1. Introduction

Metal nanoparticles dispersed on solid oxide supports are increasingly applied in a wide range of applications such as heterogeneous catalysis, electrochemical conversion and photocatalysis. Bimetallic nanoparticles, composed of two metal species, often show distinct catalytic properties and stability as compared to individual metals, which is typically ascribed to changes in the electronic and/or geometric structures that occur when the metals are combined. Bimetallics are usually prepared by assembly or co-deposition methods and varying their particle size, composition (ratio of metals involved), structure (alloys, core–shells, heterostructures, etc.) and morphology, can lead to a wide range of functional materials.

Redox exsolution, an alternative to assembly and deposition methods, has the potential to produce supported metal nanoparticles with combined high activity and stability. In this method, active species are substituted in a perovskite oxide matrix and subsequently emerge as metal nanoparticles at the surface, normally driven by thermal or electrical reduction. Exsolved nanoparticles are epitaxially grown from the parent oxide and partially socketed in it. This results in a strained particle-oxide interface which endows the nanoparticles with enhanced stability against sintering and can also enhance resistance to poisoning by carbon deposition and sulfur, as well as high activity.

Co-exsolution of two metals, while less studied than single metal exsolution, can lead to attractive structures and functionality, including synergistic effects between the two co-exsolved metals. There are roughly 70 papers on bimetallic exsolution published in the past decade, from which statistical information on the compositions and applications of the exsolved bimetallics is extracted. The Fe-containing compositions are the overwhelming majority followed by Ni-based systems (Figure 1a). However, other bimetallic compositions have also been occasionally reported, as well as alloys containing more than two metals and more complex heterostructures. Interestingly, there are no bimetallic materials containing two noble metals reported. The use of bimetallic exsolved systems spans over all kinds of applications including but not limited to electrochemistry (71%), catalysis (19%) and membranes (3%) (Figure 1b). Among these, electrochemistry is the most common application but there are also a few studies focusing on catalytic applications such as methane conversion, CO oxidation or the water-gas-shift reaction.

In spite of these exciting developments, to the best of our knowledge, there is no review that summarizes the advances on bimetallic exsolution. Here we aim to review the trends that underpin the exsolution of bimetallic systems in terms of design, tailoring and application and propose future directions for the development of the field.

2. Mechanism of Alloy Exsolution

Simultaneous exsolution of two or more reducible metal species from an oxide backbone will, in most instances, lead to the formation of alloy particles as evidenced by modelling studies. Generally, two possible exsolution mechanisms exist, namely the “bulk alloy formation” and “surface alloy formation” as schematically illustrated in Figure 2a and b, respectively. Exsolution is promoted by the oxygen vacancies introduced by

Gibbs energy of reduction is a function of the strength of the metal-oxygen bonds of both substituted metals and hence the energy can be decreased by introducing more reducible ions (Figure 2d).¹¹c–e Besides, it is also reported that doping of Co...

Kalliopi Kousi received her degree in Chemistry from the University of Patras, Greece in 2011. She has an MRes (2013) and a PhD (2016) on 'Catalysis for Environmental Protection and Clean Energy Production' and has worked as post-doctoral research associate at the department of Chemical Engineering focusing on catalysts for LPG conversion. She joined The Application of Ion Transport Group at Newcastle University as a post-doctoral research associate in April 2017. Her research interest lies in new materials and structures for different catalytic applications, currently focusing on emergent nanomaterials for energy conversion processes.

Dragos Neagu obtained his degree in chemical engineering from University Politehnica of Bucharest, Romania, in 2008. He received his PhD on materials and devices for electro-chemical energy conversion from the University of St Andrews, UK in 2013. He then worked as a postdoctoral researcher at the University of St Andrews and Newcastle University. In 2020 he joined the University of Strathclyde as Lecturer in the Department of Chemical and Process Engineering. His research interests are in the design, preparation, multiscale characterization and application of nanostructured, functional materials for renewable energy conversion technologies.

Ian Metcalfe obtained his first degree in chemical engineering from Imperial College and then studied at Princeton University. He is currently Professor of Chemical Engineering at Newcastle University. Ian is a Fellow of the Institution of Chemical Engineers and a Fellow of the Royal Society of Chemistry. He was elected a Fellow of the Royal Academy of Engineering (RAEng) in 2012. He currently holds an RAEng Chair in Emerging Technologies. His research concerns the thermodynamics of chemical conversion with an emphasis on energy processes. He has a particular interest in membrane processes, solid–gas reactions and solid state chemistry.
increases the total energy of the perovskite system and the Co–Fe bond would form more easily than the Fe–Fe bond due to the lower formation energy, which also accounts for the promoting effects of Co on the Fe exsolution.\textsuperscript{[11f]}

3. Bimetallic Alloy Nanoparticle Systems

Generally, in perovskite-based systems the A-site stoichiometry dictates which types of exsolution can occur: irreversible or reversible (also called intelligent concept). In the latter, the original matrix is stoichiometric and thus upon exsolution the thermodynamically stable perovskite segregates into a less thermodynamically stable mixture of A-site oxide and B-site exsolved components. Thus, these phases could recombined, giving the exsolved nanoparticles the ability to re-dissolve depending on the environmental conditions, in turn leading to materials with high durability due to the fact that they can regenerate. This applies both for single metals\textsuperscript{[22]} as well as for bimetallic systems.\textsuperscript{[6a, 7g, h, 10, 11c, e, 13]}

For example, Fe–Co nanoparticles from La\textsubscript{0.7}Sr\textsubscript{0.3}Fe\textsubscript{2}Co\textsubscript{0.3}O\textsubscript{3} were found to completely redisolve into the perovskite when re-oxidized at 800 °C while they remained on the surface as transition-metal oxide at 700 °C\textsuperscript{[3g]}. On the other hand, during exsolution from A-site deficient perovskites which are thermodynamically metastable, A-site stoichiometric perovskite forms alongside the exsolved particles which makes re-dissolution less likely and thus this exsolution irreversible. Moreover, nanoparticles exsolved from A-site deficient perovskites are partially socketed in the surface and less likely to redissolve into the perovskite lattice under re-oxidation leading to coking resistant, highly active materials mainly due to the alignment and socketting between the support and the exsolved particles.\textsuperscript{[3, 5]} For example, Ni–Co nanoparticles exsolved from La\textsubscript{0.7}Sr\textsubscript{0.3}Co\textsubscript{2}Ni\textsubscript{0.1}Ti\textsubscript{0.9}O\textsubscript{3} did not redissolve when treated under oxidizing conditions, but demonstrated coking resistance and matched noble metal commercial catalysts in automotive exhaust reaction conditions.\textsuperscript{[9c]}

The reversible/intelligent exsolution method accounts for about 15% of the total papers published until today on bimetallic exsolution systems,\textsuperscript{[15]} giving the exsolved nanoparticles the ability to re-dissolve depending on the gas environment, which in turn leads to materials with high durability due to the fact that they can regenerate. This applies both for single metals\textsuperscript{[22]} as well as for bimetallic systems.\textsuperscript{[6a, 7g, h, 10, 11c, e, 13]}

Adapted with permission.\textsuperscript{[20]} (b) HRTEM image showing socketed interface between a exsolved Fe–Ni particle and a SrFe\textsubscript{1.3}Ni\textsubscript{0.7}O\textsubscript{3} substrate. (c) Enhanced CO\textsubscript{2}RR performances due to exsolution of Fe–Ni nanoparticles. DFT calculations showing (d) the energies of CO\textsubscript{2}RR over the perovskite surface and the interface between the exsolved Fe–Ni and the perovskite, and (e, f) the optimized reaction pathway at the metal-support interface (magenta sphere and circle represent oxygen atom and vacancy involved in the reaction, respectively). Adapted with permission.\textsuperscript{[14]}

Exsolved Fe–Ni alloys have demonstrated excellent catalytic activity, durability and resistance to coking and sulfur poisoning when used as anode materials for SOFCs.\textsuperscript{[3a,b, 7c, d]} For instance, Sr\textsubscript{0.65}Fe\textsubscript{0.2}Mo\textsubscript{0.35}O\textsubscript{3.5} was found to partially decompose to a mixed Ruddlesden–Popper (RP) type layered Sr\textsubscript{0.65}Fe\textsubscript{0.2}Mo\textsubscript{0.35}O\textsubscript{3.5} substrate.\textsuperscript{[16]}

Exsolved Fe–Ni nanoparticles were reported to improve hydrogen dissociative adsorption (rate-limiting step) thus leading to increased catalytic activity.\textsuperscript{[17]} Interestingly, a general thermodynamic model was developed to predict the composition of those exsolved particles based on the approximation that the more reducible metal (Ni) completely exsolved while the content of the other metal (Fe) in the exsolved alloy is dependent on \(P_O\).\textsuperscript{[11c]}

Doping a small amount of alkali metals like Na on the A-sites of a Sr\textsubscript{0.65}Fe\textsubscript{0.2}Mo\textsubscript{0.35}O\textsubscript{3.5} perovskite was
found to facilitate the phase transition into a RP structure after reduction, increase the Ni content in the exsolved Fe–Ni alloys, and also introduce more surface oxygen vacancies ultimately leading to higher activity and enhanced coking resistance when employed in a SOFC anode under H\textsubscript{2} and CH\textsubscript{4}.\textsuperscript{[18]} Lastly, exsolved Fe–Ni materials have also demonstrated potential to be used as electrodes for symmetrical SOFCs, as they exhibited improved activity for both fuel oxidation and oxygen reduction reaction, good durability and resistance to carbon deposition.\textsuperscript{[19]}

Exsolved Fe–Ni alloy systems have also been employed as catalytic materials for reactions of methane reforming\textsuperscript{[8a, b]} and CO oxidation.\textsuperscript{[9a]} For the former, the effect of the A-site cations on the materials’ activity (LnFe\textsubscript{0.7}Ni\textsubscript{0.3}O\textsubscript{x}) was studied and it was found that PrFe\textsubscript{0.7}Ni\textsubscript{0.3}O\textsubscript{d} composition resulted in the highest activity and stability due to the optimal composition of exsolved Fe–Ni nanoparticles (higher Fe content) and the redox properties of the oxide matrix.\textsuperscript{[8b]} In addition, an increase in the Ni doping level resulted in an increase in the oxygen deficiency of the perovskites due to the reduction of Fe\textsuperscript{4+}/Fe\textsuperscript{3+} and Ni\textsuperscript{2+}/Ni\textsuperscript{3+} species to lower cation valences which in turn enhanced Fe–Ni nanoparticle exsolution, resulting in improved activity for CH\textsubscript{4} conversion (20 times over that of the pristine perovskite).\textsuperscript{[8c]} Fe–Ni exsolved catalysts have also been prepared through a so-called “topotactic exsolution” method. Here, Fe was introduced as the guest cation (via infiltration or atomic layer deposition) on the surface of a Ni-containing perovskite and the exsolution process was promoted by ion exchange between Fe and Ni driven by the different segregation energies of the two metals.\textsuperscript{[20, 21]} Thus, more Ni was dragged to the surface forming alloyed Fe–Ni nanoparticles with high population (Figure 4). This resulted in higher activity for methane dry reforming compared to that of monometallic Ni catalyst prepared via normal exsolution while still maintaining excellent durability.\textsuperscript{[20, 21]} For the latter, when used in CO oxidation, exsolved Fe–Ni nanoparticles from La\textsubscript{0.8}Sr\textsubscript{0.2}Fe\textsubscript{0.7}Ni\textsubscript{0.3}Ti\textsubscript{0.2}O\textsubscript{4} exhibited high activity, good long-term stability over 170 h and sulfur tolerance.\textsuperscript{[8c]}

Finally, using Fe–Ni nanoparticles exsolved from Sr\textsubscript{0.9}Fe\textsubscript{0.8}Ta\textsubscript{0.2}Pb\textsubscript{0.1}FeO\textsubscript{4} in a catalytic membrane reactor for methane partial oxidation, resulted in almost full CH\textsubscript{2} conversion and nearly 100% selectivity to CO and H\textsubscript{2}. Oxidising reaction conditions can cause exsolved nanoparticles to redissolve into the perovskite lattice (depending on the presence of A-site deficiency) which can prove detrimental for their catalytic activity. Here, the oxygen-permeable membrane could act as an oxygen distributor controlling oxygen partial pressure near the particles hence suppressing their dissolution in the perovskite during oxidation.\textsuperscript{[24]}

### 3.2. Fe–Co

Exsolution of Fe–Co nanoparticles has also been studied extensively as anode materials for SOFCs and similar to their Fe–Ni counterparts, they demonstrate a plethora of promising properties such as high activity, stability, coking resistance and sulfur tolerance.\textsuperscript{[6b, c, 7e–g]} A Co-doped La\textsubscript{0.8}Sr\textsubscript{0.2}FeO\textsubscript{4} (LSF) anode was found to achieve high power density and lower polarization resistance in a SOFC cell as compared to its Mn-doped counterpart due to the high catalytic activity of the exsolved Fe–Co particles towards hydrogen oxidation and the higher oxygen-ion conductivity of the newly formed LaSrFeO\textsubscript{4}–La(Sr)Fe(Co)O\textsubscript{2} (the perovskite phase of the Mn-doped LSF was retained without formation of other phases after reduction).\textsuperscript{[22]} Similarly, an SOFC anode material comprising of Fe–Co nanoparticles distributed on RP-type layered Sr\textsubscript{2}FeMoO\textsubscript{6} was prepared by reducing Sr\textsubscript{2}FeMoO\textsubscript{6}CO\textsubscript{3}O\textsubscript{5} in hydrogen, resulting in greatly improved electrical conductivity and catalytic activity. Thus, the resulting SOFCs achieved high maximum power densities in H\textsubscript{2} approximately 1.4 times higher than those of SOFCs employing a conventional Ni–Sm\textsubscript{0.8}Ce\textsubscript{0.2}O\textsubscript{4} anode while at the same time also exhibiting high performance and coking resistance in C\textsubscript{4}H\textsubscript{6}.\textsuperscript{[23]} More interestingly, a double-layered perovskite (Pr\textsubscript{0.4}Sr\textsubscript{0.6})(Fe\textsubscript{0.8}Co\textsubscript{0.2})O\textsubscript{3} decorated with Fe–Co nanoparticles, was used as the anode in a direct ethane-fuelled proton-conducting SOFC; high power density and high ethylene yield with ethylene selectivity of >91% were achieved together with excellent stability and coking resistance in ethane.\textsuperscript{[18b]} A Pr\textsubscript{0.6}Sr\textsubscript{0.4}Co\textsubscript{0.2}Fe\textsubscript{0.8}Nb\textsubscript{0.2}O\textsubscript{3} perovskite was employed as semiconducting material in a single-layer fuel cell and, despite the lower cell performance, it demonstrated enhanced stability as compared to the conventional lithiated metal oxides. Additionally, exsolution of Fe–Co alloy nanoparticles enhanced the performance of the starting perovskite, which improved electrode reaction kinetics, facilitated charge separation and ionic conduction.\textsuperscript{[24]}
Notably, exsolution of metal particles is sometimes accompanied by a phase transition of the perovskite substrate. In this case, the exsolved nanoparticles usually contribute to high catalytic activity while the oxide substrate affects the pathway for electron/ion conduction, hence they are both important for determining the SOFC anode performance. However, a phase transition of the substrate is not always beneficial since studies have shown that extreme reducing conditions that promote the perovskite substrates, can also result in decreased conductivity.[23]

The exsolved Fe–Co particle systems also find application in electrolysis and various symmetrical cells due to their activity for CO₂RR[11] and oxygen evolution reaction (OER).[26] For example, CO₂ electrolysis performance of La₀.₆Sr₀.₄Co₀.₈Fe₀.₂Mo₀.₁O₃₋₃ was enhanced after exsolution of Fe–Co nanoparticles, which seemed to originate from the metal–oxide interface that strengthened CO₂ adsorption and activation. At the same time, the material also demonstrated good stability, coking resistance and redox recyclability.[11] Additionally, approximately 40 times higher activity for OER was demonstrated by an exsolved Fe–Co/LaCo₀.₆Fe₀.₄O₃₋₃ system compared to the pristine perovskite. Operando X-ray adsorption spectroscopy indicated that the enhancement in activity comes from the fact that exsolved nanoparticles self-reconstructed into (Co/Fe)O(OH) with unsaturated coordination of metal ions in alkaline media during the OER, which acted as active species.[26] Besides, exsolved Fe–Co materials have also been used as electrodes in symmetrical solid oxide cells for the oxidation of different kinds of fuels (e.g., H₂, LPG, C₃H₇OH and CH₃OH) as well as for the electrolysis of H₂O and/or CO₂, exhibiting promising electrochemical performance and stability.[13c,27]

Last but not least, Fe–Co particles have also been used in chemical looping applications where CoFeAlO₃ was designed as an oxygen carrier material for chemical looping water gas shift reaction, based on the known stability of alumina spinels and the high capacity and reactivity of cobalt ferrites. Here the redox cycle of the reaction caused exsolution and re-dissolution of active Fe–Co particles. Interestingly, it was found that when reduced by mixed CO and CO₂ the exsolved Fe–Co particles remained embedded in the support demonstrating high redox stability, while under CO, the spinel support was over-reduced to Al₂O₃ and the metal-support interface structure resembled a deposited-like manner which led to easy sintering (Figure 5).[10]

3.3. Ni–Co

Ni–Co exsolution studies mostly refer to electrochemical applications,[29b] in which these particles demonstrate similar characteristics to those of their Fe based counterparts (Section 3.1 and 3.2). Recently, it was reported that an anode material based on Ni–Co alloy nanoparticles exsolved from La₀.₈₃Sr₀.₁₇Co₀.₃Ni₀.₇O₃₋₃ exhibited high catalytic activity towards NH₃ decomposition and H₂ oxidation due to the abundant active sites and the balanced NH₃ adsorption and N₂ desorption process ascribed to the synergistic effects of Ni and Co in the alloy. Additionally the electrode demonstrated good long-term stability due to the strong interactions between exsolved nanoparticles and the parent oxide.[28] Besides, interesting structural configurations seem to arise from compositions that are co-doped with Ni and Co. It was reported that discrete CoO₃ and NiO nanoparticles could exsolve on the surface of Sr₇CoMo₁₋ₓNi₉O₃₋₅, designed to be used as a supercapacitor electrode. The exsolved material showed high specific capacitance with dual energy storage mechanisms, namely a surface Faradaic reaction and an oxygen intercalation process, which were related to the presence of the exsolved nanoparticles and the increased availability of oxygen vacancies formed in perovskite, respectively.[29] In catalytic applications, Ni and Co were also reported to exsolve as alloyed nanoparticles from an A-site deficient perovskite La₀.₇Ce₀.₃Co₀.₃Ni₀.₇Ti₀.₃O₃₋₃ and, by tracking individual nanoparticles throughout various chemical transformations, it was demonstrated that these particles have the ability to re-shape into highly active cubes under reducing conditions. The material achieved high catalytic activity matching a noble metal commercial catalyst (Pt/Al₂O₃) when applied for oxidation of both CO and NO over hundreds of hours of operation.[30] More recently, a concept of endogenous-exsolution has emerged where Ni–Co nanoparticles were exsolved both on the surface and in the bulk of the parent perovskite La₀.₇Ce₀.₃Co₀.₃Ni₀.₇Ti₀.₃O₃₋₃. The particles seem to have Ni segregated at the core while Co was more homogeneously dispersed throughout the nanoparticles. The system demonstrated high oxygen capacity, high stability over redox cycling and resistance to deactivation mechanisms like sintering and coking while still exhibiting good surface activity, all significant properties for redox cycling applications.[34]

3.4. Other bimetallic systems

Exsolution of copper containing alloys has been reported in electrochemical applications[34,13d,30] For example, a composite...
electrode comprising of NiCu alloy nanoparticles exsolved in situ on the redox-reversible support of NiO was applied as a cathode for direct CO₂ electrolysis. The ratio of the two components of the alloy appeared to have a significant effect on the electrocatalytic activity of the system with NiCu as determined as the optimal ratio. Moreover, a perovskite electrode based on SrFeₐCuₜNb₉O₂₃ that allowed for reversible exsolution of an Fe–Cu alloy was reported to show high conductivities in both oxidising and reducing atmospheres making it a promising candidate both for SOFCs and SOECs. Finally, the emergence of Cu–Co nanoparticles from a vanadate Ce₉₅Sr₇₅CuₐₜCo₉₅VO₄₃ was accompanied by a phase transition of the host into a perovskite structure Ce₉₅Sr₇₅CuₐₜCo₉₅VO₄₃. Particles seemed to be Cu-enriched on their surface, probably due to the lower surface free energy of Cu. Such structures were found to demonstrate high activity and stability under hydrocarbon feeds in SOFC anodes, the catalytic activity was thought to be provided by the Co phase while the suppression of carbon formation was attributed to the Cu-rich surface layer.

Interestingly, noble metals can be paired with base metals like Ni and Fe mainly, in order to boost the catalytic activity of base metals. Pt–Ni alloy (Pt₃Ni) nanoparticles were exsolved from La₈₉Mn₂₉O₃₉0.₂Ni₀₂₂O₭₀ and the newly exsolved material exhibited enhanced activity for oxygen reduction reaction (ORR) comparable to that of the commercial catalyst Pt/C, but also higher stability over Pt/C. It was also demonstrated that the enhanced activity was not solely due to the formation of Pt₃Ni nanoparticles but also their strong interaction with the perovskite substrate. Additionally, Ru–Fe alloy nanoparticles were reported to exsolve from a Sr₂Tlb₉FeₙRu₄ₙOₙ₄ₓₚ in a SOFC anode resulting in lower polarization resistance and higher maximum power density especially at low temperatures and hydrogen partial pressures, as compared to the cell using the Ru-free perovskite anode. This was attributed to the promoting effect of the exsolved Ru–Fe nanoparticles on hydrogen adsorption which was the rate limiting step for the Ru-free anode.

4. Multielement, Nanostructured Systems

Aside from the traditional bimetallic systems, multi-metal exsolution has been demonstrated, as well as the formation of other nanostructures, such as nano-rods and nano-fibres, core–shell nanoparticles and even more complex heterostructures. These not only add to the structural diversity of the exsolved systems, but also to multi-metallic systems in general, hence opening more possibilities for tailorable, enhanced catalytic performance.

Simultaneous exsolution of metals has been shown to be able to lead to particles with a core–shell structure. For instance, exsolution of Pd and Ni resulted in Pd-NiO core–shell particles whose shell thickness and particle size could be modulated by the initial Ni doping content and reduction temperature, respectively (Figure 6). The exsolved core–shell particles were reported to be firmly socketed on the surface of the oxide support resulting in good structural stability under methane dry reforming reaction conditions.

Interestingly, apart from “conventional” co-exsolution, a different approach has also been used to prepare bimetallic systems. Exsolution was used in combination with infiltration of a second metal also resulting in bimetallic systems. For instance, Rh was impregnated on a three-dimensionally ordered macroporous (3DOM) Ni-doped perovskite support, and Ni exsolved during reduction formed alloy nanoparticles with the impregnated Rh. The catalyst showed good activity and stability for CO₂ methanation owing to the unique 3D porous structure, the exsolved Ni–Rh alloys and their strong interaction with the support. Moreover, a system where Rh was infiltrated on a perovskite with endo- and exo-Ni exsolved particles was used in a chemical looping methane partial oxidation process. Notably, the infiltrated Rh particles did not form any bond with the Ni particles but the modification did result in lowering the temperature at which methane was converted in dynamic temperature programmed experiments by 200°C additionally increasing activity by 40%.

Reports have also demonstrated the exsolution of alloys involving three metals, and examples include Fe–Ni–Ru from LnFeₓ₂₋ₓNiₓRuₓO₃₋ₓ (Ln = La, Pr) and Re–Ni–Fe from La₉ₓReₓFeₓO₁₋ₓ₃₋ₓ both being highly active and stable for methane dry reforming. Spinel oxides CuₓNiₓFeₓO₄ were totally reduced to form a structure of exsolved metallic nanoparticles on a metal matrix (e.g., Cu–rich Cu–Ni–Fe alloys on a Fe-rich Fe–Ni–Cu matrix from CuₓNiₓFeₓO₄). The material served as a highly active anode for electrochemical H₂ oxidation and demonstrated much smaller anodic polarization resistance than that of a conventional NiFe alloy anode, which was ascribed to the unique alloy structure.

Another intriguing aspect of exsolution is that it can sometimes cause such pronounced changes to the host matrices, that it can generate more complex structures than simple exsolved particles. For instance, exsolution of B-site metals accompanied by the segregation of A-site oxides at the surface of perovskites is possible, hence a SrO phase was detected to
exsolve from La_{0.4}Sr_{0.55}Co_{0.2}Fe_{0.8}Nb_{0.5}O_{3.5} matrix alongside exsolved Fe–Co nanoparticles (Figure 7a). Similarly both CaO phase and Fe–Ni alloy nanoparticles were also observed on the surface of La_{0.4}Ca_{0.4}Fe_{0.8}Ni_{0.4}O_{3.8} after reduction. The two materials showed high electrolysis current density for steam splitting and CO\textsubscript{2}RR, respectively, attributed to the increased water/CO\textsubscript{2} adsorption provided by the SrO/CoO phase and the high activity provided by the exsolved alloy nanocatalysts. The reduction of the A-site deficient perovskite (Pr_{0.5}Ba_{0.5})Fe_{0.6}Mn_{0.4}O_{3} enabled exsolution of Fe/MnO nanoparticles (Figure 7b) producing a very active cathode for CO\textsubscript{2} electrolysis, due to the improved CO\textsubscript{2} chemical adsorption and CO\textsubscript{2} dissociation through electron transfer from the exsolved nanoparticles. Interestingly, CoO and La_{0.2}Fe_{0.8}O nanoparticles were exsolved within a few seconds on the surface of La_{0.6}Sr_{0.4}Co_{0.4}Fe_{0.8}O_{3.8} after the in situ polarization-exsolution treatment under reductive (H\textsubscript{2}) atmosphere. The resulting material demonstrated enhanced performance for ORR with decreased polarization resistance, increased peak power density and good stability as compared to the pristine perovskite.

Lastly, exsolution of two metals can also lead to other morphologies like nano-rods and nano-fibres. For the former, the Ni doping level in perovskites can affect the exsolution behaviour of Fe–Ni alloys, which will in turn influence the electrochemical performance of materials. Specifically, it was demonstrated that the number of exsolved Fe–Ni nanoparticles from Sr_{0.2}Fe_{0.8}Co_{0.2}Ni_{0.5}O_{3.5} matrix increased with increasing Ni content up to x = 0.2 while the particles remained round and of the order of about 25 nm as compared to the nanorod-like Fe–Ni alloys that formed when x > 0.2. The self-assembly of nanoparticles into nanorods seem to have been facilitated by the excessive amount of Fe and Ni ions that left the host. Thus, x = 0.2 was found to be the optimal Ni doping content for the highest activity in steam electrolysis. Additionally, a study focused on exsolution from LSF under different conditions observed that when treated in dry H\textsubscript{2}, Fe exsolved in the form of nanorods (Figure 7c, left), which indicates that the exsolution process was limited by oxygen removal rather than the transport of Fe cations. If the transport of iron species is much faster than oxygen removal itself only one nucleus is formed which acts as a “iron drain” leaving the Fe-containing structure no other way than to grow but in a rod like manner. No exsolution was observed under humidified H\textsubscript{2} but impregnating Ni on LSF considerably changed the exsolution behaviour of the cations and in this case Fe was found to exsolve from Ni–LSF in humidified H\textsubscript{2} but formed Fe–Ni alloys instead of nanorods (Figure 7c, middle). When treated in dry H\textsubscript{2} in addition to the Fe–Ni particles, exsolution of SrO nanorods (Figure 7c, right) was also observed which seemed to be triggered by the presence of Ni due to the dissociative oxygen activation around Ni particles. Moreover, another study reported the preparation of a high-performance composite anode involving exsolved Fe–Cu in the form of nano-fibres. The solid state method used allowed for a nominal oxide La_{0.3}Sr_{0.6}Cu_{0.1}Ni_{0.2}O_{2.8} to self-assemble into a mixture of a single perovskite (Sr_{0.6}La_{0.4}FeO_{2.8} type) and a RT-type layered perovskite (SrLaFeO_{2.7} type) and hence create a hetero-interface which, in addition to the unique nano-fibre morphology of the exsolved Fe–Cu, mitigated the coarsening of substrate grains and sintering of the exsolved nanoparticles.

5. Summary and Outlook

Exsolution is a relatively new research hotspot which can be traced back to 2002. Exsolution of bimetallic species has gained increased attention even more recently. Herein we have reviewed the, approximately, 70 studies published so far, on bimetallic exsolution and identified research trends in this area. It has been demonstrated that exsolution can endow bimetallic particles with advantages in the terms of high catalytic activity, improved electrochemical properties, prolonged durability and strong resistance to deactivation in a wide range of applications mainly including electrochemistry and catalysis. Moreover, alloying such particles also allows for tuning of the adsorption properties, catalytic activity and stability of the exsolved particles due to the synergistic effects of different metals. However, most of these studies reported so far are application-oriented while less attention has been paid on the principles of material design. In order to further improve the performance of the exsolved bimetallic systems and unleash their full potential, some challenging issues should be resolved, including but not limited to the ones identified below.

Firstly, reduction conditions, initial composition and defects of the parent materials can directly affect the ratio of the metals of the exsolved alloys which in turn could determine catalytic activity and selectivity. Taking this into consideration more systematic study is still required of this aspect to allow for fine tuning of the chemical nature of the exsolved alloys and indeed to improve understanding of the exsolution process itself.

Secondly, as compared to the exsolved monometallic particles that are usually in the form of simple spheres or ellipsoids, exsolution of different metals offers richer diversity of structures which can bring additional emergent functionalities to materials. However, studies on this aspect are still very limited, and creating, characterising and applying novel structures of exsolved bimetallic materials is highly desirable.
Finally, the importance of modelling studies should be highlighted, which combined with the experimental observations will strengthen the understanding of the mechanism of bimetallic exsolution ultimately allowing for full control over the design of such materials.
