuracy for most properties, except the gas mass, which shows significant improvement, particularly in cluster environments.
- We apply the trained model to the P-MILLION simulation and analyse the projected two-point correlation function. We are able to predict the clustering of galaxies out to much larger scales than in the periodic hydro simulations ($> 10^{7} \text{ Mpc}$), as well as analyse the clustering of rarer, high-mass galaxies, and find that EAGLE is in good agreement with observational constraints from GAMA on large scales. On smaller scales we conclude that baryonic effects on haloes affect the clustering statistics.
- The predicted galaxy stellar mass function is in excellent agreement with that given by the periodic hydro simulations at low and intermediate masses, and extends the relation to higher masses.
- The black hole – stellar mass and stellar mass – metallicity relations are well reproduced, though with less scatter, as seen in other machine learning models.
- The normalisation of the star-forming sequence is slightly under-predicted at the characteristic mass, which reflects both the lower normalisation in the training data, but also the lower predicted stellar masses on the test set. However, the general form is in good agreement.
- $V_{\text{max}}$ is the most important feature in all simulation sets. Measures of the local environment, such as the satellite flag, host halo mass and local density, do not show high importance in any of the models.

We stress that our model is not intended as a replacement of traditional galaxy formation models: it is in fact wholly reliant on such models to train from. It does, however, provide a means of expanding the predictions from such models to much larger periodic volumes. These larger volumes are useful for a number of science questions. Galaxy clustering is a particularly important application we have demonstrated here, allowing us to test the clustering statistics of high-resolution hydrodynamic simulations in the high-mass, large-separation regime. As demonstrated by Jo & Kim (2019), additional features, such as the halo merger history and its assembly and formation time, are expected to have a significant positive impact on the prediction accuracy. Whilst we have found that features describing the local environment are not highly important, additional parameters describing, for example, the tidal shear (e.g. Lucie-Smith et al. 2019), may also encode more useful information for the machine to learn from. It may also be possible to make predictions at multiple redshifts simultaneously by providing the machine with the scale factor, as demonstrated in Moster et al. (2020).

The C-EAGLE sample provides a wealth of training data on rich cluster environments, however those environments on the opposite end of the overdensity distribution, extreme underdensities or cosmic voids, are less well sampled in our training set. Void regions do not have as obvious an effect on their constituent galaxies properties as rich cluster environments, where galaxy mergers are far more common and extreme processes such as ram-pressure stripping occur, however noticeable effects are still seen in voids in the fiducial periodic EAGLE volumes (Paillas et al. 2017; Xu et al. 2020). Larger, more significantly underdense regions are, as for overdense regions, not well sampled in the periodic volumes, however such voids are an important constituent of the universe, making up $\sim 60\%$ of the cosmic volume (Pan et al. 2012). In future work we will use resimulations of a range of overdensities down to low redshift to better populate this region of overdensity space, reducing generalization errors for galaxies in these environments.

We have focused on six key baryonic properties, but other baryonic properties are simple to add, as well as the emission properties of galaxies if combined with post-processing pipelines. This will allow for the construction of extremely large lightcones (as demonstrated in Hearin et al. 2020, using their empirical modelling plus simulation-calibrated approach), necessary for making predictions for wide field surveys from the upcoming Roman and Euclid space-based observatories (Potter et al. 2017). To this end, in future work we will explore predictions during the epoch of reionisation, where we will leverage the FLARES simulations (Lovell et al. 2021). A unique aspect of FLARES is that it consists of resimulations of a range of overdensities, providing training data in extreme over- and under-dense environments, which may aid predictions of galaxy properties across all environments.

ACKNOWLEDGEMENTS

The authors wish to thank the anonymous referee for a detailed report that improved this manuscript. We also wish to thank Daniel Farrow for providing the GAMA clustering data, John Helly for help reading the P-Millennium data, and Aswin Vijayan, Rob Crain, Joop Schaye and Scott Kay for helpful comments and discussions. Thanks also to the
EAGLE team for their efforts in developing the EAGLE simulation code. We acknowledge the following open source software packages used in the analysis: scipy (Virtanen et al. 2020), Astropy (Robitaille et al. 2013), matplotlib (Hunter 2007), seaborn (Waskom 2021) and halotools (Hearin et al. 2017, v0.7).

DATA AVAILABILITY

The public EAGLE database can be used to access the subhalo properties for the periodic hydrodynamic simulations in this paper (McAlpine et al. 2016). Other data underlying this article will be shared on reasonable request to the corresponding author. The code used to train and analyse the models, and produce all plots, is made available at github.com/christopherlovell/ML-cosmo.

APPENDIX A: STELLAR MASS COMPLETENESS

Before model training we pre-select haloes based on their dark matter properties only, to ensure the same selection can be applied to any DMO simulation the model is applied to. This is intended to avoid a situation where a model is applied to haloes with properties that were not present in the training set. Since the selection is done on DMO properties only, we here check whether galaxies below the resolution limit in the hydro simulation are included, and the incompleteness of galaxies above the resolution limit. Figure A1 shows a histogram of stellar mass in the L100Ref simulation for different DMO subhalo mass limits from the matched subhalo list. The grey shaded area designates the stellar mass resolution limit (M⋆/M⊙ > 1.8 × 109, or 100 star particles at the initial baryon mass).

In order to provide a qualitative assessment of the ERT model we choose to fit a simple model to the relationship between each predictor and a single feature. We use subhalo mass and Vmax as our chosen features as these are commonly used in SHAM approaches. We fit each relation with an Isotonic regression model, which ensures monotonicity. We do this for the training set, and evaluate the performance on the test set. Each relation, and the corresponding fits, are shown in Figure B1. The percentage of galaxies where the predicted value is within 0.2 dex of the true value is quoted in each panel. In each case this percentage is lower than that achieved with the ERT model.

We also show the pearson correlation coefficient for the

Figure A1. Histogram of stellar masses in the L100Ref simulation for different DMO subhalo mass limits from the matched subhalo list. The grey shaded area designates the stellar mass resolution limit (M⋆/M⊙ > 1.8 × 109, or 100 star particles at the initial baryon mass).

APPENDIX B: ISOTONIC FITS TO A SINGLE FEATURE

In order to provide a qualitative assessment of the ERT model we choose to fit a simple model to the relationship between each predictor and a single feature. We use subhalo mass and Vmax as our chosen features as these are commonly used in SHAM approaches. We fit each relation with an Isotonic regression model, which ensures monotonicity. We do this for the training set, and evaluate the performance on the test set. Each relation, and the corresponding fits, are shown in Figure B1. The percentage of galaxies where the predicted value is within 0.2 dex of the true value is quoted in each panel. In each case this percentage is lower than that achieved with the ERT model.

We also show the pearson correlation coefficient for the
ERT model as well as the Isotonic regression model for each feature in Figure B2. The ERT model outperforms the Isotonic regression model for all predictors, though the performance is comparable using $V_{\text{max}}$ for the stellar mass, stellar velocity dispersion, and stellar metallicity. This is expected from the strong correlation between the predictor and $V_{\text{max}}$ in each of these cases, shown in Figure B1. Figure 11 also shows that these three predictors are particularly dependent on $V_{\text{max}}$, whereas other predictors have greater contributions from other features. It is also interesting to see that subhalo mass is the more accurate predictor for gas mass, black hole mass and star formation rate compared to $V_{\text{max}}$, which highlights that using one or the other feature in a SHAM approach may not lead to optimised predictions for all galaxy features – the ML approach, on the other hand, simply incorporates all features, and chooses the best for each predictor.

In Figure B3 we show the impact of using the Isotonic regression model (using subhalo mass as the feature) on the projected correlation function and the GSMF. The GSMF is mostly reproduced, as expected due to the strong correlation between feature and predictor. However, the projected correlation function (for $11 < M_\star/\text{M}_\odot < 11.5$) shows a deficit in the normalisation compared to the ERT model, particularly on small scales. One explanation is that high mass satellite galaxies, which are not common in the training set, may be more common in the larger P-Millennium volume. The ERT model then handles these objects better than the Isotonic model, utilising other features that are more important in these environments (e.g. the satellite flag).

This paper has been typeset from a TeX/LaTeX file prepared by the author.

Figure B1. Relations between features commonly used in SHAM approaches (Subhalo mass and $V_{\text{max}}$: x-axis) and each predictor (y-axis). Each panel shows a 2D histogram of the distribution (blue) alongside a fitted monotonic linear relation (black line). The percentage of galaxies where the predicted value is within 0.2 dex of the true value is quoted in each panel.
Figure B2. Pearson correlation coefficient for the ERT model (L050AGN+ZoomAGN) as well as isotonic regression models trained using subhalo mass and $V_{\text{max}}$. Each predictor is shown on the x-axis.

Figure B3. Predictions for the projected correlation function (top panel) and galaxy stellar mass function (bottom panel) using the isotonic regression model (using subhalo mass; brown lines), compared to the ERT model (blue) with all features.
