Abstract

Background: Caring of patients with corona virus infection disease may have had an impact on the occupational burnout, resilience, and parenting of the nurses.

Purpose: Evaluation occupational burnout, resilience, and parenting stress in nurses caring for COVID 2019 patients.

Methods: This cross-sectional study is based on strengthening the reporting of observational studies in epidemiology statement. A total of 630 nurses caring for COVID 2019 patients in 5 hospitals were selected via convenience sampling. Participants completed the scales online. Data were analyzed in SPSS v. 22.

Results: A total of 420 nurses completed and returned the questionnaires. Occupational burnout has a negative correlation with resilience and a positive correlation with parenting stress and can predict 61.32% of changes in the occupational burnout variance of nurses.

Conclusion: Resilience, parenting stress, marital status, number of children, employment status, and gender predicated high percentage of the nurses' occupational burnout variance. The nurse managers should use these findings to provide appropriate environments for nurses, to develop more comprehensive plans in support of nurses for the current and future crises.

Background

Corona virus infection disease (COVID 2019) emerged in China in 2019, very quickly became a pandemic, and has caused a large number of deaths in many countries so far [1]. The initial symptoms of COVID 2019 are similar to those of the influenza, but the infection gradually develops and causes severe cardiopulmonary and renal disorders, and can eventually cause death [2]. As a little-known disease, its genetic structure constantly changes, new symptoms are continuously recorded in the infected people, and, most importantly, there is not a definite cure or specialized vaccine for it. Thus, over 8.3 million people in the world have contracted the disease in the past three months, over 224,000 of whom have lost their lives as a result [3, 4].

In Iran, however, the spread of COVID 2019 has been complex. At the beginning of the pandemic, Iran had the third highest reported cases of COVID 2019, after China and Italy. Currently, Iran is faced with the third wave of the pandemic, while many other countries are going through the second wave [5]. Although the majority of Iranians wear masks, inappropriate economic situation has resulted in few restrictions on work, social activity and travel in all cities of Iran. As a result, large numbers of people use public transportation daily, streets are crowded, all employees are at work, and telecommuting from home is not common [5]. These factors have caused about 530,500 cases of infection over 30,500 of whom have lost their lives[5, 6].
The high worldwide fatality rate of COVID-19 has caused many people to experience considerable tension with adverse effects on their social activities and psychological security [7]. Due to the special nature of their occupation, nurses are at higher risk of suffering serious physical and psychological harms, including stress and depression. It is obvious that these psychological crises can influence nurses’ personal and family responsibilities as well, subject them to occupational burnout, and adversely affect parental duties [8, 9]. In January 2020, WHO declared the COVID-19 pandemic as a public health emergency of international concern (PHEIC) [10]. Accordingly, nurses play a significant role in healthcare and treatment systems in caring for and improving the health of patients infected with the coronavirus [1, 8]. However, caring for COVID-19 patients has subjected nurses to great psychological tension and work stress, hence the need for taking measures to protect nurses’ psychological and physical well-being [1]. In this regard, Stuijfzand et al. (2020) state that healthcare professionals during the epidemic and pandemic (severe acute respiratory syndrome (SARS), middle east respiratory syndrome coronavirus (MERS), ebola virus disease), experience myriad mental health problems including psychological distress, insomnia, alcohol/drug misuse, posttraumatic stress disorder (PTSD), depression, anxiety, anger and burnout [11]. Also, Lehmann et al. (2020) revealed that health care professionals reported depression, stress, social isolation, and job fatigue during the ebola outbreak. Social isolation has been largely due to parenting stress and concerns about the transmission of the disease to children and other family members. On the other hand, although job stress and fatigue can affect tolerance, they have overcome these tensions and work pressures with team working and observing the principles of infection control [12]. A study conducted by Liu et al. (2020) confirms that, compared to other members of medical staff, nurses experience higher levels of anxiety and depression in caring for COVID-19 patients and face more challenges in professional duties, family responsibilities and daily activities [7]. Similarly, the study of Roy (2020) shows that nurses experience high degrees of stress, anxiety, depression, and post-traumatic stress disorder (PTSD) during the COVID-19 crisis. Thus, it is essential that the executive administrators of healthcare systems and the crisis committees of hospitals consider the status of nurses’ psychological well-being, anxiety, depression, and occupational burnout [13]. The present study is an attempt to measure occupational burnout, resilience, and parenting stress in nurses who care for COVID-19 patients in Iran.

Methods

1.1 Study design and aims

This cross-sectional study was conducted based on strengthening the reporting of observational studies in epidemiology (STROBE) statement from February to June 2020. We tried to obtain the following two aims: evaluation of occupational burnout, resilience, and parenting stress in nurses who care for COVID-19 patients; and investigating the relationship between occupational burnout with resilience, parenting stress and demographic characteristics in nurses who care for COVID-19 patients.

1.2 Participants and sampling
In this study, the sample size has been estimated at 630 subjects according to the study of Roy et al., with \( \beta = 0.80 \), \( \alpha = 0.05 \), and taking into account the 10% attrition in each group. The participants were selected via convenience sampling. The correspondence author collected the emails of all the nurses working in COVID 2019 wards from the office of nursing services, in 5 hospitals affiliated with University of Medical Sciences in the west of Iran. Therefore, nurses who provided care to COVID-2019 patients were invited via email and selected through convenience sampling to participate in the study. The inclusion criteria were the following: being willing to participate, being in practice in one of the hospitals assigned for Covid-19 patients, and having at least one month of work experience in caregiving wards for patients with COVID2019. The subjects who failed to answer more than half of the items on the questionnaires or did not turn in the questionnaires were excluded. The subjects were asked to complete and submit the questionnaires—a personal (demographic) characteristics questionnaire, an occupational burnout scale, resilience scale, and, the parenting stress scale (if they were parents) online. The researchers sent emails and reminder messages to the participants, so that, the majority of the questionnaires (90%) were gathered in June.

**Measurements**

1.2.1. The occupational burnout scale

Developed by Maslach in 1996, the burnout inventory is the most commonly used scale for measuring occupational burnout [14]. The scale consists of 22 items which address three dimensions of occupational burnout: 9 items for emotional exhaustion, 5 items for depersonalization, and 8 items for personal accomplishment. The items measure the frequency and degree of burnout on an 8-point Likert scale: from 0 (very little) to 7 (very high). In the domain of emotional exhaustion, scores of 27 and above indicate severe emotional exhaustion, scores of 16 and below show slight emotional exhaustion, and scores of between 17 and 26 denote average emotional exhaustion. In the domain of depersonalization, scores of above 13 represent severe depersonalization and in the domain of personal accomplishment, scores of below 31 reveal low levels of personal accomplishment. The internal reliability of this scale was calculated as a Cronbach's alpha of 0.80 [14]. In their study, Baher et al. (2014) find the Cronbach's alpha of the scale at 0.79 [15].

1.2.2. The self-report caregiver burden inventory

The caregiver burden inventory was developed by Novak and Guest in Canada in 1988 to measure caregivers' burden. The scale consists of 24 items which assess caregivers’ burden in five domains: time-dependence burden (5 items (1, 2, 3, 4, 5), developmental burden (5 items 6, 7, 8, 9, 10), physical burden (4 items 11, 12, 13, 14), social burden (5 items 15, 16, 17, 18, 19), and emotional burden (5 items (20, 21, 22, 23, 24). Completion of the scale requires approximately 15 minutes. The items are scored on a 5-point Likert scale ranging from 0 (Not at all) to 4 (Absolutely). The score range is between 0 and 96: 0 to 32 indicate low burden, 33 to 64 moderate burden, and 65 to 96 great burden [16]. In their study conducted in Iran, Hormozi et al. report the reliability of the inventory at 0.82, which is a satisfactory value [17].
1.2.3. Parenting stress index-short form (PSI-SF)

Created by Abidin in 1995, the parenting stress index comprises 3 subscales: parental distress (items 1 through 12), parent-child dysfunctional interactions (items 13 through 24), and child characteristics (items 25 through 36). The scale measures parental stress on a 5-point Likert scale ranging from 1 (=completely disagree) to 5 (=completely agree). [18]. In their studies, Yeh (2001) and Reitman (2002) report the reliability of the scale to be 0.89 and 0.90 respectively [19, 20]. Assessing the reliability and validity of the scale in Iran, Shirzadi finds the reliability of the various dimensions of the index to be between 0.59 and 0.86, which are acceptable values [21].

1.3 Statistical methods

After data collection, they were analyzed using descriptive statistics (frequency, percentage, mean, and standard deviation) in SPSS v. 22. To investigate the relationship between occupational burnout on the one hand and resilience and parenting stress on the other, the researchers applied the chi-square test, independent t-test, and ANOVA. Significance level was set at 0.05. Subsequently, the variables of demographics, resilience, and parenting stress which were found to correlate with occupational burnout (p<0.25) were entered into multiple linear regression with the backward technique. Before running the analysis of multiple linear regressions, the researchers examined the assumptions of normality of data, homogeneity of variance, and independence of residuals.

Results

A total of 420 e subjects completed and returned the questionnaires via e-mail or a social network application, making the response rate to stand at 66.7%. The nurses' reasons for not participating in this study were heavy workload, intensive shifts, and infection with COVID 2019.

2.1 Demographic Information

Of the 420 nurses who participated in the study, 71.4% were female and 28.6% were male. The range of the participants’ ages was between 23 and 55 years with the mean of 35.24±3.56 years. The majority of the participants (73.8%) were married, 54.8% of whom had two children. Also, most of the participants had a bachelor of science in nursing (63.1%), were contractual employees (50.5%), had 11 years of work experience, and worked 32 rotating shifts per month. The findings of the study showed that there was a statistically significant relationship between occupational burnout on the one hand and marital status, number of children, employment status, and gender on the other.

2.2 Resilience, occupational burnout and parenting stress in the participants

The resilience mean score of the nurses who participated in the present study was 32.33±2.57, and the occupational burnout mean score was 32.33±2.57. Also, the parenting stress mean score of the 310 nurses who were married and had children was found to be 17.53±1.58 during the COVID-19 crisis (Table 2).
2.3 The relationship between the participants’ resilience, occupational burnout, and parenting stress

The findings of the study show that there is a strong and inverse correlation between occupational burnout and resilience in nurses who care for COVID 2019 patients (p<0.001, r=-0.70). Also, a stronger and more inverse correlation was found to exist between occupational burnout and resilience in married nurses than single nurses. The results showed a positive correlation between the occupational burnout and parenting stress scores of the nurses with children (p<0.001, r=0.74) (Table 3).

2.4 The predictor variables of occupational burnout in nurses who care for COVID-19 patients

The variable of resilience, parenting stress, number of children, marital status, employment status, and gender which had a p-value of smaller than 0.25 were entered into multiple linear regressions with the backward technique. These variables remained in the model and accounted for about 61.32% of the occupational burnout variance in the nurses who provided care to COVID2019 patients (Table 4).

Discussion

This study showed that nurses have reported high levels of occupational burnout, low levels of resilience, and high levels of tension in their relationship with children. Although a few studies have addressed work stress, knowledge, and awareness of nurses who care for COVID 2019 patients, there are not any studies of resilience, occupational burnout, or parenting stress in this group of caregivers. Therefore, the researchers had to use articles which measure resilience, occupational burnout, or parenting stress in nurses who care for patients with other specific diseases. The occupational burnout means score of the nurses was found to be 32.33±2.57, which indicates a high burnout. Occupational burnout in nurses is an issue of concern in nursing associations. Studies show that the physical and psychological pressures of caring for patients lead to occupational burnout in the long run and, thus, nurses’ length of service, work shifts, and salary must be redefined according to the type of patients they care for and the units where they work [22]. However, most of these studies report the occupational burnout of nurses with 5 years or more of work experience to be average, which is not consistent with the findings in the present study [22-24]. This discrepancy can be attributed to the sudden emergence of COVID 2019 which is highly infectious and has significantly increased nurses’ workload and caused them to have to work longer shifts and stay away from their families in the past few months. The results of the present study show a statistically significant difference between the married and single participants in terms of their occupational burnout scores (p<0.033). This difference may be due to the fact that, in addition to stress in the workplace, married nurses, especially those with children, are subject to greater psychological tension (p<0.031) as a result of disruption in marital and parental duties [22, 25-27]. The results of the study also show that contractual nurses (p<0.039) and female nurses (p<0.041) suffer from greater occupational burnout. Job insecurity, lower salaries, and the lower physical-psychological resilience of female nurses can account for the statistically significant difference between the occupational burnout scores of contractual and permanent nurses and male and female nurses [22, 27]. Similarly, the study of Salahian et al. shows that nurses’ employment status and gender have an impact on their occupational
burnout [22]. In the present study, the resilience means score of the nurses was found to be 32.33±2.57, which is considered low [28, 29]. In contrast, other studies report average to high levels of resilience for nurses, even for those who provide care to critically or terminally ill patients. The discrepancy can be attributed to lack of a definite treatment for COVID 2019 and the high speed and rate of the infection which have subjected nurses to severe physical and psychological tension with extremely adverse effects on their resilience [28-30]. The parenting stress means score of 298 participants was found to be 17.53±1.58. There are studies on parenting stress in working mothers or parents with a chronically ill child [31, 32]; however, there has not been much research into parenting stress in nurses. This lack of research may be due to the fact that nurses who work in rotating shifts can spend at least a few hours a day with their children and attend upbringing. But in the COVID 2019 crisis, many nurses have to work longer hours caring for the infected and, due to the high transmissibility of the disease, would rather reside in hospitals temporarily or have relatives take away their children to their own homes to ensure safety. Stress in the workplace, fear of transmitting the infection to children, having to stay away from children, and inability to monitor children's upbringing have subjected nurses with children to extra psychological tension and, consequently, elevated occupational burnout in them.

The results of the present study show a strong and inverse correlation between the participants' occupational burnout with resilience, and a strong and direct correlation between the participants' occupational burnout with parental stress. In addition, the variable of resilience, parenting stress, number of children, marital status, employment status, and gender explained about 61.32% of the occupational burnout variance in the nurses who provided care to COVID-2019 patients. There has been no study on the evaluation and prediction of the relationship between occupational burnout with resilience, parenting stress and demographic characteristic in nurses at the same time. In this regard, Amini et al. stated that there is an inverse relationship between occupational burnout with resilience of nurses [28]. Also, Zou et al. found that occupational burnout was negatively related to resilience [33], which are consistent with the results of the present study. In addition, Salahian et al. stated that nurses who worked in the infectious diseases ward reported more occupational burnout than nurses in other wards. Also, job stress, role clarity, and workload predicted about 36.5% of the nurses’ occupational burnout variance [22]. However, which is consistent with the results of present study.

Rafiee et al. and Ahmadi et al. found that individual characteristics of nurses (gender, work experience) and workplace affect nurses' occupational burnout, which is consistent with the present study [34, 35].

Finally, the results of the study show that nurses who provide care to COVID 2019 patients and have had to work more shifts in recent months are affected by higher levels of occupational burnout, have less resilience, and experience more tension in their relationship with their children than those before the emergence of the pandemic. In view of the persistence of the COVID 2019 crisis in Iran and the world in the coming months, it is recommended that health administrators take effective measures to reduce nurses’ occupational burnout and enhance their physical and psychological well-being.
One of the major limitations of the present study was the relatively low return rate of the questionnaires via e-mail which could be due to the hectic work schedules of nurses in the crisis. Moreover, the variables addressed in the present study were measured over a 6-month period—it is suggested that future studies assess occupational burnout, resilience, and parenting stress in nurses who care for COVID 2019 patients in the coming months and years in other societies and larger samples in order to acquire a more accurate understanding of nurses’ occupational burnout in this crisis. Health administrators and policy-makers can use these findings to develop more comprehensive plans for the current and future crises.

**Conclusion**

In the present study, the nurses who care for COVID-19 patients were found to be suffering from high levels of occupational burnout. Also, the results showed that nurses’ occupational burnout correlates with their resilience, parenting stress, marital status, number of children, employment status, and gender: these variables predicated 61.32% of the subjects’ occupational burnout variance. The nurse managers and policy makers of health organizations should examine and use the findings of this study in order to provide appropriate environments for nurses, also to develop more comprehensive plans for the support of nurses during the current and future crises.

**Declarations**

**Ethics approval and consent to participate**

The institutional review board of the medical universities located in the west of Iran provided ethics approval (approval number: 9904242498). Also at the beginning of study, the researcher got the emails of all the nurses that working in COVID 2019 wards from the office of nursing services, and invited them to participate in the study. In addition, the researcher introduced herself and explained the goals of the study and assured that all information would remain confidential and that they could withdraw from the study at any time. Finally, Participants completed the written consent forms and sent them to the researcher with email.

### Table 2. The means and standard deviations of the participants’ resilience, occupational burnout and parenting stress scores

| Variable               | Dimension                     | Means ±SD per dimension | Total Means ±SD |
|------------------------|-------------------------------|--------------------------|-----------------|
| Resilience             | Time-dependence burden       | 14.32±1.42               | 32.33±2.57      |
|                        | Developmental burden         | 15.76±2.18               |                 |
|                        | Physical burden              | 10.42±1.53               |                 |
|                        | Social burden                | 16.78±1.34               |                 |
|                        | Emotional burden             | 10.11±1.28               |                 |
| Occupational burnout   | Emotional exhaustion         | 48±3.22                  | 32.33±2.57      |
|                        | Depersonalization            | 23±2.13                  |                 |
|                        | Personal accomplishment      | 39±2.38                  |                 |
| Parenting stress       | Parental stress              | 18±1.09                  | 17.53±1.58      |
|                        | dysfunctional interactions    | 17±2.53                  |                 |
|                        | Child characteristics        | 15±1.12                  |                 |
Table 3. The relationship between resilience, occupational burnout, and parenting stress in married and single nurses and the entire participants

| Occupational burnout | Resilience (married nurses) | r= -0.71 | p<0.001 |
|----------------------|-----------------------------|----------|----------|
|                      | Resilience (single nurses)  | r= -0.69 | p<0.001 |
|                      | Resilience (total)          | r= -0.70 | p<0.001 |
| Occupational burnout | Parenting stress (married nurses) | r= 0.74 | p<0.001 |

Table 4. The predictor variables of occupational burnout in nurses who care for COVID-19 patients

| Variable                | Unstandardized coefficients | Standard deviation | Standardized coefficients | T     | P-value |
|-------------------------|-----------------------------|--------------------|---------------------------|-------|---------|
|                        | B                           | β                  |                           |       |         |
| Resilience             | -0.634                      | 2.53               | -0.643                    | -3.32 | 0.001   |
| Parenting stress       | 0.568                       | 2.49               | 0.572                     | 2.78  | 0.001   |
| Number of children     | 0.113                       | 2.28               | 0.441                     | 2.54  | 0.012   |
| Marital status         | 0.298                       | 2.54               | 0.301                     | 3.87  | 0.024   |
| Employment status      | 0.382                       | 2.34               | 0.214                     | 1.98  | 0.022   |
| Gender                 | 0.331                       | 1.89               | 0.186                     | 1.64  | 0.039   |

Adjusted R2: 61.32%
