**ABSTRACT**

Eumycetoma is a chronic infection due to filamentous fungi. Herein, we report a case of eumycetoma presenting as a subcutaneous encapsulated lesion on the right leg with no previous traumatic implantation. From microscopic morphological characteristics and molecular analysis, the pathogenic fungal species were identified as *Biatriospora mackinnonii*. Surgical excision of the entire lesion was performed to reduce the fungal load and improve antifungal therapy response.

1. Introduction

Mycetoma is a chronic, progressively destructive disease of the subcutaneous tissues recognized by the World Health Organization (WHO) as a neglected tropical disease with a significant worldwide burden [1]. Based on the etiology, it is divided into two groups: eumycetoma, caused by true filamentous fungi, and actinomycetoma, due to aerobic filamentous actinomycetes [2]. Herein, we report a case of subcutaneous encapsulated eumycetoma due to *Biatriospora mackinnonii* (formerly *Nigrograna mackinnonii*).

2. Case

A previously healthy 44-year-old farmer from southeastern Mexico presented with a 30-year history of a slowly growing nodule over his right leg with seropurulent discharge and scarring, leading to malleolus deformity. The patient had no medical history of previous trauma. Direct examination in potassium hydroxide preparation revealed black grains, deformity. The patient had no medical history of previous trauma. Direct examination in potassium hydroxide preparation revealed black grains, due to aerobic filamentous actinomycetes [2]. Herein, we report a case of subcutaneous encapsulated eumycetoma due to *Biatriospora mackinnonii* (formerly *Nigrograna mackinnonii*).

Wide local excision was necessary to remove the complete encapsulated lesion to reduce the fungal load and improve antifungal therapy response (Fig. 2) (Fig. 3).

Skin biopsy showed granulomatous inflammation with black fungal grains (Fig. 4).

The fungus was identified as *B. mackinnonii* based on colony morphology, microscopic appearance, and molecular identification was done by rDNA internal transcribed spacer region (ITS) was amplified using primers ITS1 and ITS4, and the large ribosomal subunit (LSU) was amplified using primers LR5R and LR5. Treatment with itraconazole 400 mg/daily continued without relapse.

3. Discussion

Eumycetoma is a chronic implantation mycosis characterized by granulomatous infiltrates of the skin and the subcutaneous tissues. In Mexico, eumycetoma cases are rarely found and are caused by black fungi, representing only 5.39% of cases [3]. *Madurella mycetomatis* is the most typical organism among the etiological agents, followed by *Madurella pseudomyelomycetoma*, *Trematosphaeria grisea*, and *Biatriospora mackinnonii* [2]. *B. mackinnonii* is a known eumycetoma-causative agent in Latin America; four cases have been reported in Mexico [4]. This implantation mycosis develops slow-growing subcutaneous swelling and nodules, progressing to supplicative lesions and multiple draining sinus tracts that discharge black grains [5–7].

According to the natural habitat of this fungus in the soil, we can hypothesize that rural activities may expose the patients to repeated skin...
trauma, triggering subcutaneous mycosis. Over 75% of patients have a lesion in the lower extremity, most commonly in the foot (70%), followed by the hand (sites exposed to traumatic skin wounds). Since the incubation period varies from 3 months to 9 years before the first medical evaluation, patients may forget the initial trauma, as in our case [1,2].

Diagnosis of mycetoma must include the following classic clinical triad: 1) painless firm subcutaneous nodule, 2) multiple sinus formation, and 3) grain-containing purulent or seropurulent discharge [2]. Direct clinical and microscopic examinations, and culture, are low-cost specific diagnostic tools; culture is the gold standard for species identification [1]. However, in the present case, due to chronic disease, the infection presented as an encapsulated lesion and an absence of grain-containing discharge; this is rarely seen in eumycetoma.

Newer techniques, including fine-needle aspiration cytological examination and imaging, mainly cutaneous ultrasound and magnetic resonance imaging (MRI), are used to overcome diagnostic difficulties, playing an essential role in early diagnosis [8]. The “Dot in circle” sign is definite for mycetoma, consisting of single or multiple hypoechoic, thick-walled cavities with no acoustic enhancement. The grains often appear as sharp hyperechoic lesions [9]. High-intensity “circles” on MRI correlate with granulomatous infiltrates; central low signal “dots” correspond to the fungal grains, and the peripheral rim of hypointensity zones refers to the fibrous matrix [10]. These MRI findings correlate with ultrasonography (USG) [11].

Eumycetoma requires long-term medical therapy; however, the
treatment is not entirely successful, showing low cure rates (26%) [2]. Low minimum inhibitory concentrations (MIC) for amphotericin B and azoles are often observed in B. mackinnonii; moreover, MIC for azoles is three to four-fold dilutions higher than M. mycetomatis [12]; therefore, treatment duration often ranges between six months to three years, then surgical intervention is usually needed. Wide local surgical excision is the treatment of choice for non-responding eumycetoma and small, well-localized lesions, allowing better response to medical therapy [13, 14]. However, postoperative recurrence rates occurred in up to 50% of cases [15].

In conclusion, we present a case of eumycetoma due to B. mackinnonii, Latin America’s one of the most common eumycetoma agent. The diagnosis was based on culture, specific radiologic signs, histopathological examination, and molecular analysis. Surgical intervention is recommended for eumycetoma but not for actinomycetoma. In this case, the surgical intervention improved clinical and mycological outcomes.
