Contact-induced negative differential resistance in short-channel graphene FETs

Roberto Grassi, Member, IEEE, Tony Low, Antonio Gnudi, Member, IEEE, and Giorgio Baccarani Fellow, IEEE

Abstract—In this work, we clarify the physical mechanism for the phenomenon of negative output differential resistance (NDR) in short-channel graphene FETs (GFETs) through nonequilibrium Green’s function (NEGF) simulations and a simpler semianalytical ballistic model that captures the essential physics. This NDR phenomenon is due to a transport mode bottleneck effect induced by the graphene Dirac point in the different device regions, including the contacts. NDR is found to occur only when the gate biasing produces an n-p-n or p-n-p polarity configuration along the channel, for both positive and negative drain-source voltage sweep. In addition, we also explore the impact on the NDR effect of contact-induced energy broadening in the source and drain regions and a finite contact resistance.

I. INTRODUCTION

GRAPHENE has attracted considerable interest in recent years for applications in analog radio frequency (RF) electronics [11]–[4]. The reason lies in the fact that the high carrier mobility and Fermi velocity of graphene could allow device operation up to the THz range of frequencies, while the small on-off current ratio resulting from the zero bandgap, which currently prevents the use of graphene in digital electronics, does not pose a problem in principle for analog applications [5]. Indeed, an integrated RF circuit made of graphene devices has already been demonstrated [6]. However, in more general analog circuits, devices with current saturation, i.e. small output conductance $g_d$, are usually required. This is because the intrinsic voltage gain $g_m/g_d$, where $g_m$ is the device transconductance, must be large. Unfortunately, current saturation in graphene devices is not easily obtained due to the lack of a bandgap.

A quasi-saturation of the output characteristics has actually been reported for some experimental long-channel devices [7]–[9]. This quasi-saturation is commonly attributed to a charge “pinch-off” effect due to the crossing of the quasi-Fermi level with the channel potential [11], [10], [11], but a similar phenomenon has also been predicted in the ballistic limit [12], [13]. Recent experiments have shown that not just quasi-saturation ($g_d \to 0$) but also negative differential resistance ($g_d < 0$) is possible [14], [15]. Indeed, the NDR effect can also be explained with a simple charge “pinch-off” argument [14] within a diffusive transport framework, where the quasi-saturation arises as a particular case. Besides being potentially useful for applications in digital electronics (e.g. memory cells and clock generators), NDR is of particular interest as a means to engineer the current saturation for analog applications.

In this work, we focus on NDR in short-channel graphene transistors operating in the ballistic regime. This phenomenon has been predicted by previous quantum transport studies [16]–[18], but in such works the origin of NDR was not completely elucidated, in particular with regard to the effect of contacts and self-consistent electrostatics, which we found to play an important role in the operating regimes of NDR. It is the purpose of this work, which is an extension of [19], to clarify the origin of NDR in ballistic GFETs and provide guidance to future experiments.

The paper is organized as follows. Section II reviews the current interpretations of the quasi-saturation in long- and short-channel GFETs, which prepares the ground for understanding the mechanism behind NDR. Then, Section III describes our simulation models for GFETs. The results are shown in Section IV followed by a discussion in Section V Conclusions are finally drawn in Section VI.

II. REVIEW OF QUASI-SATURATION AND NDR IN LONG- VS. SHORT-CHANNEL GFETS

For long-channel GFETs, the phenomenon of quasi-saturation and NDR can be explained using drift-diffusion models, which assume semiclassical diffusive transport [7], [10], [11]. The drain current $I$ is given by

$$I = q \left[ n(x) + p(x) \right] v(x) W,$$

(1)

where $q$ is the electronic charge, $n(x)$ and $p(x)$ the sheet concentration of electrons and holes respectively, $v(x)$ the common drift velocity along the transport direction, and $W$ the channel width. The output conductance then consists of two contributions:

$$g_d = \frac{\partial I}{\partial V_{DS}} \propto \frac{\partial \left[ n(x) + p(x) \right]}{\partial V_{DS}} v(x) + \left[ n(x) + p(x) \right] \frac{\partial v(x)}{\partial V_{DS}}.$$

(2)

While $v(x)$ generally increases with $V_{DS}$ due to the increasing bending of the quasi-Fermi level $E_F(x)$, the sum $n(x) + p(x)$ instead is decreasing when $E_F(x)$ approaches and eventually crosses the Dirac point in the channel $E_d$ at the drain side.

The semi-analytical model assumes a simple ideal square potential barrier, as shown in Fig. 1 top, where \( \Delta E_{\text{con}} \) is the energy of the Dirac point in the source/drain/channel region. This is a good approximation for the case of self-aligned contacts as shown later by comparison with our numerical treatment. The related metal-induced doping \([23]\) is introduced through a fixed difference \( \Delta E_{\text{con}} \) between the Fermi level and the Dirac point in the source and drain regions (Fig. 1 top).

The transport model is composed of the following equations for the electron and hole concentration in the channel region and for the drain current:

\[
\begin{align*}
\nu &= \int_{E_{d,G}}^\infty dE \left[ D_L(E) f_s(E) + D_R(E) f_D(E) \right], \\
p &= \int_{-\infty}^{E_{d,G}} dE \left[ D_L(E) (1 - f_s(E)) + D_R(E) (1 - f_D(E)) \right], \\
I &= \frac{2q}{\hbar} \int_{-\infty}^{\infty} dE M(E) [f_s(E) - f_D(E)],
\end{align*}
\]

where \( D_L/R(E) \) is the density of states (DOS) in the channel at energy \( E \) relative to injection from source/drain and \( f_s/D(E) \) the contact Fermi distribution with Fermi level \( \mu_{S/D} \). In turn, the model for \( D_L(E), D_R(E), \) and \( M(E) \) is given by

\[
\begin{align*}
D_L(E) &= \frac{|E - E_{d,G}|}{(\pi\hbar v_F)^2} 2\left[ \theta_S + (\theta_D - \theta_S) \theta(\theta_D - \theta_S) \right], \\
D_R(E) &= \frac{|E - E_{d,G}|}{(\pi\hbar v_F)^2} 2\left[ \theta_D + (\theta_D - \theta_S) \theta(\theta_D - \theta_S) \right], \\
M(E) &= \min \{ M_S(E), M_D(E), M_G(E) \},
\end{align*}
\]

where \( \theta \) is the Heaviside step function and

\[
M_{S/D/G}(E) = \frac{2W}{\pi} k_{S/D/G}.
\]

The numerical value for \( v_F \) is set using the equation \( v_F = (3/2) \alpha_c c t / \hbar \), in which \( \alpha_c = 1.42 \) Å is the carbon-carbon distance in graphene and \( t = -2.7 \) eV the tight-binding parameter describing hopping between nearest neighbor \( p_z \) orbitals. The quantities \( k_{S/D/G} \) and \( \theta_{S/D} \) are defined as (their physical meaning is illustrated in Fig. 1 bottom)

\[
\begin{align*}
k_{S/D/G} &= \frac{|E - E_{d,S/D/G}|}{\hbar v_F}, \\
\theta_{S/D} &= \begin{cases} 
\sin^{-1}(k_{S/D}/k_G) & \text{if } k_{S/D} < k_G, \\
\pi/2 & \text{otherwise}.
\end{cases}
\end{align*}
\]

The Dirac point in the channel \( E_{d,G} \) is self-consistently computed with \( n \) and \( p \) through a plane-capacitor model which accounts for electrostatics:

\[
q(n - p) = C_{ox} (-\mu S/q + V_{GS} + E_{d,G}/q),
\]

where \( C_{ox} \) is the gate oxide capacitance and a zero workfunction difference is assumed between gate and graphene.

The model in Eqs. 9-11 corresponds to the solution of the ballistic Boltzmann equation in the channel region assuming energy and transverse momentum conservation at the two junctions and including Klein tunneling \([24]\) with tunneling probability equal to 1. As an example, Fig. 1 bottom shows the

---

**Fig. 1.** Semi-analytical model: profile of the Dirac point \( E_d(x) \) (top) and population of states in \( k \)-space (bottom) corresponding to the indicated energy \( E \). The cones represent the graphene dispersion relation \( E(k) = E_d + \hbar v_F |k| \). States populated with the Fermi function of the source/drain are indicated with a thick red/blue (light-gray/dark-gray) line.

This charge “pinch-off” is the effect used to explain the quasi-saturation or even NDR \([13]\) in the diffusive regime. It is also possible that velocity saturation, due to scattering with substrate polar phonons, contribute to quasi-saturation \([7, 20]\) and NDR \([15]\), since it implies \( \partial v(x)/\partial V_{DS} \to 0 \) in the r.h.s. of Eq. 4.

For ballistic GFETs instead, quasi-saturation can be understood using the Landauer formalism \([12]\). Assuming for simplicity the zero-temperature approximation, the energy window for transport is the one between the Fermi levels \( \mu_D \) and \( \mu_S \) within the drain and source regions, respectively. The current is then given by

\[
I = \frac{2q}{\hbar} \int_{\mu_D}^{\mu_S} M(E) dE,
\]

where \( h \) is Planck’s constant, \( M(E) = 2W |E - E_d| / (\pi \hbar v_F) \) the number of propagating modes in the graphene channel at energy \( E \), \( h = h/(2\pi) \), and \( v_F \) the graphene Fermi velocity. In this case, the output conductance is

\[
g_d = \frac{\partial I}{\partial V_{DS}} \propto qM(\mu_D) + \int_{\mu_D}^{\mu_S} \frac{\partial M(E)}{\partial V_{DS}} dE.
\]

\( M(E) \) is shifted up or down in energy by varying \( E_d \), which in turn is determined by the gate electrostatics. Assuming that \( E_d \) does not depend on \( V_{DS} \), the second term in the r.h.s. of Eq. 4 is zero. Consequently, it can be seen that the current tends to saturate when \( \mu_D \) approaches \( E_d \) because \( M(\mu_D) = 0 \) (here we neglect the graphene minimum conductivity \([21, 22]\)). The sign of \( g_d \) in Eq. 4 can be negative only if \( \partial M(E)/\partial V_{DS} \) is negative, which is not obvious from this simple picture. In the following, we will generalize this simple model to include the effects of contacts and self-consistent electrostatics, and show that \( \partial M(E)/\partial V_{DS} \) can indeed be negative within the energy window for transport.

**III. MODELS**

In this section, we describe in detail the semi-analytical model and the numerical model which are used to investigate the device behavior. In the considered GFETs the source and drain regions are assumed to be made of a graphene layer with a metal layer deposited on top.
distribution function in $k$-space corresponding to the potential in Fig. 1 top and at the indicated energy $E$. The red/blue (light-gray/dark-gray) color represents $f_{S/D}(E)$. The plot can be understood by assuming that the transmission probability across each junction, for an incident electron with transverse momentum $k_y$, is either $1$, if states with the same $k_y$ are available on the other side of the junction, or $0$ otherwise. In the figure, electrons from the source (red or light gray) are perfectly transmitted through both junctions, thus populating only rightward propagating states in the channel (note that the group velocity is opposite to $\vec{k}$ for states in the valence band). The ones from the drain (blue or dark gray) enter the channel with probability one; at the source-channel junction, they are either perfectly transmitted if $|k_y| < k_S$ or totally reflected if $|k_y| > k_S$, thus populating both left- and rightward propagating states.

We highlight the fact that the current contribution at a given energy is determined by the region where the Fermi surface has the smallest radius (Eq. 10), which means a transport bottleneck effect due to the series of graphene junctions. This model for $M(E)$ was first discussed in [25] and was also used to describe NDR in single p-n junction devices [26]. It is worth noting that, if $k_S, k_D > k_G$ (i.e., if the number of modes in the contacts is larger than in the channel), the same model for charge and current as in [12] is recovered.

To benchmark the semianalytical model, we use an atomistic full-quantum code [27], based on the self-consistent solution of the tight-binding (TB) NEGF and 3D Poisson equations and optionally including graphene acoustic phonon (AP) and optical phonon (OP) scattering. The source and drain regions are treated as in the semianalytical model with a fixed $\Delta E_{\text{con}}$, semi-infinite extensions, and zero underlap between the source and drain contacts and the gate (as in [18]). Both ballistic simulations and simulations with phonon scattering have been performed; in the latter case, we use the parameters $D_{\omega,\text{AP}} = 0.03$ eV$^2$, $D_{\omega,\text{OP}} = 0.027$ eV$^2$, and $\hbar\omega_{\text{OP}} = 160$ meV, whose definitions can be found in [28].

So far, we have assumed that the source and drain regions are described by the same cononical electronic dispersion relation as the channel (Eq. 12). In reality, the graphene DOS in the contacted regions is broadened due to the coupling with the metal contacts, so that a finite DOS (and thus a finite current injection) is induced at the Dirac point. In the following, we study separately the effect of contact-induced energy broadening. Regarding the NEGF code, we include the broadening as a constant imaginary diagonal self-energy $-i\Delta$ for the source and drain regions [18]. We have verified that the resulting DOS in the source/drain region, $D_{S/D}(E)$, can be well reproduced by the formula

$$D_{S/D}(E) = \frac{2}{\pi} \sqrt{(E - E_{d,S/D})^2 + \Delta^2}$$

(15)

where $\Delta$ is a fitting parameter. Assuming the same relation between $M_{S/D}$ and $D_{S/D}$ as in the case without broadening,

$$M_{S/D}(E) = D_{S/D}(E) \hbar v_F W,$$

(16)

we get an effective dispersion relation

$$k_{S/D} = \frac{\pi}{2W} M_{S/D}(E) = \sqrt{(E - E_{d,S/D})^2 + \Delta^2} / \hbar v_F,$$

(17)

which we use in place of Eq. 12 for $k_{S/D}$ to capture the effect of energy broadening within the semianalytical model.

IV. RESULTS

We consider n-type doped source and drain regions. Unless stated otherwise, we assume the values $\Delta E_{\text{con}} = 0.4$ eV, $\Delta = \Delta_0 = 0$, and an equivalent oxide thickness (EOT) of the gate dielectric of 0.5 nm. All the results presented in the following are at room temperature. With $V_{GS} = 0$ and at equilibrium, the channel Dirac point is aligned with the source and drain Fermi levels and the channel is intrinsic; by applying a positive (negative) $V_{GS}$, the bands in the channel are shifted down (up) thus creating an n-n-n (n-p-n) double junction. We explore in the following both the n-n-n and n-p-n bias conditions.

A. Quasi-saturation in n-n-n structure with $V_{DS} > 0$

In Fig. 2 left, we plot the output characteristics for $V_{GS} \geq 0$ (n-type channel) from the semianalytical model and the one obtained by setting $k_S, k_D > k_G$ and thus $\theta_S = \theta_D = \pi/2$ in Eqs. 8-11 (cfr. 12). It can be seen that the two models give similar results at large $V_{GS}$, both predicting the quasi-saturation behavior discussed above. This means that the mode reflection at the two junctions has no significant effect in this bias condition. However, at lower $V_{GS}$, the two models depart significantly for large $V_{DS}$. Indeed, at small $V_{GS}$ and large $V_{DS}$, the channel doping is actually turned p-type by the drain contact and the transport regime is similar to the n-p-n case discussed below.

B. NDR in n-p-n structure with $V_{DS} > 0$

The output characteristics for $V_{GS} \leq 0$ (p-type channel) are shown in Fig. 2 right. While the model neglecting the finite number of modes in the source and drain predicts
a monotonically increasing current, the one proposed here clearly gives NDR.

The origin of the NDR effect is explained by looking at Fig. 3 which compares the band profile, number of modes, and current spectrum (integrand in Eq. 7) obtained at two different $V_{DS}$ bias along the $V_{GS} = -0.4$ V curve. NDR is the combination of two effects. First, for energies close to $E_{d,S}$, $M(E)$ is limited by the number of modes in the source: in particular, for $E = E_{d,S}$ we have $M(E) = 0$, and this leads to the quasi-saturation behavior of the current for $\mu_D$ approaching $E_{d,S}$, as already pointed out in [18] and mathematically represented (in the zero-temperature approximation) by the first term in the r.h.s of Eq. 4. Secondly, by lowering $\mu_D$, the flux of electrons injected from the drain into the channel is reduced, while the flux from the source is kept fixed, causing a hole pile-up in the channel: due to the electrostatic feedback, $E_{d,G}$ is lowered. Since for energies close to $E_{d,G}$, $M(E)$ is limited by the number of modes in the channel, the lowering of $E_{d,G}$ causes a decrease in $M(E)$ for a portion of the energy range within $\mu_S$ and $\mu_D$, leading to a decrease of the current rather than a saturation, as expressed (in the zero-temperature approximation) by the second term in the r.h.s of Eq. 4. The fact that the decrease in $M(E)$ is not fully compensated by the larger $(\mu_S - \mu_D)$ is confirmed by the plot in Fig. 5 right, where the area under the red curve (current at higher $V_{DS}$) is slightly smaller than the area under the black curve (current at lower $V_{DS}$).

We highlight the necessity of two Dirac points, one in the channel and the other one in either the source or the drain, for NDR to be possible instead of saturation. Also, we note that a similar explanation for NDR was given in [17], even if a simple, not self-consistent model for barrier lowering was used (shift of $E_{d,G}$ by $-V_{DS}/2$ with respect to the value at $V_{DS} = 0$).

The qualitative shape of the output characteristics is confirmed by ballistic NEGF simulations considering a 50-nm-channel length (Fig. 4 see positive $V_{DS}$ axis, the results for negative $V_{DS}$ being discussed in the following section). In Fig. 5 we plot the band profiles and current spectra obtained from the two models. In the ballistic NEGF formalism, the number of propagating modes $M(E)$ in the current expression is replaced by the transmission function $T(E) = \sum_{j=1} T_j(E)$, where $T_j(E)$ is the transmission probability from source to drain of mode $j$ [29]. From the figure, it can be seen that the assumption of square potential barrier is well justified and that the barrier lowering is similar; the lower current spectrum in the NEGF case can be explained with wavefunction mismatch at the junctions, causing $T_j(E) < 1$ for propagating modes even in the case of an abrupt potential step [24, 25].

Finally, we have investigated the effect of scattering due to graphene longitudinal acoustic and optical phonons and found that, at this channel length, it is too weak to affect the current (see Fig. 6 in [19]).

C. NDR in n-p-n structure with $V_{DS} < 0$

We have also studied the device behavior when the polarity of the drain voltage is reversed (Fig. 3). Another NDR effect, not previously reported, is observed at $V_{DS} < 0$ in both the results of the semianalytical model and NEGF simulations.

To help understand the origin of the phenomenon, we plot in Fig. 6 the band profile and spectra for two negative $V_{DS}$ values along the $V_{GS} = -0.4$ V curve. The mode bottleneck induced by the Dirac point at $E = E_{d,G}$ is responsible for the current
saturation as $\mu_D$ approaches $E_{d,G}$, since it gives $M(\mu_D) \to 0$ in Eq. 4. At the same time, when $\mu_D$ is raised, the mode bottleneck at $E = E_{d,D}$ causes a decrease of $M(E)$ within the energy window between $\mu_S$ and $\mu_D$, due to the rigid shift of $E_{d,D}$ with $\mu_D$. This corresponds to $\partial M(E)/\partial V_{DS} < 0$ in Eq. 4 so that NDR rather than saturation occurs. The reason why $E_{d,G}$ is almost unchanged when varying $V_{DS}$, as opposed to the $V_{DS} > 0$ case, is related to the vanishing DOS in the channel for $E = E_{d,G}$ (cfr. Eq. 3), so that the charge variation in the channel induced by the lifting of $\mu_D$ tends to zero for $\mu_D$ approaching $E_{d,G}$.

We conclude that the mechanisms for NDR at the two drain voltage polarities are very similar and essentially related to the combined effect of two Dirac points, one in the channel and the other in either the source or the drain, in limiting the current. However, NDR at $V_{DS} < 0$ does not involve an electrostatic feedback in the channel as opposed to its counterpart at $V_{DS} > 0$. We note that, in the former case, since $E_{d,G}$ does not move with respect to $\mu_S$ at fixed $V_{GS}$, the NDR effect reported here is essentially the same as the one predicted for single p-n junctions in [26].

While the optimization of NDR is beyond the scope of this work, we just show in Fig. 7 how NDR at $V_{DS} < 0$ can be modulated by varying the electrostatic doping of the contacts, i.e. $\Delta E_{con}$, and EOT. From the figure, it can be seen that both the voltage swing $|V_M - V_m|$ and the peak-to-valley current ratio $I_M/I_m$ (the symbols are defined in the inset of Fig. 7) can be somewhat enhanced by increasing the contact doping, which also enlarges the $V_{GS}$ window where the phenomenon occurs. The use of a thicker gate dielectric just shifts the onset of NDR to higher $V_{GS}$ values and, at the same time, enlarges the $V_{GS}$ window.

D. Effect of energy broadening in the source and drain regions

To study the effect of energy broadening due to metal-graphene coupling in the source and drain regions, we set $\Delta = 50$ meV in the NEGF code and $\Delta = 162$ meV in the semianalytical model. The former value is taken from [18]; the latter has been fitted to provide the same value of DOS at the Dirac point, $D_{S/D}(E_d,S/D) = 3 \times 10^{13}$ cm$^{-2}$ eV$^{-1}$, as in the NEGF case. The resulting output characteristics are plotted in Fig. 8. The two methods give qualitatively similar results. At $V_{DS} > 0$, NDR disappears as already observed in [18]. However, we find here that quasi-saturation is still possible at $V_{DS} < 0$, according to the NEGF model. The experimental verification of the effect should thus be easier in the $V_{DS} < 0$ case.

E. Effect of contact resistance

We finally consider the effect of a series contact resistance $R_C$ equally split between the source and drain terminals (inset of Fig. 9). The semianalytical model is modified accordingly, by replacing the Fermi level $\mu_{S/D}$ entering the equations for $f_{S/D}$ and $E_{d,S/D}$ with the Fermi level $\mu_{S/D}^*$ of the intrinsic source/drain. The latter is calculated self-consistently with the current $I$ through the resistor equation

$$\mu_{S/D}^* = \mu_{S/D} \mp q \frac{R_C}{2} I,$$

where the upper/lower sign holds for source/drain. The $I$ vs. $V_{DS}$ characteristics for different values of $R_C$ and two values of $V_{GS}$ are shown in Fig. 9 together with the extracted values of $g_d$ at the inflection point of each curve (defined as the $V_{DS}$...
voltage where \( \partial^2 I / \partial V_{DS}^2 \) changes its sign). It can be seen that NDR tends to disappear with increasing \( R_C \) due to the increasing voltage drop across the two resistors. Already at \( R_C = 300 \, \Omega \cdot \mu m \), which is a typical experimental value \[14\], the output curve resembles the linear characteristic of a resistor, for both values of the gate voltage considered, indicating that contact resistance is a major problem for the operation of short-channel devices which must be addressed in future developments. Progress has recently been made in reducing \( R_C \) below 100 \( \Omega \cdot \mu m \) \[30\].

V. DISCUSSION

The analysis above indicates that, given a specific type of doping of the contacted graphene regions, the gate voltage needs to be biased such that an n-p-n or p-n-p double junction is formed, in order for NDR in ballistic GFETs to be possible. In addition, NDR is expected to be more likely for drain voltages with the same polarity as \( V_{GS} \), due to the higher robustness of NDR against energy broadening in this case. It is interesting to compare these findings with the actual bias conditions employed in experiments to observe NDR.

We note that the long-channel devices in \[14, 15\] were biased in an n-n-n or p-p-p configuration thus ruling out our interpretation of the phenomenon. Indeed, for channel lengths of the order of 1 \( \mu m \), scattering is expected to cause significant momentum and energy relaxation and charge inhomogeneity along the channel, so that the drift-diffusion interpretation discussed in Section \(I\) seems more appropriate.

On the other hand, in the Supporting Information of \[14\], results for GFETs with channel lengths of about 100 nm have been reported too. Some of these devices show NDR for gate voltages around 0 V: this biasing could be the counterpart case of the one mentioned at the end of Section \(IV-A\) (incompletely formed p-type channel, p-type contacts, and \( V_{DS} < 0 \)), so that our explanation of NDR could apply in this case. However, further experimental evidence is needed to prove this hypothesis (for example by exploring all the \( V_{GS} \) and \( V_{DS} \) polarities).

VI. CONCLUSIONS

Through a semianalytical model and detailed quantum simulations, we have clarified the nature and bias conditions for NDR in short-channel GFETs. The origin of the phenomenon is attributed to the transport-mode bottleneck induced by the graphene Dirac point. The combined effect of two Dirac points, one in the channel and the other in either the source or the drain, is necessary for NDR to occur instead of quasi-saturation. This is verified in the n-p-n or p-n-p configuration, for both polarities of \( V_{DS} \). It is found that a large doping concentration of the contacts enhances NDR, although the maximum achievable peak-to-valley ratio is limited to about 1.6. In the presence of energy broadening due to the metal-graphene coupling in the source and drain regions, NDR disappears at one \( V_{DS} \) polarity, but quasi-saturation is still attainable at the other one. It is also found that contact resistance at typical experimental values suppresses NDR, representing a major obstacle for the verification of the phenomenon in experiments.

The NDR mechanism could offer new possibilities for the optimization of the saturation behavior of the output characteristics of analog GFETs. The semianalytical model presented here, providing a good physical insight of NDR, could be a useful simulation tool for such an optimization study.

ACKNOWLEDGMENT
