ABSTRACT: The objective with this study was to study the changes in foliar nutrient content and grain yield of maize crop with the application of vinasse doses during three crops. The study was developed under field conditions in the municipality of Alegre, ES, during 2013, 2014 and 2015. Each cultivar was set up following a scheme of subdivided plots in a randomized block design with six treatments and four replicates. The treatments were composed by mineral fertilization (NPK) and five vinasse dosages, corresponding to 50, 100, 150, 200 and 250 m³ ha⁻¹. In the leaf samples, the contents of N, P, K, S, Ca, Mg, B, Cu, Fe and Zn were analyzed. In addition, the grain yield for each treatment was also evaluated. Based on the obtained results, the agricultural use of vinasse at doses higher than 50 m³ ha⁻¹ promoted the leaf contents of N, P, K, S, Ca, Mg and B similar to the result attained by supplying mineral fertilization, in the three crops. Regarding grain yield, the best performances were obtained at the dosages corresponding to 150 m³ ha⁻¹ for the years of 2013 and 2014 and 100 m³ ha⁻¹ for the year of 2015, with a production higher than 12 t ha⁻¹ in the three crops.

Key words: agricultural yield; effluent application; leaf nutrition; organic residue; Zea mays L.

Teores foliares de nutrientes e produtividade do milho com aplicação de vinhaça durante três safras

RESUMO: Objetivou-se estudar as alterações nos teores foliares de nutrientes e a produção de grãos da cultura do milho com a aplicação de doses de vinhaça, durante três safras. O estudo foi desenvolvido em condições de campo no município de Alegre, ES, nos anos de 2013, 2014 e 2015. Cada cultivo foi instalado seguindo um esquema de parcelas subdivididas em um delineamento em blocos casualizados com seis tratamentos e quatro repetições. Os tratamentos foram compostos pela adubação mineral (NPK) e cinco doses de vinhaça, correspondentes a 50, 100, 150, 200 e 250 m³ ha⁻¹. Nas amostras foliares foram analisados os teores de N, P, K, S, Ca, Mg, B, Cu, Fe e Zn. Além disso, foi avaliada a produção de grãos referente a cada tratamento. Com base nos resultados obtidos, observou-se que o uso agrícola da vinhaça nas doses superiores a 50 m³ ha⁻¹ promoveram teores foliares de N, P, K, S, Ca, Mg e B semelhantes àqueles obtidos com o fornecimento da adubação mineral, nas três safras. Quanto à produção de grãos, os melhores rendimentos foram obtidos nas doses correspondentes a 150 m³ ha⁻¹, para os anos de 2013 e 2014 e 100 m³ ha⁻¹ para o ano de 2015, com uma produção superior a 12 t ha⁻¹, nas três safras.

Palavras-chave: produtividade agrícola; aplicação de efluente; nutrição foliar; resíduo orgânico; Zea mays L.
Introduction

Among the industries that generate considerable effluent volume in Brazil, the sugar and the alcohol sector stand out, which according to data from Conab (2016), in the 2015/16 crop, 10.87 million hectares of planted area produced 665.58 million tons of sugarcane and 30.46 billion liters of ethanol.

In the production stages of this sector, a liquid residue known as vinasse is generated, in which is estimated that for each liter of ethanol or spirit produced, about 10 to 14 liters of vinasse is obtained (Mapa, 2007; Silva et al., 2014). Considering the current annual production of ethanol and spirits of 30.46 and 1.80 billion liters, respectively, and taking into account the technological level of national distilleries, the mean production is of 387.12 billion liters of vinasse each year.

Developed researches aiming at the agricultural use of this vinasse, point to this activity as an alternative of properly disposing this residue, since when used with technical criteria, vinasse has the potential of improving yield rates of interest crops and reducing the need of using mineral fertilization (Jiang et al., 2012; Christofoletti et al., 2013).

However, when applied with no technical criteria, it can cause undesirable effects, such as compromising the quality of the produced crop, in addition to changes in the chemical, physical and microbiological attributes of the soil (Lamaison et al., 2015).

Given the above, this research aimed to study the changes in leaf nutrient content and the grain production in the maize crop, resulting from the application of vinasse dosages, during three crops, in the Jerusalem rural community, municipality of Alegre, ES.

Materials and Methods

The experiment was conducted in field conditions during the years of 2013, 2014 and 2015, in the Jerusalem rural community, municipality of Alegre, ES. The site is located under the geographical coordinates of 41°32’58’’W longitude and 20°47’11’S latitude. The soil in the study area was classified as a clayey Red-Yellow Latosol (Oxisol) (Embrapa, 2013).

According to the Köppen international classification, the predominant climate in the region is the Cwa type, characterized by a dry winter and rainy summer. The accumulated precipitation and the average monthly temperature in the Jerusalem rural community, municipality of Alegre, ES, during the study period (Figure 1), were obtained through the automatic weather station of Alegre - A617 (Inmet, 2018), and by using a pluviometer installed in the study area.

The experiment was set up in a randomized block design with six treatments and four replicates. The treatments were composed by mineral fertilization after the sowing (NPK) and five vinasse dosages, corresponding to 50, 100, 150, 200 and 250 m³ ha⁻¹. Mineral fertilization was based on the Fertilization and Lime Recommendation Manual for the Espírito Santo State (Prezotti et al., 2007). As a mineral fertilization source, granulated urea (45% N), simple granulated superphosphate (18% P₂O₅) and granulated potassium chloride (60% K₂O) were used.

Total occupied area of the experiment was of 190.08 m², with the experimental plots measuring 2.20 x 3.60 m (7.92 m²). Therefore, each experimental unit was composed by four 2.20 m-long rows, spaced 0.90 m apart from each other. In each of these rows, 11 pits were opened, spaced 0.20 m apart among themselves. Each experimental plot was fixed, thus the experiment was set up in the same location in the three crops, with each plot consisting of 44 plants from the AG 1051 hybrid maize, grown in the spacing of 0.20 m between pits and 0.90 m between rows. Sowing was carried out in September of each one of the three years.

Excluding the border, the useful area of each experimental plot, where the variables were obtained, corresponded to 1.60 x 1.80 m (2.88 m²), with a total of 16 useful plants, in which they were collected for conducting analyzes.

The vinasse used in the experiment was collected in a spirit production unit close to the place where the experiment was conducted.
Foliar nutrient content and maize yield with vinasse application during three crops

Results and Discussion

By analyzing the obtained results, after the analysis of variance, it was verified that vinasse application in the maize crop provided significant changes (α ≤ 0.05) in the contents of macro and micronutrients in leaf tissue. Thus, Table 2 shows that the leaf contents of N, P, K and Ca, in the plots that had the vinasse application of 100, 150, 200 and 250 m³ ha⁻¹, did not show significant difference in relation to the mineral fertilization treatment (NPK), in the three evaluated years.

In turn, the leaf contents of these nutrients were lower for the 50 m³ ha⁻¹ dosage, in the three years. Therefore, with the exception of the one corresponding to 50 m³ ha⁻¹, the other applied vinasse dosages supplied the crop nutritional demand, with no significant difference in the results obtained with the mineral fertilizer application.

This absorption of macro and micronutrients by the crop, in the plots that had application of vinasse dosages above 50 m³ ha⁻¹ in the three years, can be associated with the fact that it had enabled a greater nutrients supply to the soil (Malavolta, 2008; Taiz & Zeiger, 2013). Moreover, the organic matter, supplied to the soil via vinasse, has the ability to complex the exchangeable aluminum which in turns raises the soil pH, so its cation exchange capacity is naturally increased, and the exchangeable cations are also in greater concentration in the soil exchange complex (Hagvall et al., 2015; Zhao et al., 2017).

Such behavior may partly justify the greater accumulation of some cations such as calcium and magnesium in the maize crop leaf tissue, in the plots that received the vinasse dosages of 200 and 250 m³ ha⁻¹, when in comparison to those that received the mineral fertilization or other dosages (50, 100 and 150 m³ ha⁻¹), mainly in 2015.

When applying vinasse, the foliar nitrogen and sulfur contents, with the exception of the 50 m³ ha⁻¹ dosage, showed values within the acceptable limit for the crop, while the mineral fertilization conditioned contents of this element below the minimum required in 2013, which can contribute to a reduction in crop production (Furlani, 2004; Taiz & Zeiger, 2013).

However, in 2014 and 2015, except for the 50 m³ ha⁻¹ dosage, the absorption of both nutrients was adequate in the plots that received vinasse, as well as in the plots that received mineral fertilization. In a similar manner, for the leaf...

| 100 m³ ha⁻¹ |      |      |      |      |      |      |      |      |      |      |
| 150 m³ ha⁻¹ |      |      |      |      |      |      |      |      |      |      |
| 200 m³ ha⁻¹ |      |      |      |      |      |      |      |      |      |      |
| 250 m³ ha⁻¹ |      |      |      |      |      |      |      |      |      |      |
| CV (%)     |      |      |      |      |      |      |      |      |      |      |

phosphorus contents, with except for the 50 m³ ha⁻¹ dosage, when applying vinasse or mineral fertilization, the leaf content of this nutrient was within the limit considered as appropriate (from 0.20 to 0.40 dag kg⁻¹), in the three years.

Regarding foliar potassium content, the vinasse used in this study has a mean potassium concentration of 2.98 g L⁻¹ (Table 1), thus the potassium content added to the soil that received the highest vinasse dosage was significantly higher than the plots that received the lowest dosages. This reflected directly on the leaf potassium content in maize plants, so that in the plots that received 250 m³ ha⁻¹ of vinasse, the leaf potassium content was 21.39; 26.02 and 8.69% above that obtained in the parcel that received mineral fertilizer, in the years of 2013, 2014 and 2015, respectively.

According to Hagvall et al. (2015), the application of organic residues to the soil enables a more stable environment due to the organic matter contribution, which in turn allows a greater concentration of binding substances, having as one of its characteristics the retention of these cations.

In a similar way, in the experiment implemented by Basso et al. (2013) in a maize cultivation with vinasse application, when compared to the cultivation done by means of conventional management, increases in the concentrations of potassium and nitrogen in the crop leaf tissue were observed with the rising vinasse dosages. The same pattern was observed in the present study.

With the exception of zinc, the micronutrients boron, copper and iron in the maize leaf tissue were within the maximum limit defined as acceptable for the crop, regardless of the applied vinasse dosage, in the three years. However, the leaf boron content in the dose corresponding to 50 m³ ha⁻¹ of vinasse was below the adequate, with contents of 8.74; 9.42 and 9.80 mg kg⁻¹, for the years of 2013, 2014 and 2015, respectively, which represents an average deficit of 6.80% of boron in the crop leaf tissue, in the three years. For the other applied dosages, the boron content were adequate.

For zinc levels, in the years of 2013, 2014 and 2015, in the doses corresponding to 50 and 100 m³ ha⁻¹ of vinasse, there was a leaf accumulation above 70 mg kg⁻¹, which can compromise the crop development (Martinez et al., 1999; Prezotti et al., 2007). However, in the other applied dosages, the found contents were adequate to the maize crop, in the three evaluated years.

In addition, the availability of the micronutrients copper, iron and zinc rises in soils with lower pH (Garcia-Mina et al., 2004). Therefore, in the present study, with the vinasse agricultural use, there was an inverse situation due to the rising pH of the soil, which partly explains the reductions verified in these micronutrients leaf contents in maize plants.

Regarding grain production, Table 3 shows that the mean weight of ears and of grains had a similar behavior in the three evaluated years, with a production lower than that
obtained when supplying mineral fertilizer, in the vinasse dose corresponding to 50 m³ ha⁻¹. However, there were no significant differences for these variables in the other applied vinasse dosages in relation to mineral fertilization, in the three years.

Table 3 also shows that grain production at doses corresponding to both 50 and 250 m³ ha⁻¹ of vinasse were lower than the production found when supplying mineral fertilizer in the three years. However, at 100 and 150 m³ ha⁻¹ dosages, the production attained was higher than the when mineral fertilizer (NPK) was applied, in the years 2013 and 2014.

In the following year, this result was repeated only at the dose equivalent to 100 m³ ha⁻¹ of vinasse. In turn, the doses corresponding to 100, 150 and 200 m³ ha⁻¹ conditioned the grain production without a significant difference from that found with the mineral fertilization application, in the three years (Table 3).

Such obtained results, displayed in Table 3, demonstrate that in up to three crops, the application of vinasse dosages between 100 and 250 m³ ha⁻¹ in a maize production system enabled grain production per ear without significant differences in relation to the mineral fertilization, demonstrating the agronomic potential of this residue.

In this aspect, grain production is considered as the most noble and profitable portion of the ear and it is desirable that its proportion in relation to the ear weight is as high as possible.

Table 3. Mean values of the total ear weight, grain weight and total grain production per hectare of the maize crop as a function of mineral fertilization and vinasse in the three years.

| Treatments | Ear weight (g) | Grains weight | Grains yield (t ha⁻¹) |
|------------|---------------|---------------|----------------------|
| NPK        | 318.71 a      | 228.61 a      | 11.43 a              |
| 50 m³ ha⁻¹ | 237.43 b      | 172.93 b      | 8.65 b               |
| 100 m³ ha⁻¹| 336.69 a      | 235.24 a      | 11.76 a              |

| 200 m³ ha⁻¹| 269.22 a      | 198.26 a      | 9.91 b               |
| CV (%)     | 11.12         | 7.16          | 10.30                |
|            | 382.88 a      | 259.61 a      | 12.98 a              |
| NPK        | 267.57 b      | 178.33 b      | 8.92 b               |
| 50 m³ ha⁻¹ | 387.06 a      | 262.05 a      | 13.10 a              |
| 100 m³ ha⁻¹| 397.67 a      | 258.12 a      | 12.91 a              |
| 150 m³ ha⁻¹| 305.37 a      | 204.21 a      | 10.21 a              |
| 200 m³ ha⁻¹| 290.15 a      | 193.71 a      | 9.69 b               |
| CV (%)     | 8.17          | 8.80          | 11.90                |

Means followed by the same lowercase letter in the column do not differ statistically from the NPK fertilization (control), at the level of 5% probability by Dunnett’s test. CV (%): Coefficient of variation.

OBS: Total grain yield was found by multiplying the mean grain weight per ear by the estimated ear yield, which was of 50,000 ears per hectare.

In this sense, the present study showed that the mean proportion of grains produced per ear, in the first year (2013), was 69.87 and 71.73% with the application of the dose equivalent to 100 m³ ha⁻¹ of vinasse and mineral fertilization, respectively. These results are in agreement with those obtained by Mendes et al. (2013), applying nitrogen fertilizer sources in the cultivation of maize hybrids, obtaining in some cases a proportion of grains less than 50% of the total ear weight.

In a similar manner, in the experiment implemented by Gott et al. (2014), when cultivating hybrid maize for grain production, a mean production of around 9.00 t ha⁻¹ of grain was obtained in a conventional cultivation system with the supply of different nitrogen sources. These results are below those obtained in the present study, since with the exception of the 50 m³ ha⁻¹ dosage, an estimated production above 9.30 t ha⁻¹ of grain was verified in the three years, with the mineral fertilizer application and other vinasse dosages.

However, according to Embrapa Milho e Sorgo, the productive potential of grains in Brazil is greater than 16.00 t ha⁻¹, yet the national mean production in the 2014/15 crop was of 5.01 t ha⁻¹. For the state of Espírito Santo, the mean grain production was lower, reaching 2.18 t ha⁻¹ in the same crop (Conab, 2016). Hence, under the conditions in which the present study was developed, it was possible to achieve a grain production higher than the national mean and that of the Espírito Santo state, both for the application of mineral fertilization and for the vinasse dosages.

Therefore, if used with technical criteria and in suitable dosages, vinasse becomes a by-product of agronomic interest, presenting real possibilities of use in agricultural crops, as it was demonstrated with the results found in the present study.

Conclusions

Vinasse dosages above 50 m³ ha⁻¹ promote leaf content of N, P, K, S, Ca, Mg and B, similar to those obtained with supplying mineral fertilizer, in the three crops.

Regarding grain yield, the best performances were obtained at the dosages corresponding to 150 m³ ha⁻¹, for 2013 and 2014, with production greater than 12 t ha⁻¹. In 2015, however, the best yield was obtained at a dosage corresponding to 100 m³ ha⁻¹, with a greater yield than 13 t ha⁻¹.

Vinasse dosages between 100 and 150 m³ ha⁻¹ promote grain yield results in the order of 12 to 13 t ha⁻¹.
