A consequence of local equilibration and heterogeneity in glassy materials

Ludovic Berthier

(Dated: November 13, 2018)

The existence of a generalized fluctuation-dissipation theorem observed in simulations and experiments performed in various glassy materials is related to the concepts of local equilibration and heterogeneity in space. Assuming the existence of a dynamic coherence length scale up to which the system is locally equilibrated, we extend previous generalizations of the FDT relating static to dynamic quantities to the physically relevant domain where asymptotic limits of large times and sizes are not reached. The formulation relies on a simple scaling argument and has thus not the character of a theorem. Extensive numerical simulations support this proposition. Our results quite generally apply to systems with slow dynamics, independently of the space dimensionality, the chosen dynamics, or the presence of disorder.

Materials can be far from their equilibrium state for two main reasons. First, the relaxation time can be very large compared to the experimental time scale and the system does not reach equilibrium. This is typically the case for a liquid supercooled through its melting transition below its glass transition. The glass state is thus a non-stationary non-equilibrium state, where the glass is said to age. ‘Glass phases’ are extremely commonly encountered in condensed matter [1]. Second, when some external drive mechanism is applied to the system, it also leaves its equilibrium state. Typical situations can be driven interfaces, or soft materials perturbed by a mechanical flow. In this paper, we consider these two types of situations in the specific case of systems with slow dynamics. We discuss theoretically and numerically the existence and formulation of a generalization of the equilibrium fluctuation-dissipation theorem and its link to equilibrium properties.

Important results for the understanding of the non-equilibrium dynamics of glassy materials have been obtained in the last decade from the asymptotic solution of the dynamics of various infinite-range glassy models in the two types of situations described above [2]. It is established that much information on the dynamics is gained by studying two-time correlation and response functions, the relationship between them, and the link between dynamic and static properties. In the case of an aging dynamics, for instance, two-time functions explicitly retain a dependence on their two time arguments, and conjugated correlation and response functions do not satisfy the relation they follow at equilibrium, the fluctuation-dissipation theorem (FDT). In the case of driven dynamics, time translation invariance might be preserved even in the glassy phase, but the equilibrium FDT is not satisfied.

These ‘mean-field’ results have been used as a guide to interpret numerical and experimental studies of realistic glassy materials [3]. However, since no exact solution is known in that case, a naive mean-field interpretation of experimental results can be misleading. It is our aim to discuss the interpretation of experimental and numerical measurements of correlation and response functions in terms of static quantities. For this purpose, we extend previous analysis to the physically relevant domain where large times and sizes are not accessible. Our approach, which relies on the concepts of a spatially local equilibration and heterogeneity of the system, closely follows the line of thought suggested in Refs. [4, 5, 6, 7, 8, 9, 10], where the need to take into account spatial aspects of slow dynamics was already emphasized in this particular context.

The paper is organized as follows. In Section II we define the static and dynamics quantities of interest and briefly review the known relevant results. In Section III we use a scaling argument to support our generalization of the FDT. Numerical simulations of aging and driven dynamics in a spin glass model in finite spatial dimensions \( d = 3 \) and \( d = 4 \) are reported in Section IV. Section V concludes the paper.

I. GENERALIZED FDT: WHAT DO WE KNOW?

In this section, we introduce the basic concepts and quantities of interest for this paper. The exact results obtained in infinite-range glass models are first presented. We then review the argument given to support a possible larger validity of the mean-field results, and conclude the section with the experimental and numerical evidence available. The goal of this section is also to recall what is known, what is only supposed, and most importantly to emphasize what is not known.
A. Infinite-range glass models

The solution of the non-equilibrium dynamics of infinite-range glass models consists of the asymptotic analysis of coupled dynamical equations involving two-time correlation functions, \(C(t_1, t_2)\), and their thermodynamically conjugated response functions, \(R(t_1, t_2)\). Alternatively, integrated responses, or susceptibilities, \(\chi(t_1, t_2) = \int_{t_2}^{t_1} dt' R(t_1, t')\), can be studied, with the advantage that \(\chi(t_1, t_2)\) is easier to measure in a simulation or an experiment. Adopting notations appropriate to magnetic systems, those functions read for instance

\[
C(t_1, t_2) = \frac{1}{N} \sum_{i=1}^{N} s_i(t_1) s_i(t_2),
\]

for a system composed of \(N\) spins \(s_i (i = 1, \ldots, N)\). The fields \(h_i\) are thermodynamically conjugated to the spins. Since \(11\) and \(12\) are self-averaging, no average of any kind is required if the thermodynamic limit, \(N \to \infty\), is taken.

It turns out that in infinite-range glass models, a generalized form of the FDT is satisfied in the asymptotic limit of large times in the aging case, or small driving forces for the driven case. The limits respectively read \(t_1, t_2 \to \infty\) with \(C(t_1, t_2)\) fixed, or \(\varepsilon \to 0\) with \(C(t_1 - t_2)\) fixed, where \(\varepsilon\) generically refers to the amplitude of the driving force (see below for examples). This asymptotic form of the FDT reads

\[
R(t_1, t_2) = \frac{X[C(t_1, t_2)]}{T} \frac{\partial C(t_1, t_2)}{\partial t_2},
\]

where \(T\) is the temperature, and \(X(C)\) is called the fluctuation-dissipation ratio (FDR). The equilibrium FDT is recovered when \(X(C) = 1\). The finding of a generalized FDT for non-equilibrated systems suggests the possibility to develop a non-equilibrium extension of standard statistical mechanics or thermodynamics. In particular, the quantity \(T/X\) has been shown to play the role of a non-equilibrium effective temperature for the slow modes of the system \(12\), leading to an important body of related works \(13\).

Moreover, in infinite-range glass models which statically exhibit a full replica symmetry breaking pattern, the new dynamical quantity \(X(C)\) was found to be directly related to the static order parameter involved in the replica symmetry breaking, the distribution of overlaps \(P(q)\), through the very simple relation \(11\),

\[
X(C) = \int_{0}^{C} dq' P(q').
\]

The ‘Parisi function’ is defined as

\[
P(q) = \lim_{N \to \infty} \left\langle \delta \left( \frac{1}{N} \sum_{i=1}^{N} s_i^{\alpha} s_i^{\beta} - q \right) \right\rangle,
\]

where \(s_i^{\alpha}\) denotes the value of spin \(i\) in the configuration \(\alpha\), and \(\left\langle \ldots \right\rangle\) represents an average over configurations \((\alpha, \beta)\) weighted by their Boltzmann probability.

Equation \(4\) has a remarkable form, since it relates two quantities of completely different origin. The FDR in the left hand side of \(4\) is measured in the off-equilibrium dynamics, while the Parisi function in the right hand side is computed statically using the equilibrium Gibbs measure. Note also that the computation of \(X(C)\) does not involve replicas.

Finally, we recall the remarkable result that a generalized FDT as in Eq. \(4\) is asymptotically obeyed in the case of the driven dynamics \(12\), \(14\), with the same value of the FDR, so that Eq. \(4\) remains unchanged in that case \(15\).

B. Stochastic stability

Further developments have taken a more speculative form, in the sense that no exact result has been obtained for finite dimensional models. However, it was argued that Eq. \(4\) is generally true for finite dimensional glassy systems \(15\). We now briefly review the formal derivation of this result to emphasize the main hypothesis which are made. Following Refs. \(11\), the generalized susceptibilities \(\chi^r\) are first introduced:

\[
\chi^r = \frac{r!}{N^{r-1}} \sum_{i_1 < \cdots < i_r} \frac{\partial s_{i_1} \cdots s_{i_r}}{\partial h_{i_1 \cdots i_r}} \bigg|_{h=0}.
\]

The ‘derivation’ of Eq. \(4\) simply consists of the comparison between a static and a dynamic computation of \(\chi^r\). A static average gives

\[
\left\langle \chi^r \right\rangle_{\text{stat}} = \lim_{N \to \infty} \lim_{t \to \infty} \left\langle \chi^r (t) \right\rangle = \frac{1}{T} \int_{0}^{1} dq P(q)(q^r - 1). \quad (7)
\]

A dynamical average leads instead to

\[
\left\langle \chi^r \right\rangle_{\text{dyn}} = \lim_{t \to \infty} \lim_{N \to \infty} \left\langle \chi^r (t) \right\rangle = \frac{1}{T} \int_{0}^{1} dC \frac{dX(C)}{dC}(C^r - 1). \quad (8)
\]

Equation \(4\) directly follows by requiring the equality \(\left\langle \chi^r \right\rangle_{\text{stat}} = \left\langle \chi^r \right\rangle_{\text{dyn}}\) for all \(r\).

There are, however, several assumptions in this derivation. First, one assumes that a non-trivial form of the FDT given by Eq. \(4\) is valid in the large time limit. Similarly, the static computation is performed in the thermodynamic limit, \(N \to \infty\). A third assumption is that static and dynamic calculations give the same result. This can be justified by a standard nucleation argument \(15\), although exceptions are known \(11\). The last and strongest hypothesis has been called ‘stochastic stability’ \(15\). The name originates from the fact that the susceptibility \(\chi^r\) probes the behaviour of the system under the random perturbation

\[
H_{\text{perturbation}} = \delta \sum_{i_1 < \cdots < i_r} h_{i_1 \cdots i_r} s_{i_1} \cdots s_{i_r}, \quad (9)
\]
in the limit $\delta \to 0$. Here, the field $h_{i\ldots i}$ is a random Gaussian variable of mean 0 and variance $r/(2N^{r-1})$. Stochastic stability implies thus that the limits $\delta \to 0$ [or equivalently $h \to 0$ in Eq. (4)], $N \to \infty$, and $t \to \infty$ can all be inverted. This last assumption is completely uncontrolled, so that Eq. (4) is made physically plausible by this calculation, but has no ‘theorem’ character. A measurable test of this last hypothesis in a realistic system is to check the relation (4) it implies, thus making the argument a bit circular. Interesting examples and counterexamples were discussed in detail in Ref. [3].

C. Numerical and experimental results

Since the generalization of the FDT through Eqs. (3) and (4) cannot be rigorously proved, numerical simulations and experiments are necessary in order to make some progress. The advantage of simulations is that both equations can be separately checked, while experiments can obviously not compare dynamical to static data, since there are no experimental way to directly measure the Parisi function. Its indirect determination through Eq. (4) would thus be a major result, as pointed out in Ref. [3]. It is the principal aim of this paper to discuss the issue of what is precisely determined from a dynamical measurement performed in a physically accessible time window.

Dynamic results have been numerically obtained in many different glassy models, as reviewed in Ref. [13]. More recently, experiments have also been able to independently probe two-time susceptibilities and correlations in a number of glassy materials. [16, 17, 18, 19]. The standard way to present data and test Eq. (3) is to build an ‘FD plot’ of the susceptibility $\chi(t_1, t_2)$ as a function of the correlation function $C(t_1, t_2)$, parameterized by the time difference $t_1 - t_2$, conventionally taken as positive. If Eq. (3) holds, one gets indeed

$$\chi(t_1, t_2) = \frac{1}{T} \int_{C(t_1, t_2)} dq X(q),$$

implying that the $\chi(C)$ relation is independent of time, and has a slope related to the FDR,

$$\frac{\partial \chi}{\partial C} = \frac{X(C)}{T}. \quad (11)$$

We have implicitly assumed that $C(t_1, t_1) = 1$ to simplify the notations. It is important to notice that neither simulations nor experiments have ever reported an asymptotic FD plot, i.e., a time independent relation between $\chi$ and $C$. Quite strikingly then, physically accessible time scales are such that Eq. (3) is not valid. As a consequence, it is necessary to theoretically investigate preasymptotic behaviours where times are large, but finite. Equivalently for the driven dynamics, the case of small but finite driving forces has to be considered.

Far less works have investigated the validity of Eq. (4). Numerically, it is possible to compute the Parisi function in an equilibrium simulation, obtaining thus the function $P(q, L)$, where $L$ is the—necessarily finite—linear size of the system. The $L$-dependence is explicitly kept since it is again important to note that no numerical work has yet been able to report the asymptotic form of this function, $P(q, L \to \infty)$, in a glassy system. Moreover, the system size will play an important role below.

Early studies have then empirically compared static and dynamic data through the comparison of the curves $\chi(C, t_2)$ obtained in the dynamics for times $t_2$ ‘as large as possible’, to the static curve $S(C, L)$ measured statically in a system of size $L$ ‘as large as possible’ [20, 21]. We have defined

$$S(C, L) = \frac{1}{T} \int_{C} dq \int_{0}^{q} dq' P(q', L). \quad (12)$$

With these definitions, Eq. (4) can be synthetically rewritten as

$$\chi(C) = S(C), \quad (13)$$

where $S(C) = \lim_{L \to \infty} S(C, L)$.

The remarkable coincidence between static and dynamic data initially found in numerical simulations of finite dimensional spin glasses in dimensions $d = 3$ and $d = 4$ was first taken as the sign that both quantities had converged to their asymptotic limits. [20]. Conclusions on the correct description of the low-temperature phase in spin glasses phase were then drawn.

These conclusions were however premature, as strikingly demonstrated in recent experiments which have shown that even in the experimental time window the FD plots still have a clear time dependence [18]. This again emphasizes the necessity of a careful theoretical study of preasymptotic behaviours in order to get a correct interpretation of experimental data. This issue is discussed throughout the rest of the paper.

II. GENERALIZED FDT WITH SPACE

A. What about space? A scaling argument

To understand preasymptotic behaviours, a physical picture of the slow dynamical processes involved in the system is needed, since infinite-range glass models provide us with no relevant prediction in that regime. Unfortunately, due to their mean-field nature, they do not provide us with a clear description of the physics either. One has thus to resort to more phenomenological descriptions.

It is now well established, at least in the case of spin glasses, that slow dynamics is accompanied by the existence of a ‘coherence length’ scale, $\ell$: the larger the coherence length the slower the dynamics. Here, an analogy with coarsening phenomena in non-disordered ferro-
magnetic systems is quite illuminating. When the coarsening dynamics proceeds, larger and larger magnetized domains are present, and the dynamics indeed becomes slower and slower. The extent to which slow dynamics is always accompanied by a large coherence length in any glassy material is an important open problem in this field.

In this paper, we adopt the point of view that this is indeed the case. See Refs. [22, 23] for related discussions.

Using this spatial description of slow dynamics, preasymptotic behaviours were conjectured in Refs. [4, 5] to obey a generalization of Eq. (1). The physical picture is the following. At a given wait time, \( t_2 \), of the aging dynamics, the system has become locally equilibrated up to a coherence length scale, \( \ell(t_2) \). It can thus be seen as a heterogeneous mosaic of independent and quasi-equilibrated sub-systems of size \( \ell(t_2) \). Translating this idea into an equation, one arrives at the conjecture that the following generalization of Eq. (1) can be valid [4, 5]:

\[
X(C, t_2) = \int_0^C dq' P(q', L), \quad L = \ell(t_2),
\]

which implies that non-equilibrium properties of the system at time \( t_2 \), as encoded in the FDR, are related to the equilibrium properties of a system of finite size \( L = \ell(t_2) \), as encoded in the Parisi function. Note also that static and dynamic preasymptotic effects are explicitly present in Eq. (14), since both finite times, \( t_2 \), and sizes, \( L \), are taken into account.

The conjecture [14] was first formulated and tested in Ref. [4] in the context of the non-equilibrium critical dynamics of the 2d XY model, and further studied in Refs. [3, 24] in the numerical simulation of the Ising spin glass in dimension \( d = 2 \). In both cases, the observed behaviours were by construction preasymptotic, since for both models the true asymptotic behaviour was simple equilibrium with \( X(C) = 1 \) and \( P(q) = \delta(q) \). However, on numerically accessible time scales, a non-trivial behaviour reminiscent of the one observed, say, in realistic spin glasses was found, and the conjectured relation [14] was indeed obeyed to a very good precision.

It is straightforward to obtain the relation corresponding to Eq. (14) in the case of a driven glassy material:

\[
X(C, \varepsilon) = \int_0^C dq' P(q', L), \quad L = \ell(\varepsilon),
\]

where the relevant control parameter in the dynamics is now the amplitude of the driving force, \( \varepsilon \). The advantage of this formulation, as exemplified in the numerical simulations below, is that the dynamics is stationary, so that the coherence length itself does not change during the dynamical measurement, as is the case in the aging regime.

B. Single-site quantities

A different generalization of Eq. (1) was recently discussed in the literature [3, 10]. Inspired by numerical results obtained in a disordered spin system [3], the argument reviewed in section [13] was reformulated using single-site quantities defined for a given sample [10]. Therefore, disordered systems only are concerned by this approach.

Consider the alternative single-site definition of a generalized susceptibility [10]:

\[
\chi_i^r = \frac{r!}{M^{r-1}} \sum_{a_1 < \ldots < a_r} \frac{\partial s_i^{a_1} \ldots s_i^{a_r}}{\partial h_{a_1 \ldots a_r}} \bigg|_{h=0},
\]

where \( M \) thermodynamically coupled copies of the same system have been introduced, so that \( s_i^a \) denotes the value of spin \( i \) in the copy \( a \). The role of a small coupling of amplitude \( k \) between the \( M \) copies is discussed in Ref. [10]. Its presence is necessary to properly define single-site overlap distributions \( P_i(q) \), although its precise form is inessential.

If an inversion of the limits \( M \to \infty, t \to \infty, k \to 0 \) and \( h \to 0 \) is again allowed, then a reasoning analogous to the one developed in section [13] leads to the equality

\[
X_i(C) = \int_0^C dq' P_i(q'),
\]

between the single-site FDR and local overlap distributions. The single-site FDR is obtained by averaging local correlation, \( C_i(t_1, t_2) = s_i(t_1)s_i(t_2) \), and response functions, \( R_i(t_1, t_2) = \partial s_i(t_1)/\partial h_i(t_2) \), over various realizations of the thermal history for a single realization of the disorder. We note finally that the derivation of this local FDT makes use of the same type of (uncontrolled) hypothesis of the global one.

C. Single-box quantities

Although Eqs. (17) and (14) are different, they are also consistent, because Eq. (17) physically follows from the concept of a local equilibration in space, so that dynamical properties at site \( i \) can be linked to static properties at the same site \( i \).

The disadvantage of this single-site formulation is however evident, since it entirely relies on the presence of quenched disorder in the system. A slight generalization of Eq. (17) would be to consider single-box quantities instead of single site to get similarly:

\[
X_i^v(C) = \int_0^C dq' P_i^v(q'),
\]

where the box FDR \( X_i^v(C) \) is defined from box dynamical functions, \( C_i^v(t_1, t_2) = v^{-1} \sum_j s_j(t_1)s_j(t_2) \) and \( \chi_i^v(t_1, t_2) = v^{-1} \sum_j \partial s_j(t_1)/\partial h_j(t_2) \), and the sums run...
over a box of finite volume $v$ centered around site $i$. The corresponding static box overlap distribution is defined as \[ P_i^v(q) = \lim_{N \to \infty} \left\langle \delta \left( \frac{1}{v} \sum_{j=1}^{v} s_i^s s_j^s - q \right) \right\rangle, \] (19)

using the same notations as in \[5\]. The interest of the formulation [15] is that it should become independent of the considered site $i$ for a sufficiently large box volume $v$. A second interest is that it suggests an alternative to Eqs. [14] and [15], namely

\[ X(C, t_2) = \int_0^C dq \, P_i^v(q), \quad v = \ell^d(t_2), \] (20)

for the aging case, and

\[ X(C, \varepsilon) = \int_0^C dq \, P_i^v(q), \quad v = \ell^d(\varepsilon), \] (21)

for the driven case.

III. SIMULATIONS OF AGING AND DRIVEN DYNAMICS

We now turn to a numerical investigation of the two relations [14] and [15] discussed in the preceding section. We first present the model studied and some technical details, before giving our results both for a driven and an aging dynamics.

A. Model and details of the simulations

In this section, we study numerically the Edwards-Anderson model of a spin glass defined by the Hamiltonian [20]

\[ H = - \sum_{(i,j)} J_{ij} s_i s_j, \] (22)

where $s_i (i = 1 \cdots N)$ are $N = L^d$ Ising spins located at the sites of a cubic lattice when $d = 3$, or a hypercubic lattice when $d = 4$, of linear size $L$. The coupling constants $J_{ij}$ are random Gaussian variables of mean 0 and variance 1 and the sum in [22] runs over nearest neighbours. We use a standard Monte Carlo algorithm where the spins are randomly updated. Times are given in Monte Carlo steps, where one step represents $N$ attempts to update a spin. Sizes are given in units of the lattice spacing. To study the dynamics of the system, a large system size, $L = 40$ ($d = 3$) and $L = 24$ ($d = 4$), is chosen, so that few realizations of the disorder are needed, typically 10. Such large sizes are necessary, as the Fig. 1 discussed below will clearly demonstrate.

This implies that conclusions drawn for systems as small as $L = 10$ have to be taken with much caution [27].

The aging dynamics is simulated by preparing the system at initial time in a random configuration, thus mimicking an infinite temperature state. The temperature is then changed at time $t = 0$ to its final value. We will present below data for the temperature $T = 0.77T_c$ in both $d = 3$ and $d = 4$, where $T_c = 0.95$ and $T_c = 1.8$, respectively. Dynamical measurements are then performed during the resulting aging process.

To simulate the driven dynamics, we use the same type of perturbation as in Ref. [15]. On each link $(i, j)$ of the lattice, a coupling $\tilde{J}_{ij}$ is added, where $\tilde{J}_{ij}$ is drawn from a Gaussian distribution of mean 0 and variance $\varepsilon$, which defines then the amplitude of the driving mechanism.

The key information about the $\tilde{J}$‘s is that they are chosen to be antisymmetric, $\tilde{J}_{ij} = -\tilde{J}_{ji}$, which implies that their effect cannot be incorporated in a Hamiltonian force of the type [22]. Hence, the effect of the $\tilde{J}$‘s is that of a non-conservative force, and the system is thus externally driven. As a result, a driven stationary state is reached at sufficiently large times, even for temperatures below $T_c$: aging is stopped by the driving force [15]. In that case, measurements are performed in the stationary regime, meaning that a considerable amount of the data corresponding to transient behaviours has to be discarded.

In both cases, dynamical measurements consist of the measurements of the global functions (1) and (2). Since these measurements are by now classic, we do not discuss them further here [13].

In order to perform a comparison with static data, we shall make use of the published equilibrium data of Ref. [28] in $d = 3$ and Ref. [29] in $d = 4$. Fortunately, box-overlap data exist in $d = 3$ and we shall also make use of those [24].

B. Time is length

To accurately test the relations [14] and [15], the following steps must be followed.

- Identify and measure in the dynamics the coherence length $\ell$.
- Measure global correlation and response functions, from which the corresponding FD plot is built.
- Measure in equilibrium simulations the overlap distribution functions.
- Compare static and equilibrium data with carefully chosen values of the parameters (size, time, driving force), as suggested by Eqs. [14] and [15].

The first point, the identification of a coherence length, has been discussed for the aging dynamics of the Ising spin glass in various dimensions in Refs. [30, 31, 32], so that the existence, temperature and wait time behaviour of this quantity is well-characterized.
The coherence length $\ell$ which is however inessential. We have no explanation for this difference, the 'compressed' exponential form reported in the aging regime [32]. We have thus measured in the driven stationary state the standard four-spin correlation function [32]:

$$C_{4}(r) = \frac{1}{N} \sum_{i=1}^{N} \langle s_{i}^{a} s_{i+r}^{a} s_{i}^{b} s_{i+r}^{b} \rangle, \quad (23)$$

where the overline means an average over the disorder, and $(a,b)$ are two independent copies of the system. Some corresponding curves are shown in Fig. 1 for $d = 3$. Very similar results are also obtained for $d = 4$. The features observed in this figure are expected. The amplitude of the driving force is known to control the relaxation time, $t_{\text{rel}} = t_{\text{rel}}(\varepsilon)$, of the system, the smaller $\varepsilon$ the larger $t_{\text{rel}}$ [13]. From Fig. 1 we recognize that a slower dynamics also implies the existence of a larger coherence length, $\ell(\varepsilon)$, as revealed by a slower spatial decay of $C_{4}(r)$.

A non-ambiguous definition of the coherence length is obtained, as in the aging regime, through the study of the scaling properties of $C_{4}(r)$. For the aging, it is known that the correlation [24] is well described by the scaling form [22, 23]

$$C_{4}(r) \approx \frac{1}{r^{\alpha(T)}} C \left( \frac{r}{\ell} \right), \quad (24)$$

which can be seen as the definition of the coherence length $\ell$. We find that the same scaling behaviour [24] is obeyed in the driven dynamics as well, with the same value of the temperature-dependent exponent $\alpha(T)$ as in the aging regime. As an example, we report the scaled data for $T = 0.7T_{c}$ and $d = 3$ in Fig. 2. We find that the scaling function $C(x)$ is well described by a simple exponential form, $C(x) = \exp(-x)$. This contrasts with the 'compressed' exponential form reported in the aging regime [22]. We have no explanation for this difference, which is however inessential.

The results of Figs. 1 and 2 allow us to obtain the relationship between the coherence length $\ell$ and the amplitude of the driving force, $\varepsilon$. From the time dependence of the correlator [1], it is also possible to extract a relaxation time, $t_{\text{rel}}(\varepsilon)$. It is thus natural to eliminate $\varepsilon$ to obtain the relationship between time and length. Not surprisingly, we find that the relation $\ell(t_{\text{rel}})$ in the driven regime, is well compatible with the relation $\ell(t_{2})$ measured in the aging regime at the same temperature.

Although this coincidence might seem anecdotic in this context, we emphasize its physical importance. This suggests indeed that whatever the control parameter for the dynamics is, waiting time or driving force, the dynamics is such that the same dynamic scaling $\ell(t)$ is obeyed: ‘Time is length’.

### C. Generalized FDT for the driven dynamics

Following the program presented in section III B, we compute in the driven dynamics correlations and susceptibilities, and build the corresponding FD plots. Collecting the static data of Refs. [22, 25, 29], we are in a position to start and investigate the validity of the relations [14, 15, 20, 24].

We present in Fig. 3 the results obtained in $d = 4$. In this figure, there are three different FD plots, represented with points, and corresponding to three different values of the driving force, and thus to three different coherence lengths $\ell(\varepsilon)$. The lines correspond to the double integral $S(C, L)$ defined in Eq. 12 of the Parisi function $P(q, L)$ for three different system sizes. The agreement between the two sets of curves is extremely good. That this is not a mere coincidence is supported by three important facts:

- The two types of measurements are performed entirely independently, in completely different physical situations;
- The agreement between the two sets of curves is very good on the whole range of the curve, not on a single point. If one remembers that each curve is
built from a rather complex manipulation of various quantities without any fitting procedure or free parameter, the agreement becomes much more impressive:

- The coherence lengths measured in the dynamics are $\ell(0.2) = 1.55$, $\ell(0.16) = 2.0$, $\ell(0.12) = 2.5$. They are thus in ratio 1:1.29:1.61. The corresponding static length scales are in ratio 1:1.33:1.66. The agreement with the prediction $^{15}$ that both lengths should scale similarly is thus clearly excellent.

D. Another observable: The link overlap

To test further the hypothesis of a strong link between off-equilibrium properties and static ones resulting from the local equilibration of the material, we focus in this section on a second pair of dynamical observables. Physically, this is motivated by the picture given in section $^{[1]}$A where an off-equilibrium system was described as a mosaic of equilibrated sub-systems of size given by the coherence length. A logical consequence is that the link between static and dynamic quantities should exist for all physical observables. This is equivalent to the prediction and test of the unicity of the effective temperature in structural glasses $^{[12, 34, 35, 36]}$.

To check this hypothesis, we have investigated the following quantities:

$$C_{t} (t_1, t_2) = \frac{1}{2Nd} \sum_{i=1}^{N} \sum_{j=1}^{2d'} s_i(t_1)s_j(t_1)s_i(t_2)s_j(t_2),$$

$$R_{t} (t_1, t_2) = \frac{1}{2Nd} \sum_{i=1}^{N} \sum_{j=1}^{2d'} \frac{\partial s_j(t_1)s_j(t_1)}{\partial h_{ij}(t_2)} \bigg|_{h=0},$$

where the prime in the second sum indicates that it is restricted to the nearest neighbours of the site $i$. The field $h_{ij}$ is thermodynamically conjugated to the observable $s_is_j$, and can thus be seen as a random perturbation of the coupling constants. From these two dynamical functions, a new FD plot can be built.

Correspondingly, the static quantity to use is the link-overlap distribution function, $P(q_t)$, defined by

$$P(q_t) = \lim_{N \rightarrow \infty} \left\langle \delta \left( \frac{1}{2Nd} \sum_{i=1}^{N} \sum_{j=1}^{2d'} s_i^\alpha s_j^\beta s_i^\beta s_j^\beta - q_t \right) \right\rangle.$$

We use here the static data published in Ref. $^{[29]}$.

The comparison between the new sets of static and dynamic quantities is reported in Fig. 4 for the same parameters as in Fig. 3. It should not come as a surprise that the range of correlators covered by Fig. 4 is smaller than the one covered in Fig. 3. The long-time limit of the correlator is indeed non-zero in that case.

It is again clear that the agreement between static and dynamic data is very good. The point to emphasize is that for a given amplitude of the driving force, the same size $L$ as in Fig. 3 is used to compute static data, in agreement with the physical picture described above.

These results are a striking confirmation of the local equilibration hypothesis formulated in this paper.

E. Using the box overlap distributions

Having established numerically the validity of the relationship between static and dynamic properties in $d = 4$, we now turn to $d = 3$. This will allow us to make use of the box-overlap distribution functions published in Ref. $^{[25]}$. To compute this function, the linear size of
In this paper, we have given a scaling argument to support the proposition of Refs. [4, 5] to generalize the relationship between the off-equilibrium FDR and the equilibrium simulations, the box-overlap distribution function measured in the driven dynamics. This is a clear support of the analytical result that driven and aging dynamics should give rise to similar deviations from the FDT [12, 14, 15].

Third, we have intentionally included data for a very short wait time, $t_2 = 27$, for which the agreement with Eq. (20) is not quite as good, to underline the fact that during the dynamical measurements the coherence length itself evolves with time. This was obviously not the case when the driven dynamics was considered. For this short wait time, for instance, the final time is $t_1 = 10^3$, so that we do not expect the FD plot to follow the line built from static data obtained at a given box size corresponding to the earlier time $L = \ell(t_2)$. Indeed, a clear deviation at large times (corresponding to low values of the correlator) is observed. This was anticipated and noted in Refs. [4, 5], and was another motivation to focus also on the driven dynamics in this paper.

Fourth, we have discussed above the link between the coherence length $\ell$ and the system size or box size in terms of relative ratio. It is clear that an absolute comparison is not possible, since the coherence length has no ‘absolute value’, contrary to the box-size univocally defined in the static computation. However, the ‘large’ numerical factor between $L$ and $\ell$ reported in Ref. [20] (about 4 in $d = 3$) was an argument used against the theoretical proposition [14] formulated in this and previous works [37]. It can be seen from Fig. 6 that the factor between $\ell$ and $B$ is less than 2 when the box overlap distribution is used, thus clearly weakening this criticism.

IV. CONCLUSION

In this paper, we have given a scaling argument to support the proposition of Refs. [4, 5] to generalize the relationship between the off-equilibrium FDR and the equilibrium dynamics.
librium overlap distribution to the physically relevant domain of finite times and sizes. Inspired by previous approaches to the asymptotic relation \[ (14) \text{ - } (15) \], we proposed the relations \[ (14) \text{ and } (15) \] between the FDR computed at any moment of the dynamics, and the equilibrium box overlap distribution function, where the size of the box to be used is imposed by the dynamical coherence length.

We have argued that these relations reflect the simpler notions of the local equilibration in space and the dynamical heterogeneity of the system, two ingredients which are inherent to systems with slow dynamics, independently of their space dimensionality, their dynamics, or the presence of disorder.

We have emphasized throughout the paper that the relations \[ (14) \text{ - } (15) \] were the physically relevant ones, as compared to the asymptotic form of Eq. \[ (4) \]. Hence, they have to be taken into account before drawing conclusions on the equilibrium glass phase one seeks to study \[ (20) \]. This remark, already made in Refs. \[ (4, 5) \], is repeated here because there recently appeared FD plots built from experimental dynamic measurements in spin glasses \[ (18) \]. As anticipated \[ (3) \], this dynamical measurements are very similar to the ones observed in simulations, despite the enormous difference in time scales between experiments and simulations. This is because the growth of the coherence length is so slow in spin glasses that this difference in time scales reduces to a very modest factor in terms of the coherence length \[ (23, 32, 38) \]. This in fact implies that the ‘finite size effects’ reported in simulations, are present in experiments as well. This points towards the experimental irrelevance of the thermodynamic limit in spin glasses.

Finally, we made clear that the relations \[ (14) \text{ - } (15) \] had not the character of a theorem, meaning that more work is needed to assess their range of validity. In particular, coarsening systems are a simple counterexample of this relation. This is due to the fact that the dynamical behaviour is entirely dominated by topological defects which are absent in the equilibrium simulations, so that finite time dynamics and statics do not coincide \[ (4, 5, 39) \]. There remains to be seen to what extent this alternative ‘defect’ description of glassy dynamics generally holds in systems like supercooled liquids or soft glassy materials. This is certainly a quite challenging issue.

Acknowledgments

M. Mézard suggested to use the existing numerical results for the box-overlap distributions to weaken the criticism he had himself formulated \[ (37) \]. I thank E. Marinari, J. Ruiz-Lorenzo, H. Katzgraber, P. Young who kindly provided me with their static data \[ (23, 25, 29) \], and A. Barrat, P. Holdsworth, and M. Sellitto for early discussions and collaborations \[ (4, 5) \]. J. Kurchan made important remarks on a previous version of the manuscript and I warmly thank him for this luxury service après-thèse. This work is supported by a European Marie Curie Fellowship No HPMF-CT-2002-01927, CNRS (France) and Worcester College Oxford. Numerical simulations were started at the PSMN in ENS Lyon (France) and finished on Oswell at the Oxford Supercomputing Center, Oxford University.
