OBJECTIVE The purpose of this retrospective cohort study was to analyze the early complications and mortality associated with multilevel spine surgery for unstable fractures in patients older than 80 years of age with ankylosing spondylitis and to compare the results with an age- and sex-matched cohort of patients with unstable osteoporotic fractures.

METHODS A retrospective review of the electronic medical records at a single institution was conducted between January 2014 and December 2019. Patient demographics, surgical characteristics, complications, hospital course, and 90-day mortality were collected. Comorbidities were stratified using the age-adjusted Charlson Comorbidity Index (CCI).

RESULTS Among 11,361 surgically treated patients, 22 patients with ankylosing spondylitis (AS group) and 24 patients with osteoporosis (OS group) were identified. The mean ages were 83.1 ± 3.1 years and 83.2 ± 2.6 years, respectively. A significant difference in the mean CCI score was found (7.6 vs 5.6; p < 0.001). Multilevel posterior fusion procedures were conducted in all patients, with 6.7 ± 1.4 fused levels in the AS group and 7.1 ± 1.1 levels fused in the OS group (p > 0.05). Major complications developed in 10 patients (45%) in the AS group compared with 4 patients (17%) in the OS group (p < 0.05). The 90-day mortality was 36% in the AS group compared with 0% in the OS group (p < 0.001).

CONCLUSIONS Patients older than 80 years of age with AS bear a high risk of adverse events after multilevel spinal fusion procedures. The high morbidity and 90-day mortality should be clearly discussed and carefully weighed against surgical treatment.

KEYWORDS ankylosing spondylitis; mortality; elderly; complications; comorbidity

ANKYLOSING spondylitis (AS) is a chronic, inflammatory, progressive disease that primarily affects the spinal column; its prevalence ranges between 0.1% and 1.4%.1 Chronic inflammation causes ossification of the facet joints, ligaments, and intervertebral discs, which limits the range of motion of the spine. This remodeling process of the vertebrae produces a classic radiographic appearance known as bamboo spine, which is often accompanied by severe kyphosis.2 The ongoing inflammatory process in the spine further leads to a rigid spinal column and high osteostastic activity, resulting in poor bone quality that, in turn, can cause spinal fractures after low-energy trauma.3 Compared with a non-AS population, patients with AS have a fourfold higher risk for spinal fractures.4–6 Spinal fractures in patients with AS are often unstable due to disruption of all three columns, therefore rendering them prone to displacement. Most frequently involved are the lower cervical spine and cervicothoracic junction, followed by the thoracolumbar junction (T10–L2).4,7 With a growing elderly population due to rising life expectancy, the prevalence of patients older than 80 years of age is increasing continuously and, therefore, the incidence of AS in that age group is also increasing.8,9 Although conservative treatment can be an...
option for spinal fractures in AS, especially in the elderly who often suffer from several comorbidities, numerous studies have reported poor outcomes due to pulmonary complications, aspiration, worsening of kyphosis, dislocation, nonunion, and neurological decline. Furthermore, a higher mortality in nonsurgically treated patients has been described. Therefore, conservative treatment of spinal fractures in patients with AS is rarely recommended, even for nondisplacement injuries without neurological impairment. Additional reasons for surgical management include greater instability, which promotes secondary fracture displacement, and patient intolerance of external bracing.

Patients with AS and spinal fractures may develop higher rates of complications and mortality than patients without AS who suffer spinal fractures. Despite numerous case series, meta-analyses, literature reviews, and comparative cohort studies, no data regarding outcomes of surgically treated spinal fractures in patients with AS over 80 years of age exist in the current literature.

The purpose of the present study, therefore, is to analyze rates of early complications and 90-day mortality in patients with AS older than 80 years of age who received multilevel surgical treatment for unstable spinal fractures, and to compare these results to an age- and sex-matched cohort of patients without AS who received surgical treatment for unstable osteoporosis (OS).

**Methods**

This retrospective case-control study was approved by the IRB of Swedish Neuroscience Institute and is in accordance with the ethical standards of the 1964 Declaration of Helsinki and its later amendments. We performed a review of the electronic medical records of 11,361 consecutive patients who received surgical treatment at our institution from January 2014 to December 2019. Only patients older than 80 years of age with clearly evident AS on CT who had been surgically treated for unstable spinal fractures (AO type B or C) were included in this study (AS group) (Fig. 1A). On CT, we defined AS as ossification of the spinal ligaments, joints, and discs with a classic appearance of a bamboo spine. As a control group, we chose an age-matched cohort with acute traumatic, osteoporotic, unstable, complete burst fractures (AO type A) involving both endplates and the posterior wall (OS group) (Fig. 1B). Only patients with thoracic and thoracolumbar fractures without any other accompanying fractures or injuries were included. A Thoracolumbar Injury Classification and Severity score ≥ 4 was necessary for both groups, and a recent bone mineral osteodensitometric examination verifying osteoporosis was necessary in the OS group. Osteoporosis was defined according to the WHO guidelines with a T-score ≤ −2.5 measured within 1 year before surgical treatment. In the AS group, 7 patients (32%) had a known history of osteoporosis. Patients with a tumor or infection were excluded. A minimum follow-up of 12 months was required for all patients. Patient demographics, BMI, comorbidities, American Society of Anesthesiologists (ASA) class, pre- and postoperative neurological status (American Spinal Injury Association [ASIA] impairment grade), duration of surgery, blood loss, number of treated spinal levels, intra- and perioperative complications, hospital length of stay (LOS), intensive care unit (ICU) stay, readmission, reoperation, and mortality were recorded. Comorbidities were preoperatively assessed based on the age-adjusted Charlson Comorbidity Index (CCI). The CCI score was calculated for each patient to classify comorbidity and grouped as having no comorbidity (CCI = 0), minimal comorbidity (CCI = 1 or 2), moderate comorbidity (CCI = 3–5), or severe comorbidity (CCI > 6).

After retrieving the complications, we subdivided them as either major or minor. Major complications included deep surgical site infection, acute respiratory failure with unplanned reintubation, pulmonary embolism, myocardial infarction, cardiac arrest, acute heart failure, acute renal failure, gastrointestinal bleeding, and bowel perforation. Minor complications included delirium, acute encephalopathy, dysphagia, pleural effusion, pneumonia, urinary tract infection, deep vein thrombosis, ileus, and superficial wound infection.

All patients received open surgical treatment in the form of multilevel posterior spinal stabilization and decompression; removal of the epidural hematoma and laminectomy was necessary in two-thirds of the patients with AS (Fig. 2). Partial corpectomy from a posterior approach with anterior column augmentation was carried out in 3 patients in the osteoporosis control group.

**Statistical Analysis**

Bivariate analysis was performed to compare patients who received posterior fusion for AS with those who underwent posterior fusion for osteoporotic fractures. For categorical variables, frequency counts were computed and presented along with their percentages. For continuous variables, means were computed and presented along with their standard deviation. To compare categorical variables, the Pearson’s chi-square test was used. For
continuous outcomes, a t-test was applied. As these procedures are so rare in patients older than 80 years of age, and our sample size was small, we were unable to perform a multivariate analysis to adjust for potential confounding. All analyses were performed using Stata version 13.1 (StataCorp LLC).

**Results**

The AS group included 22 male patients with a mean age of 83.1 ± 3.1 years (range 80–91 years) and a mean BMI of 27.5 ± 5.7 kg/m². The OS group included 24 male patients with a mean age of 83.2 ± 2.6 years (range 80–91 years) and a mean BMI of 27.2 ± 4.7 kg/m². No significant difference in age or BMI was seen between the two groups (p > 0.05) (Table 1).

The thoracic spine was the region most commonly fractured in the AS group, affecting 15 patients (68%), followed by the thoracolumbar region in 7 patients (32%) (Table 2). In the OS group, 83% of the fractures involved the thoracolumbar spine, followed by the thoracic spine at 17%. No patient in this group had multilevel fractures.

**Mechanism of Trauma**

The most frequent mechanism of injury was a ground-level fall in 19 patients (86%) in the AS group and 17 patients (71%) in the OS group. The other mechanism in the AS group was a fall downstairs in 3 patients (14%). In the OS group, 6 patients (25%) incurred fractures without any distinct trauma and 1 patient (4%) reported back pain after chiropractic manipulation.

| Parameter                   | AS Group (n = 22) | OS Group (n = 24) | p Value |
|-----------------------------|------------------|------------------|---------|
| Mean age, yrs               | 83.1 ± 3.1       | 83.2 ± 2.6       | >0.05   |
| Male sex                    | 22 (100)         | 24 (100)         | >0.05   |
| Mean BMI, kg/m²             | 27.5 ± 5.7       | 27.2 ± 4.7       | >0.05   |
| Mean age-adjusted CCI score | 7.6 ± 1.4        | 5.6 ± 1.7        | <0.001  |
| Cardiac disease             | 14 (64)          | 5 (21)           | <0.001  |
| Pulmonary disease           | 7 (32)           | 4 (17)           | >0.05   |
| Cerebrovascular disease     | 4 (18)           | 3 (13)           | >0.05   |
| Renal disease               | 6 (27)           | 1 (4)            | >0.05   |
| Liver disease               | 4 (18)           | 2 (8)            | >0.05   |
| Malignancy                  | 5 (23)           | 2 (8)            | >0.05   |
| Diabetes                    | 9 (41)           | 11 (46)          | >0.05   |
| Dementia                    | 6 (27)           | 3 (13)           | >0.05   |
| ASA class                   |                  |                  |         |
| II                          | 1 (5)            | 1 (4)            | >0.05   |
| III                         | 16 (73)          | 20 (83)          | >0.05   |
| IV                          | 5 (23)           | 3 (13)           | >0.05   |
| Preop neurological deficit  | 9 (41)           | 11 (46)          | >0.05   |

Values are reported as number (%) or mean ± SD. Boldface type indicates statistical significance.
CCI Scores and ASA Classifications
The mean age-adjusted CCI score was 7.6 ± 1.4 for the AS group and 5.6 ± 1.7 for the OS group, which revealed a significant difference between the groups (p < 0.001) (Table 1). Preoperative narcotic-relevant ASA classification revealed 1 patient (4%) with ASA class II, 16 patients (73%) with ASA class III, and 5 patients (23%) with ASA class IV in the AS group. In the OS group, 1 patient (4%) was classified as ASA class II, 20 patients (83%) as ASA class III, and 3 patients (13%) as ASA class IV. No significant difference was found between the groups (p > 0.05) (Table 1).

Neurological Deficits
All patients presented with localized back pain (100%). Clinical neurological deficits were found in 41% of patients in the AS group and 46% of patients in the OS group (p > 0.05) (Table 1). Spinal cord injury was observed in 9 patients of the AS group; 5 patients had an ASIA grade D and 4 patients had an ASIA grade C. In the OS group, spinal cord injury occurred in 11 patients; 3 patients had an ASIA grade C and 8 patients had an ASIA grade D. None of the patients in either group demonstrated neurological deterioration after surgical treatment or neurological improvement at the time of discharge. The 3-month follow-up results revealed at least one grade of improvement in the AISA impairment grade for all patients in both groups who had neurological impairment (Table 2). No further improvement was seen at the 12-month follow-up.

Surgery
Open multilevel posterior fusion surgery was performed in all patients, with a mean of 6.7 ± 1.4 levels fused in the AS group and 7.1 ± 1.1 levels fused in the OS group (p > 0.05) (Tables 2 and 3). Three patients in the OS group required partial vertebrectomy with anterior column augmentation using a posterior approach. The mean intraoperative blood loss in the AS group was 584.1 ± 196.0 ml (range 300–1000 ml). In the OS group, the mean intraoperative blood loss was 570.8 ± 207.4 ml.

PDF = posterior decompression and fusion (for epidural hematoma); PF = posterior fusion; pt = patient.

### TABLE 3. Comparison of surgical characteristics between groups

| Parameter                  | AS Group (n = 22) | OS Group (n = 24) | p Value |
|----------------------------|-------------------|-------------------|---------|
| Mean surgical duration, mins | 226.5 ± 82.5      | 240 ± 51.2        | >0.05   |
| Mean EBL, ml               | 584.1 ± 196       | 570.8 ± 207.4     | >0.05   |
| Mean no. of levels fused   | 6.7 ± 1.4         | 7.1 ± 1.1         | >0.05   |
| Intraop complications      | 3 (13.6)          | 1 (4.2)           | >0.05   |

EBL = estimated blood loss
Values are reported as number (%) or mean ± SD.
The overall 90-day mortality was not noted in the OS group. At 90 days postoperatively, another 6 patients in the OS group died due to acute renal failure (n = 1), acute heart failure (n = 1), acute respiratory failure (n = 1), myoccardial infarction (n = 2), gastrointestinal bleeding (n = 1), and bowel perforation (n = 1) compared with none in the OS group. The overall 90-day mortality in the AS group was 36% compared with 0% in the OS group, which reached statistical significance (p < 0.001) (Table 5).

**LOS and ICU Stay**

Hospital and ICU stays were longer for patients with AS than for patients with osteoporotic fractures (11.5 ± 7.8 days and 3.8 ± 4.7 days vs 8.4 ± 3.3 days and 1.3 ± 1.2 days, respectively). A significantly longer ICU stay was seen in the AS group (p = 0.01) (Table 4).

**Complications**

Intraoperative complications developed in 3 patients in the AS group (dural tear) compared with 1 patient in the OS group (Table 3). No complications were noted in 9 patients in the AS group and 14 patients in the OS group. One patient in each group was readmitted within 30 days due to deep wound infection requiring surgical debridement. Minor complications developed in 8 patients (36%) in the AS group and 9 patients (38%) in the OS group during the early postoperative phase (Table 5); all of these patients could be treated successfully using conservative methods. Ten patients (45%) in the AS group developed major complications compared with 4 patients (17%) in the OS group. Four patients (18%) in the AS group and 3 patients (13%) in the OS group had both minor and major complications. No significant difference was found in terms of minor complication rates between groups (p > 0.05). In terms of total major complications, a significant difference was found between the two groups (p = 0.03) (Table 5).

**Mortality**

Two patients (9%) in the AS group died within a few days of surgery due to a perforated viscus (bowel perforation) (Fig. 3). In-hospital mortality was not noted in the OS group. At 90 days postoperatively, another 6 patients in the AS group died due to acute renal failure (n = 1), acute respiratory failure (n = 1), myoccardial infarction (n = 2), gastrointestinal bleeding (n = 1), and bowel perforation (n = 1) compared with none in the OS group. The overall 90-day mortality in the AS group was 36% compared with 0% in the OS group, which reached statistical significance (p < 0.001) (Table 5).

**Discussion**

With an increasing elderly population, the prevalence of patients older than 80 years of age is also rising. In Europe, it is estimated that the number of people older than 80 years of age will double in the next 25 years. With this changing demographic, a large portion of the healthcare infrastructure will be dedicated to a subset of the population, with limited resources for those requiring complex medical care. A study conducted in the United Kingdom concluded that age older than 80 years was a separate risk factor for postoperative complications in people undergoing both emergency and elective surgery. When elderly patients with AS present after low-energy trauma, clinicians should be aware of a higher risk of spine fractures. Authors have reported a three- to sevenfold higher risk of spine fractures in patients with AS and estimate that the risk of having a spine fracture rises by 1.3% per year after the age of 45 years. Although patients older than 80 years of age are at increased risk of encountering adverse events after surgical treatment of spine fractures, rates of complications, morbidity, and mortality are even higher when AS is present among other baseline comorbidities.

---

**TABLE 4. Clinical course in the AS group versus the OS group**

| Parameter              | AS Group (n = 22) | OS Group (n = 24) | p Value |
|------------------------|------------------|------------------|---------|
| Mean LOS, days         | 11.5 ± 7.8       | 8.4 ± 3.3        | >0.05   |
| Mean ICU stay          | 3.8 ± 4.7        | 1.3 ± 1.2        | 0.01    |

**TABLE 5. Ninety-day complication profile comparison between the AS group and the OS group**

| Complication                  | AS Group (n = 22) | OS Group (n = 24) | p Value |
|-------------------------------|------------------|------------------|---------|
| Major complications           |                  |                  |         |
| Deep wound infection          | 1 (5)            | 1 (4)            |         |

Values are reported as number (%) or mean ± SD. Boldface type indicates statistical significance.
The aim of this study was to compare rates of early complications and 90-day mortality in patients older than 80 years of age with AS who received multilevel surgical fusion surgery for unstable fractures and compare the results with an age- and sex-matched cohort of patients with unstable osteoporotic fractures. Our results showed that patients with AS had a significantly higher incidence of comorbidity as reflected by the discrepant CCI scores. Low-energy trauma was the leading cause of injury in both groups. The surgical complication rate in the AS group was higher, with dural tears observed in 3 patients compared with 1 patient in the OS group. It is unclear whether these complications were primarily due to intraoperative puncture or occult traumatic tears due to fractures of the lamina, which have been described in patients with AS.

As expected, a high postoperative complication rate was seen in both groups, with a significantly higher major complication rate in the AS group (45% vs 17%). We hypothesize that a higher proportion of comorbid conditions in the AS group may be associated with higher rates of complications. In the limited scope of this study, these findings may reflect an important trend in a highly vulnerable population that should be discussed with the patient and family prior to any intervention.

The overall 90-day mortality in surgically treated patients with AS was 36% compared with 0% in the OS group. Of the 9 deaths documented, 5 were from gastrointestinal-related complications. Although postoperative gastrointestinal complications uniformly increase with age, the incidence of such complications may be higher in patients with AS than in the general elderly population. The prevalence of inflammatory bowel disease has been described in up to 10% of patients with AS. In 2 patients with bowel perforation, Crohn’s disease and ulcerative colitis were histologically diagnosed.

**Review of the Literature**

In a series of elderly patients, Kobayashi et al. reported perioperative complications in 29% including 13% major complications. They found that age older than 85 years, blood loss more than 500 ml, and a surgical duration longer than 3 hours were significant risk factors. This study included different types of spine surgeries, from lumbar spinal stenosis to cervical spondylotic myelopathy; AS was not addressed.

In a large US database study (National [Nationwide] Inpatient Sample), Lukasiewicz et al. retrospectively analyzed 939 surgically treated patients with spinal fractures associated with AS. Of those, 253 patients (27%) were older than 80 years of age. Patients were treated either surgically or conservatively. The proportion of surgically treated patients in that study remains unclear. The overall inpatient mortality was 6.6%. Nearly 30% of patients experienced an adverse event during the inpatient stay. Rudwaleit et al. found that around 5% to 10% of patients had an underlying inflammatory bowel condition and an even larger proportion of them presented with subclinical inflammation.

Caron et al. retrospectively analyzed 122 patients with an inflammatory spinal disorder, of whom 28 patients (23%) had AS. Surgical treatment, consisting of multi-
level posterior instrumentation, was performed in 67% of patients. Complications during hospitalization developed in 84% of patients and were associated with a death rate of 32%, which correlated with older age and a greater number of comorbidities.

In 2017, Bredin et al. published a multicentric retrospective study of 31 patients with AS in whom percutaneous multilevel screw fixation was performed to treat thoracolumbar fractures. The mean age at surgery was 75 years, and an in-hospital mortality of 9.6% was reported. Complications were not described, except for 1 patient (3.2%) who required blood transfusion due to anemia after percutaneous screw fixation.

In a study by Westerveld et al., 14 surgically treated patients with AS with a mean age of 69 years were retrospectively analyzed. At least one complication was reported in 87.5% of patients. The in-hospital mortality rate was 7.1%.

Vazan et al. recently published a retrospective case series of 41 patients with ankylosing spinal disease with a mean age of 73 years. Of those, 24 patients (58.5%) had AS. The overall complication rate in the study was 48.8% and 5 patients (12.2%) died during hospitalization.

Limitations

The current study has several limitations, many of which are associated with the retrospective design and the limited number of patients in each cohort. We did not identify the subtypes of AS, which might have an influence on the clinical outcome. Furthermore, the kinetic energy required to create an unstable fracture may differ between groups, which potentially could have influenced the results. The minimum follow-up period of 12 months is relatively short, and, by gathering long-term data, other relevant findings not captured in the current study might be revealed. Furthermore, minimally invasive stabilization procedures for AS were not included. Due to a high rate of neurological deficits (46%) and epidural hematomas (64%) in the AS group, surgeons preferred to perform an open procedure with multilevel laminectomies. However, this study is unique in that it presents one of the few investigations of surgically treated AS in a population of patients older than 80 years of age. Larger studies are needed to further investigate the trends seen in our patient population.

Conclusions

Due to a steadily increasing average life expectancy, spinal surgeons will be frequently confronted with elderly patients requiring surgical treatment. The results of this and previous studies show that high complication rates are associated with treatment of patients older than 80 years of age with AS, whether they are surgically or nonsurgically treated. Despite a high morbidity and mortality, we still recommend that multilevel posterior stabilization should be considered for unstable fractures in patients with AS, although the risks should be clearly discussed with the patient and relatives. We hope that this study can help to develop a consensus about the best treatment strategy for unstable fractures in patients with AS older than 80 years of age.
