Abstract We characterize the complexity of liveness verification for parameterized systems consisting of a leader process and arbitrarily many anonymous and identical contributor processes. Processes communicate through a shared, bounded-value register. While each operation on the register is atomic, there is no synchronization primitive to execute a sequence of operations atomically. We analyze the case in which processes are modeled by finite-state machines or pushdown machines and the property is given by a Büchi automaton over the alphabet of read and write actions of the leader. We show that the problem is decidable, and has a surprisingly low complexity: it is NP-complete when all processes are finite-state machines, and is in NEXPTIME (and PSPACE-hard) when they are pushdown machines. This complexity is lower than for the non-parameterized case: liveness verification of finitely many finite-state machines is PSPACE-complete, and undecidable for two pushdown machines. For finite-state machines, our proofs characterize infinite behaviors using existential abstraction and semilinear constraints. For pushdown machines, we show how contributor computations of high stack height can be simulated by computations of many contributors, each with low stack height. Together, our results characterize the complexity of verification for parameterized systems under the assumptions of anonymity and asynchrony.

Keywords Model checking · Shared-memory systems · Parametrized verification

1 Introduction

We study the verification problem for parameterized asynchronous shared-memory systems [9,10,13]. These systems consist of a leader process and arbitrarily many identical contrib-
utors, processes with no identity, running at arbitrary relative speeds. The shared-memory consists of a read/write register that all processes can access. Processes can perform either a read operation or a write operation on the register. The register is bounded: the set of values that can be stored is finite. Read/write operations execute atomically but sequences of operations do not: no process can conduct an atomic sequence of reads and writes while excluding all other processes. In a previous paper [9,10], we have studied the complexity of safety verification, which asks to check if a safety property holds no matter how many contributors are present. In a nutshell, we showed that the problem is coNP-complete when both leader and contributors are finite-state automata and PSPACE-complete when they are pushdown automata.

In this paper we complete the study of this model by addressing the verification of liveness properties specified as \(\omega\)-regular languages (which in particular encompasses LTL model-checking). Given a property like “every request is eventually granted” and a system with a fixed number of processes, one is often able to guess an upper bound on the maximal number of steps until the request is granted, and replace the property by the safety property “every request is granted after at most \(K\) steps.” In parameterized systems this bound can depend on the (unbounded) number of processes, and so reducing liveness to safety, or to finitary reasoning, is not obvious. Indeed, for many parameterized models, liveness verification is undecidable even if safety is decidable [8,14].

Our results show that there is no large complexity gap between liveness and safety verification: liveness verification (existence of an infinite computation violating a property) is NP-complete in the finite-state case, and PSPACE-hard and in NEXPTIME in the pushdown case. In contrast, remember that liveness checking is already PSPACE-complete for a finite number of finite-state machines, and undecidable for a fixed number of pushdown systems. Thus, not only is liveness verification decidable in the parameterized setting but the complexity of the parameterized problem is lower than in the non-parameterized case, where all processes are part of the input. We interpret this as follows: in asynchronous shared-memory systems, the existence of arbitrarily many processes leads to a “noisy” environment, in which contributors may hinder progress by replying to past messages from the leader, long after the computation has moved forward to a new phase. It is known that imperfect communication can reduce the power of computation and the complexity of verification problems: the best known example are lossy channel systems, for which many verification problems are decidable, while they are undecidable for perfect channels (see e.g. [1,3]). Our results reveal another instance of the same phenomenon.

Technically, our proof methods are very different from those used for safety verification. Our previous results [10] relied on a fundamental Simulation Lemma, inspired by Hague’s work [13], stating that the finite behaviors of an arbitrary number of contributors can be simulated by a finite number of simulators, one for each possible value of the register. Unfortunately, the Simulation Lemma does not extend to infinite behaviors, and so we have to develop new ideas. In the case in which both leader and contributors are finite-state machines, the NP-completeness result is obtained by means of a combination of an abstraction that overapproximates the set of possible infinite behaviors, and a semilinear constraint that allows us to regain precision. The case in which both leader and contributors are pushdown machines is very involved. In a nutshell, we show that pushdown runs in which a parameter called the effective stack height grows too much can be “distributed” into a number of runs with smaller effective stack height. We then prove that the behaviors of a pushdown machine with a bounded effective stack height can be simulated by an exponentially larger finite-state machine.
1.1 Related work

Parameterized verification has been studied extensively, both theoretically and practically. While very simple variants of the problem are already undecidable [6], many non-trivial parameterized models retain decidability. There is no clear “rule of thumb” that allows one to predict what model checking problems are decidable, nor their complexities, other than “liveness is generally harder than safety.” For example, coverability for Petri nets—in which finite-state, identityless processes communicate via rendezvous or global shared state—is EXPSPACE-complete, higher than the PSPACE-completeness of the non-parameterized version. Depending on the formulation, verification of liveness properties can be equivalent to Petri net reachability, for which we only know non-primitive recursive upper bounds, or even undecidable. Safety verification for extensions to Petri nets with reset or transfer, or broadcast protocols, where arbitrarily many finite-state processes communicate through broadcast messages, is non-primitive recursive; liveness verification is undecidable in all cases [2,8,14]. Thus, our results, which show simultaneously lower complexity than non-parameterized problems, as well as similar complexity for liveness and safety, are unexpected.

German and Sistla [11] and Aminof et al. [4] have studied a parameterized model with rendezvous as communication primitive, where processes are finite-state machines. Model checking the fully symmetrical case—only contributors, no leaders—runs in polynomial time (other topologies have also been considered [4]), while the asymmetric case with a leader is EXPSPACE-complete. In this paper we study the same problems, but for a shared memory communication primitive.

1.2 Population protocols

Angluin et al. [5] are another well-studied model of identityless asynchronous finite-state systems communicating via rendezvous. The semantics of population protocols is given over fair runs, in which every potential interaction that is infinitely often enabled is infinitely often taken. With this semantics, population protocols compute exactly the semilinear predicates [5]. In this paper we do not study what our model can compute (in particular, we are agnostic with respect to which fairness assumptions are reasonable), but what we can compute or decide about the model.

Recently La Torre et al. [16] defined a general framework to show decidability of the safety checking problem for parameterized asynchronous shared-memory systems. A salient feature of the proposed framework is that it generalizes beyond the models of finite state and pushdown machines previously studied [10]. However, to the best of our knowledge generalizing their framework to liveness checking is a challenging research problem.

2 Formal model: non-atomic networks

In this paper, we identify systems with languages. System actions are modeled as symbols in an alphabet, executions are modeled as infinite words, and the system itself is modeled as the language of its executions. Composition operations that combine systems into larger ones are modeled as operations on languages.

2.1 Systems as languages

An alphabet $\Sigma$ is a finite, non-empty, set of symbols. A word over $\Sigma$ is a finite sequence over $\Sigma$ including the empty sequence denoted $\varepsilon$, and a language is a set of words. An $\omega$-word
over $\Sigma$ is an infinite sequence of symbols of $\Sigma$, and an $\omega$-language is a set of $\omega$-words. We use $\Sigma^*$ (resp. $\Sigma^*_{1}$) to denote the language of all words (resp. $\omega$-words) over $\Sigma$. When there is no ambiguity, we use “words” to refer to words or $\omega$-words. We do similarly for languages.

Let $w$ be a sequence over some alphabet, define $\text{dom}(w) = \{1, \ldots, n\}$ if $w = a_1 a_2 \ldots a_n$ is a word; else ($w$ is an $\omega$-word) $\text{dom}(w)$ denotes the set $\mathbb{N}\setminus\{0\}$. Elements of $\text{dom}(w)$ are called positions. The length of a sequence $w$ is defined to be $\sup \text{dom}(w)$ and is denoted $|w|$. We denote by $(w)_i$ the symbol of $w$ at position $i$ if $i \in \text{dom}(w)$, $\varepsilon$ otherwise. Moreover, let $(w)_{i,j}$ with $i, j \in \mathbb{N}$ denote $(w)_i (w)_{i+1} \ldots (w)_j$ if $i \leq j$ and $\varepsilon$ otherwise. Also $(w)_{i,\infty}$ denotes $(w)_i (w)_{i+1} \ldots$. For words $u, v \in (\Sigma^1 \cup \Sigma^*)$, we say $u$ is a prefix of $v$ if either $u = v$ or $u \in \Sigma^*$ and there is a $w \in (\Sigma^1 \cup \Sigma^*)$ such that $v = uw$.

### 2.1.1 Combining systems: shuffle

Intuitively, the shuffle of systems $L_1$ and $L_2$ is the system interleaving the executions of $L_1$ with those of $L_2$. Given two $\omega$-languages $L_1 \subseteq \Sigma^*_1$ and $L_2 \subseteq \Sigma^*_2$, their shuffle, denoted $L_1 \parallel L_2$, is the $\omega$-language over $(\Sigma^1 \cup \Sigma^2)$ defined as follows. Given two $\omega$-words $x \in \Sigma^*_1$, $y \in \Sigma^*_2$, we say that $z \in (\Sigma^1 \cup \Sigma^2)^\omega$ is an interleaving of $x$ and $y$ if there exist (possibly empty) words $x_1, x_2, \ldots, x_i, \ldots \in \Sigma^*_1$ and $y_1, y_2, \ldots, y_i, \ldots \in \Sigma^*_2$ such that each $x_1 x_2 \ldots x_i$ is a prefix of $x$, and each $y_1 y_2 \ldots y_i$ is a prefix of $y$, and $z = x_1 y_1 x_2 y_2 \ldots x_i y_i \ldots \in \Sigma^\omega$ is an $\omega$-word. Then $L_1 \parallel L_2 = \bigcup_{x \in L_1} \bigcup_{y \in L_2} x \parallel y$, where $x \parallel y$ denotes the set of all interleavings of $x$ and $y$. For example, if $L_1 = ab^\omega$ and $L_2 = ab^\omega$, we get $L_1 \parallel L_2 = (a + ab^\omega) b^\omega$.

Shuffle is associative and commutative, and so we can write $L_1 \parallel \cdots \parallel L_n$ or $\parallel_{i=1}^n L_i$.

### 2.1.2 Combining systems: asynchronous product

The asynchronous product of $L_1 \subseteq \Sigma^*_1$ and $L_2 \subseteq \Sigma^*_2$ also interleaves the executions but, this time, the actions in the common alphabet must now be executed jointly. The $\omega$-language of the resulting system, called the asynchronous product of $L_1$ and $L_2$, is denoted by $L_1 \concat L_2$, and defined as follows. Let $\text{Proj}_{\Sigma_2}(w)$ be the word obtained by erasing from $w$ all occurrences of symbols not in $\Sigma$. $L_1 \concat L_2$ is the $\omega$-language over the alphabet $\Sigma = \Sigma_1 \cup \Sigma_2$ such that $w \in L_1 \concat L_2$ iff $\text{Proj}_{\Sigma_1}(w)$ and $\text{Proj}_{\Sigma_2}(w)$ are prefixes of words in $L_1$ and $L_2$, respectively. We abuse notation and write $w_1 \concat L_2$ instead of $\{w_1\} \concat L_2$ when $L_1 = \{w_1\}$. For example, let $\Sigma_1 = \{a, c\}$ and $\Sigma_2 = \{b, c\}$. For $L_1 = (ac)^\omega$ and $L_2 = (bc)^\omega$ we get $L_1 \concat L_2 = ((ab + ba)c)^\omega$. Observe that the language $L_1 \concat L_2$ depends on $L_1$, $L_2$ and also on $\Sigma_1$ and $\Sigma_2$. For example, if $\Sigma_1 = \{a\}$ and $\Sigma_2 = \{b\}$, then $\{a^\omega\} \concat \{b^\omega\} = (a + b)^\omega$, but if $\Sigma_1 = \{a, b\} = \Sigma_2$, then $\{a^\omega\} \concat \{b^\omega\} = \emptyset$. So we should more properly write $L_1 \concat_{\Sigma_1, \Sigma_2} L_2$. However, since the alphabets $\Sigma_1$ and $\Sigma_2$ will be clear from the context, we will omit them. Like shuffle, asynchronous product is also associative and commutative, and so we write $L_1 \concat \cdots \concat L_n$. Notice finally that shuffle and asynchronous product coincide if $\Sigma_1 \cap \Sigma_2 = \emptyset$, but usually differ otherwise. For instance, if $L_1 = ab^\omega$ and $L_2 = ab^\omega$, we get $L_1 \concat L_2 = ab^\omega$.

We describe systems as combinations of shuffles and asynchronous products, for instance we write $L_1 \parallel (L_2 \parallel L_3)$. In these expressions we assume that $\parallel$ binds tighter than $\concat$, and so $L_1 \parallel L_2 \parallel L_3$ is the language $(L_1 \parallel L_2) \parallel L_3$, and not $L_1 \parallel (L_2 \parallel L_3)$.

### 2.2 Non-atomic networks

A non-atomic network is an infinite family of systems parameterized by a number $k$. The $k$th element of the family has $k + 1$ components communicating through a global store by
Initially the store is only willing to execute a write. Formally, the store is a single read or write. The store is modeled as an atomic register whose set of possible values is finite. One of the \(k+1\) components is the leader, while the other \(k\) are the contributors. All contributors have exactly the same possible behaviors (they are copies of the same \(\omega\)-language), while the leader may behave differently. The network is called non-atomic because components cannot atomically execute sequences of actions, only one single read or write.

Formally, we fix a finite set \(G\) of \textit{global values}. A \textit{read-write alphabet} is any set of the form \(A \times G\), where \(A\) is a set of \textit{read} and \textit{write} (\textit{actions}). We denote a symbol \((a, g) \in A \times G\) by \(a(g)\) and define \(G(a_1, \ldots, a_n) = \{a_i(g)\mid 1 \leq i \leq n, g \in G\}\).

We fix two languages \(D \subseteq \Sigma_D^G\) and \(C \subseteq \Sigma_C^G\), called the \textit{leader} and the \textit{contributor}, with alphabets \(\Sigma_D = G(r_d, w_d)\) and \(\Sigma_C = G(r_c, w_c)\), respectively, where \(r_d, r_c\) are called \textit{reads} and \(w_c, w_d\) are called \textit{writes}. We write \(w_\ast\) (respectively, \(r_\ast\)) to stand for either \(w_c\) or \(w_d\) (respectively, \(r_c\) or \(r_d\)). We further assume that \(\text{Proj}_{r_\ast(g), w_\ast(g)}(D \cup C) \neq \emptyset\) holds for every \(g \in G\), else the value \(g\) is never used and can be removed from \(G\).

Additionally, we fix an \(\omega\)-language \(S\), called the \textit{store}, over \(\Sigma_D \cup \Sigma_C\). It models the sequences of read and write operations supported by a single atomic register: a write \(w_\ast(g)\) writes \(g\) to the register, while a read \(r_\ast(g)\) succeeds when the register’s current value is \(g\). Initially the store is only willing to execute a write. Formally \(S\) is defined as

\[
\left( \sum_{g \in G} (w_\ast(g) (r_\ast(g))^{\omega}) \right)^{\omega} + \left( \sum_{g \in G} (w_\ast(g) (r_\ast(g))^{\omega}) \right)^* \sum_{g \in G} (w_\ast(g) (r_\ast(g))^{\omega})
\]

and any finite prefix thereof. Observe that \(S\) is completely determined by \(\Sigma_D\) and \(\Sigma_C\). Figure 1 depicts a store with \(\{1, 2, 3\}\) as possible values as the language of a transition system.

**Definition 1** Let \(D \subseteq \Sigma_D^G\) and \(C \subseteq \Sigma_C^G\) be a leader and a contributor, and let \(k \geq 1\). The \textit{k-instance of the} \((D, C)\)-network is the \(\omega\)-language \(N^{(k)} = (\langle D || S \parallel \otimes_k C \rangle)\) where \(\otimes_k C\) stands for \(\otimes_{i=1}^k C\). The \((D, C)\)-network \(N\) is the \(\omega\)-language \(N = \bigcup_{k=1}^{\infty} N^{(k)}\). We omit the prefix \((D, C)\), and it is clear from the context. It follows easily from the properties of shuffle and asynchronous product that \(N = (D || S \parallel \otimes_\infty C)\), where \(\otimes_\infty C\) is an abbreviation of \(\bigcup_{k=1}^{\infty} \otimes_k C\).

Next we introduce a notion of \textit{compatibility} between a word of the leader and a multiset of words of the contributor (a multiset because several contributors may execute the same sequence of actions). Intuitively, compatibility means that all the words can be interleaved into a legal infinite sequence of reads and writes supported by an atomic register—that is, an infinite sequence belonging to \(S\). Formally:
Definition 2 Let \( u \in \Sigma_D^\omega \), and let \( M = \{ v_1, \ldots, v_k \} \) be a multiset of words over \( \Sigma_C^\omega \) (possibly containing multiple copies of a word). We say that \( u \) is compatible with \( M \) iff the \( \omega \)-language \( (u \parallel S \parallel \bigoplus_{i=1}^k v_i) \) is non-empty. When \( u \) and \( M \) are compatible, there exists a word \( s \in S \) such that \( (u \parallel s \parallel \bigoplus_{i=1}^k v_i) \neq \emptyset \). We call \( s \) a witness of compatibility.

Example 1 Consider the network with \( G = \{ 1, 2, 3 \} \) where the leader, store, and contributor languages are given by the infinite paths of the transition systems from Fig. 1. The only \( D \)-language of \( G \) is \( (r_d(1)r_d(2)r_d(3))^\omega \) and the \( \omega \)-language of \( C \) is \( (w_c(1)r_c(3)r_c(1) + w_c(2)r_c(1)r_c(2) + w_c(3)r_c(2)r_c(3))^\omega \). For instance, \( D = (r_d(1)r_d(2)r_d(3))^\omega \) is compatible with the multiset \( M \) of 6 \( \omega \)-words obtained by taking two copies of \( (w(1)r(3)r(1))^\omega \), \( (w(2)r(1)r(2))^\omega \) and \( (w(3)r(2)r(3))^\omega \). The reader may be interested in finding another multiset compatible with \( D \) and containing only four \( \omega \)-words.

2.3 Stuttering property

Intuitively, the stuttering property states that if we take an \( \omega \)-word of a network \( N \) and “stutter” reads and writes of the contributors, e.g., going from \( w_d(1)r_c(1)w_c(2)r_d(2) \ldots \) to \( w_d(1)r_c(1)w_c(2)w_c(2)w_c(2)r_d(2) \ldots \), the result is again an \( \omega \)-word of the network.

Let \( s \in S \) be a witness of compatibility of \( u \in \Sigma_D^\omega \) and \( M = \{ v_1, \ldots, v_k \} \). Pick a set \( I \) of positions (viz. \( I \subseteq \text{dom}(s) \)) such that \((s)_i \in \Sigma_C\) for every \( i \in I \), and pick a number \( \ell_i \geq 0 \) for every \( i \in I \). Let \( s' \) be the result of simultaneously replacing each \((s)_i\) by \((s)_i^{\ell_i+1}\) in \( s \). We have that \( s' \in S \). Now let \( v = (s)_1^{\ell_1} \cdot (s)_2^{\ell_2} \cdot \ldots \), where \( i_1 = \min(I) \), \( i_2 = \min(I \setminus \{i_1\}) \), \ldots.

It is easy to see that \((u \parallel s' \parallel v_i) \triangleright \bigoplus_{i=1}^k v_i \neq \emptyset \).

We assume the reader to be familiar with basic multiset operations including multiset union and difference which we denote here by \( \oplus \) and \( \ominus \), respectively. Equipped with multiset notations, we proceed by stating the Copycat Lemma which follows easily from the stuttering property [10].

Lemma 1 (Copycat Lemma) Let \( u \in \Sigma_D^\omega \) and let \( M \) be a multiset of words of \( \Sigma_C^\omega \). If \( u \) is compatible with \( M \), then \( u \) is also compatible with \( M \oplus \{ v \} \) for every \( v \in M \).

2.4 The model-checking problem for linear-time properties

We consider the model checking problem for linear-time properties, that asks, given a network \( N \) and an \( \omega \)-regular language \( L \), decide whether \( N \parallel L \) is non-empty. We assume \( L \) is given as a Büchi automaton \( A \) over \( \Sigma_D \). Intuitively, \( A \) is a tester that observes the actions of the leader; we call this the leader model checking problem.

We study the complexity of leader model checking for networks in which the read-write \( \omega \)-languages \( D \) and \( C \) of leader and contributor are generated by an abstract machine, like a finite-state machine (FSM) or a pushdown machine (PDM). (We give formal definitions later.) More precisely, given two classes of machines \( D, C \), we study the model checking problem \( MC(D, C) \) defined as follows:

**Given:** Machines \( D \in D \) and \( C \in C \), and a Büchi automaton \( A \),

**Decide:** Is \( N_A = (L(A) \parallel L(D) \parallel S \parallel \bigoplus_{i=1}^k L(C)) \) non-empty?

In the next sections we prove that \( MC(FSM, FSM) \) and \( MC(PDM, FSM) \) are NP-complete, while \( MC(PDM, PDM) \) is in NEXPTIME and PSPACE-hard.

Example 2 Consider the instance of the model checking problem where \( D \) and \( C \) are as in Figure 1, and \( A \) is a Büchi automaton recognizing all words over \( \Sigma_D \) containing infinitely.
many occurrences of \( r_d(1) \). Since \( D \) is compatible with a multiset of words of the contributors, \( N_A \) is non-empty. In particular, \( N_A^{(4)} \neq \emptyset \).

Since \( \Sigma_A = \Sigma_D \), we can replace \( A \) and \( D \) by a machine \( A \times D \) with a Büchi acceptance condition. The construction of \( A \times D \) given \( A \) and \( D \) is standard. In what follows, we assume that \( D \) comes with a Büchi acceptance condition and forget about \( A \).

There are two natural variants of the model checking problem, where \( \Sigma_A = \Sigma_C \), i.e., the alphabet of \( A \) contains the actions of all contributors, or \( \Sigma_A = \Sigma_D \cup \Sigma_C \). In both these variants, the automaton \( A \) can be used to simulate atomic networks. Indeed, if the language of \( A \) consists of all sequences of the form \((w_d())r_c()w_c()r_d())^\omega\), and we design the contributors so that they alternate reads and writes, then the accepting executions are those in which the contributors read a value from the store and write a new value in an atomic step. So the complexity of the model-checking problem coincides with the complexity for atomic networks (undecidable for PDMs and EXPSPACE-complete for FSMs), and we do not study it further.

### 3 \( \text{MC(FSM, FSM)} \) is NP-complete

We fix some notations. A finite-state machine (FSM) \( (Q, \delta, q_0) \) over \( \Sigma \) consists of a finite set of states \( Q \) containing an initial state \( q_0 \) and a transition relation \( \delta \subseteq Q \times \Sigma \times Q \). A word \( v \in \Sigma^\omega \) is accepted by an FSM if there exists a sequence \( q_1q_2 \cdots \) of states such that \((q_i, (v)_{i+1}, q_{i+1}) \in \delta \) for all \( i \geq 0 \). We denote by \( q_0 \xrightarrow{(v)} q_1 \xrightarrow{(v)} q_2 \cdots \) the run accepting \( v \). A Büchi automaton \( (Q, \delta, q_0, F) \) is an FSM \( (Q, \delta, q_0) \) together with a set \( F \subseteq Q \) of accepting states. An \( \omega \)-word \( v \in \Sigma^\omega \) is accepted by a Büchi automaton if there is a run \( q_0 \xrightarrow{(v)} q_1 \xrightarrow{(v)} q_2 \cdots \) such that \( q_j \in F \) for infinitely many positions \( j \). The \( \omega \)-language of a FSM or Büchi automaton \( A \), denoted by \( L(A) \), is the set of \( \omega \)-words accepted by \( A \).

In the rest of the section we show that \( \text{MC(FSM, FSM)} \) is NP-complete. Section 3.1 defines the infinite transition system associated with a (FSM, FSM)-network. Section 3.2 introduces an associated finite abstract transition system. Section 3.3 states and proves a lemma (Lemma 3) characterizing the cycles of the abstract transition system that, loosely speaking, can be concretized into infinite executions of the concrete transition system. Membership in NP is then proved using this lemma. NP-hardness follows from NP-hardness of reachability [10].

#### 3.1 (FSM, FSM)-networks: populations and transition system

We fix a Büchi automaton \( D = (Q_D, \delta_D, q_0D, F) \) over \( \Sigma_D \) and an FSM \( C = (Q_C, \delta_C, q_0C) \) over \( \Sigma_C \). A configuration is a tuple \((q_D, g, p)\), where \( q_D \in Q_D, g \in G \cup \{\#\} \), and \( p : Q_C \rightarrow \mathbb{N} \) assigns to each state of \( C \) a natural number. Intuitively, \( q_D \) is the current state of \( D \); \( g \) is a value or the special value \#, modelling that the store has not been initialized yet, and no process reads before some process writes; finally, \( p(q) \) is the number of contributors currently at state \( q \in Q_C \). We call \( p \) a population of \( Q_C \), and write \( |p| = \sum_{q \in Q_C} p(q) \) for the size of \( p \). Populations are part of a larger set of mappings into \( \mathbb{Z} \). We thus can define linear combinations of populations as follows: let \( k_1 \) and \( k_2 \) be two integers, for every state \( q \in Q_C \), we have \((k_1p_1 + k_2p_2)(q) := k_1p_1(q) + k_2p_2(q)\). Also we define the ordering \( \leq \) as follows: \( p_1 \leq p_2 \) iff \( p_1(q) \leq p_2(q) \) for every \( q \). Further, given \( q \in Q_C \), we denote by \( q \) the population \( q(q') = 1 \) if \( q = q' \) and \( q(q') = 0 \) otherwise, i.e., the population with one contributor in state \( q \) and no contributors elsewhere. We stick to the convention that \( q, q', q_1, \ldots \) denote such population with one process while \( p, p', p_1, \ldots \) denote general population with any
number of processes. A configuration is accepting if the state of D is accepting, that is whenever \(q_D \in F\). Given a set of populations \(P\), we define \((q_D, g, P) := \{(q_D, g, p)|p \in P\}\).

The labelled transition system \(TS = (X, T, X_0)\) associated to \(N_A\) is defined as follows:

- \(X\) is the set of all configurations, and \(X_0 \subseteq X\) is the set of initial configurations, given by \((q_{0D}, #, P_0)\), where \(P_0 = \{kq_{0C}|k \geq 1\}\) represents an arbitrary number of contributors in their initial state \(q_{0C}\);

- \(T = T_D \cup T_C\), where

  - \(T_D\) is the set of triples \([(q_D, g, p), t, (q'_D, g', p')\)] such that \(t\) is a transition of \(D\), viz. \(t \in \delta_D\), and one of the following conditions holds: (i) \(t = (q_D, w_d(g'), q'_D)\); or (ii) \(t = (q_D, r_d(g), q'_D), g = g'\).

  - \(T_C\) is the set of triples \([(q_D, g, p), t, (q_D, g', p')\)] such that \(t \in \delta_C\), and one of the following conditions holds: (iii) \(t = (q_C, w_c(g'), q'_C), p \geq q_C\), and \(p' = p - q_C + q'_C\); or (iv) \(t = (q_C, r_c(g), q'_C), p \geq q_C\), and \(p' = p - q_C + q'_C\). In both cases, \(p'\) results from moving a contributor from \(p\) from state \(q_C\) to \(q'_C\).

Observe that \(|p| = |p'|\), because the total number of contributors of a population remains constant.

Given configurations \(c\) and \(c'\), we write \(c \xrightarrow{t} c'\) if \((c, t, c') \in T\).

**Example 3** Consider the \((D, C)\)-network of Fig. 1. In the corresponding labelled transition system, the transition \((i_d, #, 2i_c + i_c) \xrightarrow{t} (i_d, 1, 3i_c')\) captures, in a 4-instance of the network (3 contributors and the leader), that one contributor moves from \(i_c\) to \(i_c'\) and overwrites the value \# of the store with 1 while all the other processes remain unchanged.

A path (or \(TS\)-path when ambiguous) is a (possibly infinite) sequence of configurations \(c_0, c_1, \ldots\) such that \(c_{i−1} \xrightarrow{t_i} c_i\) holds for all \(i\). A path is said to be accepting if at infinitely many positions along the run, the configuration is accepting. We introduce a notation important for Lemma 3 below. We define \(\Delta(t) := p' - p\). Observe that \(\Delta(t) = 0\) in cases (i) and (ii) above, and \(\Delta(t) = -q_C + q_C'\) in cases (iii) and (iv). So \(\Delta(t)\) depends only on the transition \(t\), but not on \(p\).

**Proposition 1** Every accepting \(TS\)-path \(c_0 \xrightarrow{t_1} c_1 \xrightarrow{t_2} c_2 \ldots\) is such that the same accepting configuration is visited infinitely often.

**Proof** Note that because the total number of contributors remains constant and because \(Q_D\) and \(G\) are finite sets, the pigeonhole principle shows that along the accepting path the same configuration repeats infinitely often. \(\square\)

We conclude by observing a property of accepting \(TS\)-path which hints at the existence of finite witnesses of their existence. Given an infinite path \(c_0 \xrightarrow{t_1} c_1 \xrightarrow{t_2} c_2 \ldots\), it follows immediately from the previous result that, given any two positions \(j_1 < j_2\) where the same accepting configuration repeats, the equality

\[
\sum_{i=j_1+1}^{j_2} \Delta(t_i) = 0
\]

holds.

On the other hand, if one can establish \(c_0 \xrightarrow{s} c_h\) and \(c_{\ell_1} \xrightarrow{t_{\ell_1+1}} c_{\ell_1+1} \ldots \xrightarrow{t_{\ell_2}} c_{\ell_2}\) such that (i) \(c_h = (q, g, p_h)\), \(c_{\ell_1} = (q, g, p_{\ell_1})\) with \(p_h \geq p_{\ell_1}\), (ii) \(c_{\ell_1} = c_{\ell_2}\) (which implies
\[ \sum_{i=\ell_1+1}^{\ell_2} \Delta(t_i) = 0 \]
then there exists an infinite path from \( c_0 \) by first visiting \( c_h \) and then
firing the sequence of transitions \( t_{\ell_1+1} \ldots t_{\ell_2} \) ad infinitum. Because \( p_h \) is such that \( p_h \geq p_{\ell_1} \),
it enables more transitions and does not disable any. Thus the sequence \( (t_{\ell_1} \ldots t_{\ell_2}) \) can also
be executed from \( c_h \).

3.2 The abstract transition system

We introduce an abstraction function \( \alpha \) that assigns to a set \( P \) of populations the set of states of
\( Q_C \) populated by \( P \). We also introduce a concretization function \( \gamma \) that assigns to a set
\( Q \subseteq Q_C \) the set of all populations \( p \) that only populate states of \( Q \). Formally:
\[
\alpha(P) = \{ q \in Q_C | p(q) \geq 1 \text{ for some } p \in P \}
\]
\[
\gamma(Q) = \{ p | p(q) = 0 \text{ for every } q \in Q_C \setminus Q \}
\]
It is easy to see that \( \alpha \) and \( \gamma \) satisfy \( \gamma(\alpha(P)) \supseteq P \) and \( \alpha(\gamma(Q)) = Q \), and so \( \alpha \) and \( \gamma \)
form a Galois connection (actually, a Galois insertion). An abstract configuration is a tuple
\( (q_D, g, Q) \), where \( q_D \in Q_D, g \in G \cup \{\#\} \) and \( Q \subseteq Q_C \). We extend \( \alpha \) and \( \gamma \) to (abstract)
configurations in the obvious way. An abstract configuration is accepting when the state of
\( D \) is accepting, that is whenever \( q_D \in F \).

Given \( TS = (X, T, X_0) \), we define its abstraction \( \alpha TS = (\alpha X, \alpha T, \alpha X_0) \) as follows:
- \( \alpha X = Q_D \times (G \cup \{\#\}) \times 2^{Q_C} \) is the set of all abstract configurations.
- \( \alpha X_0 = \{(q_{0D}, \#, \alpha(P_{0})) = \{(q_D, \#, \{q_{0C}\})\} \) is the initial configuration.
- \( \{(q_D, g, Q), t, (q_D', g', Q')\} \in \alpha T \) if there is \( p \in \gamma(Q) \) and \( p' \) such that
\( (q_D, g, p) \xrightarrow{t} (q_D', g', p') \) and \( Q' = \alpha(\gamma(Q)) \) or \( p' \).

Example 4 Consider the transition of labelled transition system given at Example 3. In the
approaching, abstract labelled transition system \( (i_d, \#, [i_c', i_c]) \xrightarrow{t} (i_d, 1, [i_c', i_c]) \) is the
abstract transition corresponding to \( t \). Notice the presence of \( i_c \) on both sides of the abstract
transition. To understand why, it suffices to consider \( (i_d, \#, 2i_C + 2i_c) \xrightarrow{t} (i_d, 1, 3i_C + i + c) \)
in the labelled transition system corresponding to a 5-instance of the network.

Observe that the number of abstract configurations is bounded by \( K = |Q_D| \cdot (|G| + 1) \cdot 2^{|Q_C|} \). Let us point out that our abstract transition system resembles but is different from that of
Pnueli et al. \cite{15}. We write \( a \xrightarrow{t} a' \) if \( (a, t, a') \in \alpha T \). The notion of accepting configuration and
path are defined as expected. The abstraction satisfies the following properties:

(A) \( \gamma((q, g, Q)) \subseteq \gamma((q, g, Q')) \) for every \( q, g \) and \( Q \subseteq Q' \).

(B) For each (possibly infinite) \( TS \)-path \( c_0 \xrightarrow{t_1} c_1 \cdots \), there exists an equally long \( \alpha TS \)-path
\( a_0 \xrightarrow{t_1} a_1 \cdots \) such that \( a_i \in \gamma(a_i) \) for all \( i \geq 0 \). Moreover, if \( c_0 \in X_0 \) then there
exists an \( \alpha TS \)-path starting from \( a_0 \in \alpha X_0 \).

(C) If \( (q_D, g, Q) \xrightarrow{t} (q_D', g', Q') \), then \( Q \subseteq Q' \).

To prove this claim, consider two cases:

(a) \( t \in \delta_D \). Then \( (q_D, g, p) \xrightarrow{t} (q_D', g', p') \) for every population \( p \) (because only
the leader moves). So \( (q_D, g, Q) \xrightarrow{t} (q_D', g', Q) \).

(b) \( t \in \delta_C \). Consider the population \( p = 2 \sum_{q \in Q} q \in \gamma(Q) \). Then \( (q_D, g, p) \xrightarrow{t}
(q_D, g', p') \), where \( p' = p - qC + qC' \). But then \( p' \geq \sum_{q \in Q} q \), and so \( \alpha(p') \supseteq Q \),
which implies \( (q_D, g, Q) \xrightarrow{t} (q_D', g', Q') \) for some \( Q' \supseteq Q \).
So in every infinite $\alpha TS$-path $a_0 \xrightarrow{i_1} \alpha a_1 \xrightarrow{i_2} \alpha a_2 \cdots$, where $a_i = (q_{Di}, g_i, \bar{Q}_i)$, there is an index $i$ at which the $Q_i$ stabilize, that is, $Q_i = Q_{i+k}$ holds for every $k \geq 0$. However, the converse of (B) does not hold: given a path $a_0 \xrightarrow{i_1} \alpha a_1 \xrightarrow{i_2} \alpha a_2 \cdots$ of $\alpha TS$, there may be no path $c_0 \xrightarrow{i_1} c_1 \xrightarrow{i_2} c_2 \cdots$ in $TS$ such that $c_i \in \gamma(a_i)$ for every $i \geq 0$. Consider a contributor machine $C$ with two states $q_0, q_1$ and one single transition $t = (q_0, \omega_c(1), q_1)$. Then $\alpha TS$ contains the infinite path (omitting the state of the leader, which plays no role):

$$(\#, \{q_0\}) \xrightarrow{i} (1, \{q_0, q_1\}) \xrightarrow{i} (1, \{q_0, q_1\}) \cdots$$

However, the transitions of $TS$ are of the form $(1, k_0 q_0 + k_1 q_1) \xrightarrow{i} (1, (k_0-1)q_0 + (k_1+1)q_1)$, and so $TS$ has no infinite paths.

### 3.3 Realizable cycles of the abstract transition system

We show that the existence of an infinite accepting path in $TS$ reduces to the existence of a finite certificate in $\alpha TS$. It is similar to what is called a lasso path elsewhere in the literature, but we prefer to use the term finite certificate to avoid confusion. Lemma 2 shows how every finite certificate in $\alpha TS$ results in a counterpart in $TS$. Lemma 3 characterizes precisely those cycles in $\alpha TS$ which have a counterpart in $TS$.

**Lemma 2** Let $(q_D, g, \bar{Q})$ be an abstract configuration of $\alpha TS$ reachable from $(q_{0D}, \#, \alpha(\bar{P}_0))$ (that is, $\alpha X_0$). For every $p \in \gamma(\bar{Q})$, there exists $\hat{p}$ such that $(q_D, g, \hat{p})$ is reachable from $(q_{0D}, \#, P_0)$ and $\hat{p} \geq p$.

**Proof** The proof is by induction on the length of the abstract path of $\alpha TS$ from $\alpha X_0 = \{(q_{0D}, \#, \alpha(\bar{P}_0))\}$ to the configuration $(q_D, g, \bar{Q})$.

The base case corresponds to $(q_D, g, \bar{Q}) = (q_{0D}, \#, \{q_{0C}\})$. For every $p \in \gamma(\{q_{0C}\})$ we can just take $\hat{p} = p$.

For the inductive case (in which the $\alpha TS$-path has $n > 0$ transitions), let $(q_{1D}, g_1, \bar{Q}_1) \xrightarrow{i_1} \alpha (q_D, g, \bar{Q})$ be the last transition of the path, and assume $t \in T_C$ (in the case $t \in T_D$ we have $Q_1 = \bar{Q}$ and the result follows immediately from the induction hypothesis). Let $q_{c'}$ and $q_c'$ be the source and target state of $t$, respectively. It follows from the definition of $\xrightarrow{i} \alpha$ that:

$$Q = \alpha(\{p' | \exists p \in \gamma(Q_1) : (q_{1D}, g_1, p) \xrightarrow{i_1} (q_D, g, p')\})$$

$$= \alpha(\{p' | \exists p \in \gamma(Q_1) : p \geq q_c \land p' = p - q_c + q_c'\})$$

(1)

By (C) and (1) we have $Q = Q_1 \cup \{q_{c'}\}$. If $q_{c'} \in Q_1$, then we again get $Q_1 = Q$, and the result follows from the induction hypothesis. So assume $q_{c'} \notin Q_1$. Given an arbitrary population $p \in \gamma(Q_1)$, let $d = p - q_{c'}$ and consider the population $p_1 = p - d q_c + d q_c'$. We have $p_1(q_{c'}) = d - d = 0$, and so $p_1 \in \gamma(Q_1)$. By induction hypothesis, there exists $\hat{p}_1 \in \gamma(Q_1)$ such that $\hat{p}_1 \geq p_1$ and $(q_{1D}, g_1, \hat{p}_1)$ is reachable from $X_0$ in $TS$. Since $\hat{p}_1 \geq p_1 \geq d q_c$, the mapping $\hat{p} = \hat{p}_1 - d q_c + d q_c'$ is non-negative, and therefore a population. Now let $d$ contributors of $\hat{p}_{1}^d$ execute $t \in \delta_C$ (which is possible in a non-atomic network, thanks to the stuttering property and, in particular, the Copycat Lemma). We then have

$$(q_{1D}, g_1, \hat{p}_1) \xrightarrow{d \text{ times}} (q_D, g, \hat{p}_1 - d q_c + d q_c') = (q_D, g, \hat{p})$$

and we are done. \(\square\)
Lemma 2 does not hold for atomic networks mainly because the stuttering property does not hold anymore. Indeed, consider a contributor with transitions $q_0 \xrightarrow{w_1(1)} q_1 \xrightarrow{r_1(1):w_2(2)} q_2 \xrightarrow{r_2(2):w_3(3)} q_3$, where $r_c(i) : w_c(j)$ denotes that the read and the write happen in one single atomic step. Then we have (omitting the state of the leader, which does not play any role here):

$$(#, \{q_0\}) \xrightarrow{w_1(1)} \alpha (1, \{q_0, q_1\}) \xrightarrow{r_1(1):w_2(2)} \alpha (2, \{q_0, q_1, q_2\}) \xrightarrow{r_2(2):w_3(3)} \alpha (3, \{q_0, \ldots, q_3\}).$$

Let $p$ be the population putting one contributor in each of $q_0, \ldots, q_3$. This population belongs to $\gamma((q_0, \ldots, q_3))$ but no configuration $(3, \hat{p})$ with $\hat{p} > p$ is reachable from any population that only puts contributors in $q_0$, no matter how many. Indeed, after the first contributor moves to $q_2$, no further contributor can follow, and so we cannot have contributors simultaneously in both $q_2$ and $q_3$. On the contrary, in non-atomic networks the Copycat Lemma states that what the move by one contributor can always be replicated by arbitrarily many.

We proceed to characterize the cycles of $\alpha TS$ that can be “concretized.”

A cycle of $\alpha TS$ ($\alpha TS$-cycle) is a path $a_0 \xrightarrow{t_1} a_1 \xrightarrow{t_2} a_2 \cdots \xrightarrow{t_n} a_n$ such that $a_n = a_0$. A $\alpha TS$-cycle $a_0 \xrightarrow{t_1} a_1 \xrightarrow{t_2} a_2 \cdots \xrightarrow{t_n} a_n$ is realizable if there is a TS-cycle $c_0 \xrightarrow{t_1} c_1 \xrightarrow{t_2} c_2 \cdots \xrightarrow{t_n} c_n$ where $c_i \in \gamma(a_i)$ for every $i$ and $c_0 = c_n$.

**Lemma 3** A cycle $a_0 \xrightarrow{t_1} a_1 \xrightarrow{t_2} a_2 \cdots \xrightarrow{t_n} a_n$ of $\alpha TS$ is realizable iff $\sum_{i=1}^n \Delta(t_i) = 0$.

**Proof** ($\Rightarrow$) This direction is trivial since $c_0 = c_n$, hence $\sum_{i=1}^n \Delta(t_i) = 0$

($\Leftarrow$) Let $a_i = (q_D(i), g_i, Q_i)$ for every $0 \leq i \leq n$. By (B) we have $Q_0 \subseteq Q_1 \subseteq \cdots \subseteq Q_n = Q_0$, and so all the $Q_i$ are equal to $Q_0$. Let $p_0 = \sum_{q \in Q_0} n_q$ and let $p_i = p_n + \sum_{k=1}^i \Delta(t_k)$ for every $1 \leq i \leq n$. Then $p_i$ is a population for every $0 \leq i \leq n$, since $\sum_{k=1}^i \Delta(t_k) \leq p_0$. Also $p_0 = p_n$ since $\sum_{i=1}^n \Delta(t_i) = 0$. Moreover setting $c_i = (q_D(i), g_i, p_i)$ we find that $c_i \in \gamma(a_i)$ for all $i$. Furthermore, we find that $c_0 \xrightarrow{t_1} c_1 \xrightarrow{t_2} c_2 \cdots \xrightarrow{t_n} c_n$ holds, that it is a TS-cycle since $p_n = p_0$ and finally $c_n = c_0$.

**Theorem 1** $MC(FSM, FSM)$ is NP-complete.

**Proof** NP-membership We show membership in NP with the following high-level nondeterministic algorithm whose correctness relies on Lemmas 2 and 3:

1. Guess a sequence $Q_1, \ldots, Q_\ell$ of subsets of $Q_C$ such that $Q_i \subseteq Q_{i+1}$ for all $0 < i < \ell$. Note that $\ell \leq |Q_C|$.  
2. Compute the set $Q = Q_D \times (\emptyset \cup \{#\}) \times \{\{q_0C\}, Q_1, \ldots, Q_\ell\}$ of abstract configurations and the set $T$ of abstract transitions between configurations of $Q$.
3. Guess an accepting abstract configuration $a \in Q$, that is, an $a = (q_D, g, Q)$ such that $q_D$ is accepting in $D$.
4. Check that $a$ is reachable from the initial abstract configuration $\alpha X_0 = \{(q_D, #, \{q_0C\})\}$ by means of abstract transitions of $T$.
5. Check that the transition system with $Q$ and $T$ as states and transitions contains a cycle $a_0 \xrightarrow{t_1} a_1 \cdots a_{n-1} \xrightarrow{t_n} a_n$ such that $n \geq 1$, $a_0 = a_n = a$ and $\sum_{i=1}^n \Delta(t_i) = 0$.

We show that the algorithm runs in polynomial time. First, because the sequence guessed is no longer than $|Q_C|$, the guess can be done in polynomial time. Next, we give a polynomial algorithm for step (5):
– Compute an FSA\(^1\) \(A^\cup_a\) over the alphabet \(\delta_D \cup \delta_C\) with \(Q\) as set of states, \(T\) as set of transitions, \(a\) as initial state, and \(\{\alpha\}\) as set of final states.

– Use the polynomial construction of Seidl et al. [17] to compute an (existential) Presburger formula \(\Omega\) for the Parikh image of \(L(A^\cup_a)\).\(^2\) The free variables of \(\Omega\) are in one-to-one correspondence with the transitions of \(\delta_D \cup \delta_C\). Denote by \(x_t\) the variable corresponding to transition \(t \in \delta_D \cup \delta_C\).

– Compute the formula

\[
\Omega' = \Omega \land \bigwedge_{q_c \in Q_c} \left( \sum_{t | tgt(t) = q_c} x_t = \sum_{t | src(t) = q_c} x_t \right) \land \sum_{t \in \delta_D \cup \delta_C} x_t > 0
\]

where \(tgt\) and \(src\) returns the target and source states of the transition passed in argument. \(\Omega'\) adds to \(\Omega\) the realizability condition of Lemma 3.

– Check satisfiability of \(\Omega'\). This step requires nondeterministic polynomial time because satisfiability of an existential Presburger formula is in NP [12]. □

We now prove that the previous algorithm is sound and complete.

**Soundness** The algorithm computes a \(\alpha\)TS-cycle \(a_0 \xrightarrow{t_1} a_1 \cdots a_{n-1} \xrightarrow{t_n} a_n\) such that \(a = a_0 = a_n\) is accepting, \(\sum_{i=1}^{n} \Delta(t_i) = 0\) and \(a_0\) is reachable from \(\alpha X_0\). Hence, Lemma 3 shows the cycle has a realization \(c_0 \xrightarrow{t_1} c_1 \cdots c_{n-1} \xrightarrow{t_n} c_n\) with \(c_0 = c_n\). Also, let \(c_0 = (q_0, g_0, p_0)\). Since \(a_0\) is reachable from \(\alpha X_0\), Lemma 2 shows there exists a configuration \(\hat{c}_0 = (q_0, g_0, \hat{p}_0)\) reachable from \((q_0D, \#, P_0)\) such that \(\hat{p}_0 \geq p_0\). Because \(\hat{p}_0 \geq p_0\) enables more transitions and does not disable any, the sequence \((t_1 \ldots t_n)\) can also be executed from \(\hat{c}_0\) and reaches again \(\hat{c}_0\) at the end since \(\sum_{i=1}^{n} \Delta(t_i) = 0\). Therefore it can be repeated infinitely often. Finally, because \(c_0 \in \gamma(a_0)\) and \(a_0 = a\) is accepting, we found some accepting TS-path.

**Completeness** By Proposition 1 there exists a TS-path \(c_0 \xrightarrow{t_1} c_1 \cdots\) where the same accepting configuration is visited infinitely often. It follows that, given any two positions \(j_1 < j_2\) along that path where the same accepting configuration repeats, \(\sum_{i=j_1+1}^{j_2} \Delta(t_i) = 0\).

If follows from (B) that the TS-path \(c_{j_1} \xrightarrow{t_{j_1+1}} c_{j_1+1} \cdots c_{j_2-1} \xrightarrow{t_{j_2}} c_{j_2}\) with \(c_{j_1} = c_{j_2}\) has a counterpart \(\alpha\)TS-path \(a_{j_1} \xrightarrow{t_{j_1+1}} a_{j_1+1} \cdots a_{j_2-1} \xrightarrow{t_{j_2}} a_{j_2}\) with \(c_i \in \gamma(a_i)\) for every \(i = j_1, \ldots, j_2\). Note that both \(a_{j_1}\) and \(a_{j_2}\) can be chosen so as to be reachable from \(\alpha X_0\) following (B). We further notice that although \(c_{j_1} = c_{j_2}\), the equality \(a_{j_1} = a_{j_2}\) does not necessarily holds. All we can state at this point is that \(a_{j_1} = (q, g, Q_1)\), \(a_{j_2} = (q, g, Q_2)\) for some \(q \in Q_D\) and \(g \in G\) and \(Q_1 \subseteq Q_2\) following (C).

However, following (A) and the definition of \(\xrightarrow{\alpha}\) we find that the sequence \(t_1 \ldots t_n\) is fireable from \(a_{j_2}\). Now firing \(t_1 \ldots t_n\) from \(a_{j_2}\) results in an abstract state \(\alpha'\) such that \(\alpha' = a_{j_2}\). This is because firing \(t_1 \ldots t_n\) from \(a_{j_2}\) does not add new \(Q_C\) states to the abstract configuration (they were already added between \(j_1\) and \(j_2\)).

Let us denote this \(\alpha\)TS-path by \(a_0' \xrightarrow{t_1} a_1' \cdots a_{n-1}' \xrightarrow{t_n} a_0'\) where \(a_i' = (q_{D_i'}, g_i', Q_i)\) for every \(i\) and \(a_0' = a_0\). We find that \(Q_0 = Q_1 = \cdots = Q_{n-1}\). To show that every abstract configuration of the path belongs to the set \(Q\), and every transition to the set \(T\), it suffices to guess the right increasing sequence of states at step 1 that contains \(Q_0\).

---

\(^1\) A finite-state automaton (FSA) is an FSM which decides languages of finite words. Therefore an FSA is an FSM with a set \(F\) of accepting states.

\(^2\) In a nutshell, the Parikh image of a language \(L\) over a \(n\)-sized alphabet is a set of \(n\)-dimensional vectors of natural number. Each vector is the (Parikh) image of a word of \(L\) obtained by counting how many times each symbol occur and forgetting about the ordering, e.g. let \(L = abbb\) over alphabet \(\Sigma = \{a, b\}\) the vector \((1, 3)\) is the image of \(abbb\) by counting 1 occurrence of \(a\) and 5 of \(b\).
To conclude, we show that \( a' \) is reachable from \( \{ (q_{0D}, \#, \{q_{0C}\}) \} = \alpha X_0 \) which follows from \( a' = a_{j2} \) and the previously shown fact that \( a_{j2} \) is reachable from \( \alpha X_0 \).

So the transition system with \( Q \) as states and \( T \) as transitions contains a configuration \( a \) reachable from the initial abstract configuration, and a cycle starting and ending at \( a \).

**NP-hardness**

NP-hardness follows from the NP-hardness of the safety problem [10], which asks given a finite-state machine \( D \) for the leader \( D \) and \( C \) for the contributor \( C \)—both of which are languages of finite words—whether there exists a word of the \((D, C)\)-network \( \mathcal{N} \) that ends with an occurrence of \( w_d(\$) \). We say that \( \mathcal{N} \) is safe iff it contains no such word. Remark that, for the safety problem, \( C \) is assumed to be prefix-closed, hence every state of \( C \) is accepting. Also, we assume without loss of generality that every word of \( D \) ends with \( w_d(\$) \). The reduction goes as follows, given an instance of the safety problem turn \( D \) into an \( \omega \)-language by appending it \( r_d(\$)^\omega \). We also turn \( C \) into an \( \omega \)-language by appending it \( w_c(\#)^\omega \) where \( \# \notin \mathcal{G} \) is the corrupted value nobody else can read. At the machine level this is done by adding to each accepting state of \( D \) a selfloop labeled with action \( r_d(\$) \) and interpreting \( D \) as a Büchi automaton. On the other hand since \( C \) is prefix closed we have that all its states are accepting. We turn \( C \) into a FSM by dropping \( F \)—the set of accepting states—and by adding a self-loop labelled \( w_c(\#) \) to each state. This concludes the hardness proof. \( \Box \)

### 4 MC(PDM, FSM) is NP-complete

A pushdown system (PDM) \( P = (Q, \Gamma, \delta, q_0) \) over \( \Sigma \) consists of a finite set \( Q \) of states including the initial state \( q_0 \), a stack alphabet \( \Gamma \) including the bottom stack symbol \( \bot \), and a set of rules \( \delta \subseteq Q \times \Sigma \times \Gamma \times Q \times (\Gamma \setminus \{\bot\} \cup \{\text{pop}\}) \) which either push or pop as explained below. A **PDM-configuration** \( qw \) consists of a state \( q \in Q \) and a word \( w \in \Gamma^* \) (denoting the stack content). For \( q, q' \in Q, a \in \Sigma, \gamma, \gamma' \in \Gamma, w, w' \in \Gamma^* \), we say a PDM-configuration \( qw \) (resp. \( q'\gamma'\gamma w \)) \( a \)-follows \( qw \) if \( (q, a, \gamma, q', \text{pop}) \in \delta \) (resp. \( (q, a, \gamma, q', \gamma') \in \delta \)); we write \( qw \xrightarrow{a} q'w' \) if \( q'w' \) \( a \)-follows \( qw \), and call it a transition. A run \( \rho \) of a PDM-configuration \( c \) on a word \( v \in \Sigma^\omega \cup \Sigma^* \) is a sequence \( \rho = c_0 \xrightarrow{(v)_1} c_1 \xrightarrow{(v)_2} c_2 \cdots \) with \(|v| + 1 \) PDM-configurations such that \( c_i \xrightarrow{(v)_{i+1}} c_{i+1} \) for all \( i \in \text{dom}(v) \) and \( c = c_0 \). Unless defined otherwise, we assume that \( c = q_0 \bot \). Also we write \( c \xrightarrow{a} c' \) if there is a finite run from \( c \) to \( c' \).

A Büchi PDM is a PDM with a set \( F \subseteq Q \) of accepting states. A run \( \rho \) of a Büchi PDM is accepting if \( \rho \) visits configurations with state in \( F \) infinitely often.\(^3\) A word \( w \in \Sigma^\omega \) is accepted by a Büchi PDM if there is an accepting run on \( w \). The language \( L(P) \) of a Büchi PDM \( P \) is the set of all words \( v \in \Sigma^\omega \) accepted by \( P \).

Now we introduce the notion of effective stack height of a configuration in a run of a PDM. Consider a run of a PDM that repeatedly pushes symbols on the stack. The stack height of the configuration is unbounded, but, intuitively, the PDM only uses the topmost stack symbol during the run. To account for this we define the notion of effective stack height.

**Definition 3**

Let \( \rho = c_0 \xrightarrow{(v)_1} c_1 \xrightarrow{(v)_2} \cdots \) be an infinite run of a PDM on \( \omega \)-word \( v \), where \( c_i = q_i w_i \). The **dark suffix** of \( c_i \) in \( \rho \), denoted by \( ds(w_i) \), is the longest suffix of \( w_i \) that is also a proper suffix of \( w_{i+k} \) for every \( k \geq 0 \). Note that because the definition allows for \( k = 0 \), we have that \( ds(w_i) \) is at most \( |w_i| - 1 \) symbols long and can be \( \varepsilon \) (e.g. when \( |w_i| = 1 \)). The **active prefix** \( ap(w_i) \) of \( w_i \) is what remains: it is the prefix satisfying \( w_i = ap(w_i) \cdot ds(w_i) \).

\(^3\) For readability, we write “configuration” for “PDM-configuration.”
The effective stack height of $c_i$ in $\rho$ is $|ap(w_i)|$. Removing from $c_i$ its dark suffix results in a pruned configuration $q_iap(w_i)$.

Intuitively, the effective stack height measures the actual memory required by the PDM to perform its run. For example, repeatedly pushing symbols on the stack produces a run with effective stack height 1. Given a position in the run, the elements of the stack that are never popped are those in the longest common suffix of all subsequent stacks. The first element of that suffix may be read, therefore only the longest proper suffix is effectively useless, so no configuration along an infinite run has effective stack height 0.

Next, we show a stack property of infinite runs of PDM.

**Proposition 2** Every infinite run of a PDM contains infinitely many positions at which the effective stack height is 1.

**Proof** Let $q_0w_0 \rightarrow q_1w_1 \rightarrow q_2w_2 \rightarrow \cdots$ be any infinite run. Notice that $|w_i| \geq 1$ for every $i \geq 0$, because otherwise the run would not be infinite. Let $X$ be the set of positions of the run defined as: $i \in X$ iff $|w_i| \leq |w_j|$ for every $j > i$. Observe that $X$ is infinite, because the first configuration of minimal stack height, say $q_kw_k$, belongs to it, and so does the first configuration of minimal stack height of the suffix $q_{k+1}w_{k+1} \rightarrow \cdots$, etc. By construction, the configuration at every position in $X$ has effective stack height 1.

It follows from the previous property that every infinite run of a PDM has a “finite certificate.”

**Lemma 4** Let $c$ be a configuration of a Büchi PDM. There is an accepting run from $c$ iff there are states $q \in Q$, $q_f \in F$ and stack symbol $\gamma \in \Gamma$ such that $c \xrightarrow{*} q\gamma w$ for some $w \in \Gamma^*$ and there is a non-empty run $q\gamma \xrightarrow{*} qfu \xrightarrow{*} q\gamma w'$ for some $u, w' \in \Gamma^*$.

**Proof** The “if” direction pumps the cycle (see also [7]); we prove the “only if” direction. Let $\rho$ be an accepting run from $c$. Proposition 2 shows that at infinitely many positions $\rho$ visits a configuration with effective stack height of 1. Next, by the pigeonhole principle, there is a state $q$ and stack symbol $\gamma$ such that $\rho$ visits infinitely often a configuration of effective stack height 1, state $q$ and topmost stack symbol $\gamma$. Moreover, because $\rho$ is accepting, it also visits some state $q_f \in F$ infinitely often. Now fix three positions in the run where a configuration with effective stack height 1, state $q$ and topmost stack symbol $\gamma$ is visited twice and a configuration with state $q_f \in F$ is visited in between. We denote by $c_1, c_2$ and $c_3$ those three configurations for which there is a non-empty run $c_1 \xrightarrow{*} c_2 \xrightarrow{*} c_3$. Clearly, we have $c \xrightarrow{*} c_1$. Also since $c_1$ has an effective stack height of 1, it holds that $q\gamma \xrightarrow{*} qfu \xrightarrow{*} q\gamma w$ for some $u, w \in \Gamma^*$ and we are done.

We now show $\text{MC}(\text{PDM}, \text{FSM})$ is decidable, generalizing the proof from Sect. 3. Fix a Büchi PDM $P = (Q_D, \Gamma_D, \delta_D, q_{0D}, F)$, and a FSM $C = (Q_C, \delta_C, q_{0C})$. A configuration is a tuple $(q_D, w, g, p)$, where $q_D \in Q_D$, $w \in \Gamma_D^*$ is the stack content, $g \in \mathcal{G} \cup \{\#\}$, and $p$ is a population. Intuitively, $q_Dw$ is the PDM-configuration of the leader. We extend the definitions from Sect. 3 like accepting configuration in the obvious way.

We define a labeled transition system $TS = (X, T, X_0)$, where $X$ is the set of configurations including the set $X_0 = \{q_{0D}, \bot, \#, P_0\}$ of initial configurations, and the transition relation $T = T_D \cup T_C$, where $T_C$ is as before and $T_D$ is the set of triples $((q_D, w, g, p), t, (q'_D, w', g', p))$ such that $t$ is a transition (not a rule) of $D$, and one of the following conditions holds: (i) $t = (q_Dw \xrightarrow{w\rho(g')} q'_Dw')$; or (ii) $t = (q_Dw \xrightarrow{r\rho(g)} q'_Dw')$.
and $g = g'$. We define the abstraction $\alpha TS$ of $TS$ as the obvious generalization of the abstraction in Sect. 3. An accepting path of the (abstract) transition system is an infinite path with infinitely many accepting (abstract) configurations. As for $MC(FSM, FSM)$, not every accepting path of the abstract admits a concretization, but we find a realizability condition in terms of linear constraints. Here we use again the polynomial construction of Seidl et al. [17] mentioned in the proof of Theorem 1, this time to compute an (existential) Presburger formula for the Parikh image of a pushdown automaton.

**Theorem 2** $MC(PDM, FSM)$ is NP-complete.

**Proof** Hardness follows from the NP-hardness for $MC(FSM, FSM)$. The non-deterministic polynomial time algorithm is essentially the same as that of Theorem 1, except that we have pushdown systems instead of finite-state systems. As before, we guess a sequence $Q_1, \ldots, Q_\ell$ of subsets of $Q_C$ such that $Q_i \subseteq Q_{i+1}$ for all $i$, $0 < i < \ell \leq |Q_C|$. We construct a Büchi PDM whose states $Q$ are abstract configurations $Q_D \times (G \cup \{\#\}) \times \{\{q_0C\}, Q_1, \ldots, Q_\ell\}$, whose stack alphabet is $\Gamma_D$, whose initial state is $q_0 = (q_0D, \bot, \#, \{q_0C\})$, whose accepting states are accepting abstract configurations (i.e. where $A$ is accepting), and whose transitions are defined to mimic $\alpha TS$.

Next, we guess an abstract configuration $q$ and a stack symbol $\gamma$ and look for a “finite certificate” as given in Lemma 4. To this end, we check if there is a non-empty run on some word $u$ given by $q_0 \xrightarrow{x} q\gamma w$ for some $w \in \Gamma_D^*$. This check is equivalent to pushdown reachability and can be performed in polynomial time [7]. We construct a PDA\(^4\) $P_{q\gamma}^\odot$ over finite words that accepts a word $u \in \Sigma^*$ if there is a non-empty run on $u$ from $q\gamma$ to a configuration $q\gamma w'$ for some $w' \in \Gamma_D^*$ that passes through an accepting abstract configuration. The PDA $P_{q\gamma}^\odot$ can be computed in polynomial time.

Finally, we check if there is a word accepted by the pushdown automaton whose “weight” is $0$. For this check, as before, we compute an (existential) Presburger formula $\Omega$ for the Parikh image of $L(P_{q\gamma}^\odot)$. The free variables of $\Omega$ are in one-to-one correspondence with the transitions of the automaton. We thus adopt the convention that $x_t$ denotes the variable corresponding to transition $t \in \delta_D \cup \delta_C$. We compute $\Omega'$ by adding $|Q_C|$ variables and $|Q_C|$ constraints, one per state in $q_C \in Q_C$: $\sum_{tgt(t) = q_c} x_t = \sum_{src(t) = q_c} x_t$ where tgt and src returns the target and source states of the transition passed in argument. Add also the constraints $\sum_{t \in \delta_D \cup \delta_C} x_t > 0$ to prevent $0$ to be returned as a trivial solution. Finally, we check satisfiability of $\Omega'$ and accept if $\Omega'$ is satisfiable. This step is in NP because satisfiability of an existential Presburger formula is in NP [12].

To see that the algorithm is sound, notice that the algorithm accepts if there is a “finite certificate” such that the cyclic part has $0$ weight. What Lemma 4 shows is that for an initial population that is large enough (essentially, cubic in the size of the PDM), we can execute the operations on the path to the cycle and then execute the cycle to come back to the same configuration as the starting point of the finite certificate. This witness can be pumped infinitely often to produce an accepting run of the Büchi PDM.

For completeness, we use the “only if” direction of Lemma 4 to deduce that from an accepting run of the Büchi PDM, we can find a finite certificate. By a similar pigeonhole argument as that of Lemma 3, we conclude that we can find a cyclic path whose weight is $0$. \(\square\)

\(^4\) A pushdown automaton (PDA) is a PDM which decides languages of finite words. We define a PDA as a PDM with a set $F$ of accepting states.
**5 MC(PDM, PDM) is in NEXPTIME**

### 5.1 Outline

For this case, we can use the same general proof idea as the two previous cases, in fact we will just show how to reduce MC(PDM, PDM) to MC(PDM, FSM). Notice that in the previous cases, to build a witness from an infinite run, we heavily relied on the fact that (1) there is a fixed finite number of contributors and (2) contributors have a finite number of configurations: it sufficed then to apply a pigeonhole principle on a sufficiently long prefix of the infinite run.

In this case, however, as each contributor is equipped with an unbounded stack, we do not have (2).

To restore (2), we show, intuitively, how the work of one contributor can be done by a set of contributor each using less resources. The meaning of “less resources” will be defined precisely later but, intuitively, the substitute contributors have an upper bound on the their effective stack height, hence a bounded amount of memory suffices to describe them.

The substitution of one run by many is the key insight to restore (2). In what follows, this roughly corresponds the boundedness lemma (Lemma 6) that builds upon the distribution lemma (Lemma 5). However, if applied naively, the boundedness lemma will introduce infinitely many contributors along infinite runs, therefore breaking (1). The challenge is thus to show that there is substitution that works for infinite runs without introducing infinitely many contributors. This challenge is tackled in the proof of the reduction theorem, Theorem 4 below. A key ingredient to show finitely many substitute contributors suffices is the definition of synchronized distributions (Definition 8) and the fact that the boundedness lemma (Lemma 6) is synchronization aware. Intuitively, synchronization allows to dispatch work among substitute contributors so that finitely many of them suffice.

With the reduction theorem, the reduction to MC(PDM, FSM) is as follows: given a contributor PDM C, we build an FSM C_k that simulates all the runs of C of effective stack height k. We show that, for k \(\in O(n^3)\), where n is the size of C, the language \(L(D) \parallel S \parallel \bigcirc L(C)\) is empty iff \((L(D) \parallel S \parallel \bigcirc L(C_k))\) is empty.

### 5.2 An FSM for runs of bounded effective stack height

**Definition 4** We say that a run \(\rho\) is effectively \(k\)-bounded (or simply \(k\)-bounded for the sake of readability) if every configuration of \(\rho\) has an effective stack height of at most \(k\). Further, we say that \(\rho\) is bounded if it is \(k\)-bounded for some \(k \in \mathbb{N}\). Finally, an \(\omega\)-word of the PDM is \(k\)-bounded, respectively bounded, if it is the word generated by some \(k\)-bounded, respectively bounded, run. It suffices that there exists a \(k\)-bounded run; all runs for the same word need not be bounded.

In a \(k\)-bounded run, whenever the stack height exceeds \(k\), the \(k+1\)-th stack symbol will never become the top symbol again, and so it becomes useless. So, we can construct a finite-state machine for the words accepted by \(k\)-bounded runs.

**Definition 5** Given a PDM \(P = (Q, \Gamma, \delta, q_0)\), the FSM \(P_k = (Q_k, \delta_k, q_{0k})\), called the \(k\)-restriction of \(P\), is defined as follows: (a) \(Q_k = Q \times \bigcup_{i=1}^k \Gamma_i\) (a state of \(P_k\) consists of a state of \(P\) and a stack content no longer than \(k\)); (b) \(q_{0k} = (q_0, \perp)\); (c) \(\delta_k\) contains a transition \((q, (w)_{1,k}) \overset{a}{\longrightarrow} (q', (w')_{1,k})\) iff \(q w \overset{a}{\longrightarrow} q'w'\) is a transition (not a rule) of \(P\). As expected the alphabets of \(P\) and \(P_k\) coincide.

**Theorem 3** Given a PDM \(P\) and a word \(v \in \Sigma^\omega \cup \Sigma^*\), \(v\) admits a \(k\)-bounded run in \(P\) iff \(v\) admits a run in \(P_k\).
We first prove that if \( v \) admits an effectively \( k \)-bounded run \( \rho \) in \( P \) then \( w \) also admits a run in \( P_k \). Let \( \rho = q_0 w_0 (q_1, w_1) (q_2, w_2) \ldots \) and let \( \text{ap}(i), \text{res}. \: \text{ds}(i) \), denote the active prefix, resp. dark suffix, of \( w_i \). Recall that a state of \( P_k \) is a pair \((q, s)\), where \( q \) is a state of \( P \) and \( s \) is a non-empty stack content of length at most \( k \).

For every \( i \geq 0 \), we inductively define \((q_i, \text{ap}(i) u_i)\) where \( u_i \) is a possibly empty prefix of \( \text{ds}(i) \) and we show that \((q_i, \text{ap}(i) u_i) \xrightarrow{(u)} (q_{i+1}, \text{ap}(i+1) u_{i+1})\) is a transition of \( P_k \).

We define \( u_0 = \varepsilon \). Observe that \( \text{ap}(0) = \perp \) and \( \text{ds}(0) = \varepsilon \), therefore we find that the initial state \( q_{0k} \) of \( P_k \) is such that \( q_{0k} = (q_0, \perp) = (q_0, \text{ap}(0) u_0) \) and we are done. For the definition of \( u_{i+1} \), assuming that \( u_i \) is already defined, we consider three cases:

1. The transition \( q_i, w_i \xrightarrow{(u)} q_{i+1} v_{i+1} \) pops a symbol \( \gamma \).

   Then \( q_i, \gamma v \xrightarrow{(u)} q_{i+1} v \) is a transition of \( P \) for every \( v \), and so, in particular, \( q_i, \gamma \text{ap}(i+1) u_i \xrightarrow{(u)} q_{i+1} \text{ap}(i+1) u_i \) is a transition of \( P \). Moreover, by the definition of an active prefix, we have \( \text{ap}(i) = \gamma \text{ap}(i+1) \) and thus \( \text{ds}(i) = \text{ds}(i+1) \) therefore \( u_i \) is also a prefix of \( \text{ds}(i+1) \). By induction hypothesis, \(|\text{ap}(i) u_i| \leq k\), which implies \(|\text{ap}(i+1) u_i| < k\). Setting \( u_{i+1} \) to be \( u_i \) we thus obtain that \(|\text{ap}(i+1) u_{i+1}| \leq k\) and finally that \((q_i, \text{ap}(i) u_i) \xrightarrow{(u)} (q_{i+1}, \text{ap}(i+1) u_{i+1})\) is a transition of \( P_k \).

2. The transition \( q_i, w_i \xrightarrow{(u)} q_{i+1} w_{i+1} \) pushes a symbol \( \gamma \), and \(|\text{ap}(i) u_i| < k\).

   Then \( q_i, \text{ap}(i) u_i \xrightarrow{(u)} q_{i+1} \gamma \text{ap}(i) u_i \) is a transition of \( P \). Since \(|\text{ap}(i) u_i| < k\), we have \(|\gamma \text{ap}(i) u_i| \leq k\), hence \((q_i, \text{ap}(i) u_i) \xrightarrow{(u)} (q_{i+1}, \gamma \text{ap}(i) u_i)\) is also a transition of \( P_k \). If \( \gamma \) is popped later on, then \( \text{ap}(i+1) = \gamma \text{ap}(i) \); so \( q_i, \text{ap}(i) u_i \xrightarrow{(u)} q_{i+1} \text{ap}(i+1) u_i \) is a transition of \( P \), and we set \( u_{i+1} \) to \( u_i \). If \( \gamma \) is never popped, then \( \text{ap}(i+1) = \gamma \), and we let \( u_{i+1} \) to be \( \text{ap}(i) u_i \). In both cases, we find that \(|\text{ap}(i+1) u_{i+1}| \leq k\) and hence that \((q_i, \text{ap}(i) u_i) \xrightarrow{(u)} (q_{i+1}, \text{ap}(i+1) u_{i+1})\) is a transition of \( P_k \).

3. The transition \( q_i, w_i \xrightarrow{(u)} q_{i+1} w_{i+1} \) pushes a symbol \( \gamma \), and \(|\text{ap}(i) u_i| = k\).

   Then \( q_i, \text{ap}(i) u_i \xrightarrow{(u)} q_{i+1} \gamma \text{ap}(i) u_i \) is a transition of \( P \). Observe that since \(|\text{ap}(i) u_i| = k\) we have \(|\gamma \text{ap}(i) u_i| = k+1\). First we show that \(|u_i| > 0\) by contradiction. Assume \(|u_i| = 0\), we find that \(|\text{ap}(i)| = k\). On the other hand, since \( \text{ds}(i) \) is the longest proper suffix of all the \((w_j)_{j \geq i}\), and because \( w_{i+1} = \gamma w_i \), we find that \( \text{ds}(i) \) is also the longest proper suffix of all the \((w_j)_{j \geq i+1}\), hence \( \gamma \text{ap}(i) = \text{ap}(i+1) \), and finally \(|\text{ap}(i+1)| = k+1\) contradicting the hypothesis that the run is effectively \( k \)-bounded.

   Since \(|\gamma \text{ap}(i) u_i| = k+1\), \((q_i, \text{ap}(i) u_i) \xrightarrow{(u)} (q_{i+1}, (\gamma \text{ap}(i) u_i)_{1..k})\) is a transition of \( P_k \). If \( \gamma \) is popped later on, then \( \text{ap}(i+1) = \gamma \text{ap}(i) \) and \( u_{i+1} = (u_i)_{1..|u_i|-1} \). If \( \gamma \) is never popped, then \( \text{ap}(i+1) = \gamma \) and \( u_{i+1} = (\text{ap}(i) u_i)_{1..k-1} \). In both cases we conclude that \(|\text{ap}(i+1) u_{i+1}| \leq k\) (in the former, \(|u_i| > 0\) is crucial), hence that \((q_i, \text{ap}(i) u_i) \xrightarrow{(u)} (q_{i+1}, \text{ap}(i+1) u_{i+1})\) is a transition of \( P_k \).

Now we show that if \( v \) admits a run in \( P_k \), then it admits an effectively \( k \)-bounded run \( \rho' \) in \( P \). Let \( \rho = (q_0, w_0) \xrightarrow{(u_1)} (q_1, w_1) \xrightarrow{(u_2)} \ldots \) be a run of \( P_k \) for \( v \). The definition of \( P_k \) shows that \(|w_i| \leq k \) holds for every \( i \geq 0 \). We inductively construct \( w_0', w_1', \ldots \) such that \( \rho' = q_0 w_0' \xrightarrow{(u_1')} q_1 w_1' \xrightarrow{(u_2')} \ldots \) is a run of \( P \) satisfying the following invariant:

\[
|w_{i+1} w_{i+1}'| - |w_i w_i'| \geq |w_{i+1}| - |w_i|, \quad \text{for all } i \geq 0.
\]
We start by defining \( w'_0 = \varepsilon \), which trivially satisfies (2). Assume \( q_0 w_0 w'_0 \stackrel{(v)_0}{\longrightarrow} \cdots \stackrel{(v)_{i+1}}{\longrightarrow} q_i, w_i, w'_i \) is a run of \( P \) satisfying (2), and consider the transition \( q_i, w_i \stackrel{(v)_{i+1}}{\longrightarrow} (q_{i+1}, w_{i+1}) \) of \( P_k \). By the definition of the transitions of \( P_k \), there are two possible cases:

- \( q_i, w_i \stackrel{(v)_{i+1}}{\longrightarrow} q_{i+1}, w_{i+1} \) is a transition of \( P \).

  Then \( q_i, w_i \stackrel{(v)_{i+1}}{\longrightarrow} q_{i+1}, w_{i+1} \) is also a transition of \( P \), and we can take \( w'_{i+1} \) to be \( w'_i \), and (2) is satisfied as \( |w_i + w'_{i+1}| - |w_i| = |w_{i+1}| - |w_i| \)

- \( q_i, w_i \stackrel{(v)_{i+1}}{\longrightarrow} q_{i+1}, w_{i+1} \gamma \) is a transition of \( P \).

Then \( |w_i| = |w_{i+1}| = k \), and \( q_i, w_i \stackrel{(v)_{i+1}}{\longrightarrow} q_{i+1}, w_{i+1}, \gamma w'_i \) is a transition of \( P \). So setting \( w'_{i+1} \) to \( \gamma w'_i \) satisfies (2) as \( |w_{i+1} + w'_{i+1}| - |w_{i+1}| = |w_{i+1}| - |w_i| + 1 \).

The induction is concluded, now we explain the meaning of equation (2). First remark that performing a telescope sum, we obtain that for any \( i, j > 0, |w_{i+j} w'_{i+j}| - |w_i w'_i| \geq |w_{i+j}| - |w_i| \). Since \( |w_{i+j}| \leq k \) and \( |w_i| \geq 1 \), we obtain \( |w_{i+j} w'_{i+j}| - |w_i w'_i| \geq 1 - k \). Informally it means that the number of symbols in the stack at any position after \( i \) can’t be much smaller (much meaning \( k \)) than at position \( i \). Thus, at every position \( i \), we never eventually pop the \( k \) top symbols of the stack at that position, as this would yield a configuration after \( i \) whose stack would be too small and contradict the inequality. Therefore the run \( \rho' \) is effectively \( k \)-bounded.

\[ \square \]

5.3 The Reduction Theorem

We fix a Büchi PDM \( D \) and a PDM \( C \). In order to reduce \( \text{MC(PDM, PDM)} \) to \( \text{MC(PDM, FSM)} \) it suffices to prove the following Reduction Theorem:

**Theorem 4 (Reduction Theorem)** Let \( N = 2|Q_C|^2|\Gamma_C| + 1 \), where \( Q_C \) and \( \Gamma_C \) are the states and stack alphabet of \( C \), respectively. Let \( C_N \) be the \( N \)-restriction of \( C \). We have:

\[ (L(D) \parallel S \parallel \mathcal{L}_\infty(C_N)) \neq \emptyset \text{ if } (L(D) \parallel S \parallel \mathcal{L}_\infty(L(C_N))) \neq \emptyset. \tag{†} \]

There are PDMs \( D, C \) for which (†) holds only for \( N \in \Omega(|Q_C|^2|\Gamma_C|) \).

Theorems 4 and 2 provide an upper bound for \( \text{MC(PDM, PDM)} \). PSPACE-hardness of the reachability problem [10] gives a lower bound.

**Theorem 5** \( \text{MC(PDM, PDM)} \) is in NEXPTIME and PSPACE-hard. If the contributor is a one counter machine (with zero-test), it is NP-complete.

**Proof** The NP algorithm from the previous section, together with Theorem 4 and the exponential upper bound on the size of \( C_N \), show membership in NEXPTIME. Note that if \( C \) has only one stack symbol, the size of \( C_N \) is polynomial in the size of \( C \): only the stack height needs to be stored. In the general case, \( C_N \) may store up to \( N \) stack symbols: the size of \( C_N \) is then exponential.

The proof of Theorem 4 is very involved. Given a run of \( D \) compatible with a finite multiset of runs of \( C \), we construct another run of \( D \) compatible with a finite multiset of \( N \)-bounded runs of \( C_N \). (Here we extend compatibility to runs: runs are compatible if the words they accept are compatible).

The proof starts with the Distributing lemma, which, loosely speaking, shows how to replace a run of \( C \) by a multiset of “smaller” runs of \( C \) without the leader “noticing”. After
this preliminary result, the first key proof element is the Boundedness Lemma. Let \( \sigma \) be an infinite run of \( D \) compatible with a finite multiset \( R \) of runs of \( C \). The Boundedness Lemma states that, for any number \( Z \), the first \( Z \) steps of \( \sigma \) are compatible with a (possibly larger) multiset \( R_\sigma \) of runs of \( C_N \).\(^5\) Since the size of \( R_\sigma \) may grow with \( Z \), this lemma does not yet prove Theorem 4: it only shows that \( \sigma \) is compatible with an infinite multiset of runs of \( C_N \). This obstacle is overcome in the final step of the proof. We show that, for a sufficiently large \( Z \), there are indices \( i < j \) such that, not \( \sigma \) itself, but the run \( (\sigma)_{i+1..j} \) for adequate \( i \) and \( j \) is compatible with a finite multiset of runs of \( C_N \). Loosely speaking, this requires to prove not only that the leader can repeat \( (\sigma)_{i+1..j} \) infinitely often, but also that the runs executed by the instances of \( C_N \) while the leader executes \( (\sigma)_{i+1..j} \) can be repeated infinitely often.

### 5.3.1 The Distributing Lemma

Let \( \rho = c_0 \overset{a_1}{\rightarrow} c_1 \overset{a_2}{\rightarrow} c_2 \overset{a_3}{\rightarrow} \cdots \) be a (finite or infinite) run of \( C \). Let \( r_i \) be the PDM-rule of \( C \) generating the transition \( c_{i-1} \overset{a_1}{\rightarrow} c_i \). Then \( \rho \) is completely determined by \( c_0 \) and the sequence \( r_1 r_2 r_3 \cdots \). Since \( c_0 \) is also fixed (for fixed \( C \)), in the rest of the paper we also sometimes write \( \rho = r_1 r_2 r_3 \cdots \). This notation allows us to speak of \( \text{dom}(\rho), (\rho)_k, (\rho)_{i..j}, \) and \((\rho)_{i..\infty} \).

**Definition 6** (Distribution) Let \( \rho = c_0 \overset{a_1}{\rightarrow} c_1 \overset{a_2}{\rightarrow} c_2 \overset{a_3}{\rightarrow} \cdots \) be a (finite or infinite) run of \( C \). We say that \( \rho \) distributes to a multiset \( R \) of runs of \( C \) if there exists an embedding function \( \psi \) that assigns to each run \( \rho' \in R \) and to each position \( i \in \text{dom}(\rho') \) a position \( \psi(\rho', i) \in \text{dom}(\rho) \), and satisfies the following properties:

- \( (\rho')_i = (\rho)_{\psi(\rho', i)} \). (A rule occurrence in \( \rho' \) is matched to another occurrence of the same rule in \( \rho \).)
- \( \psi \) is surjective. (For every position \( k \in \text{dom}(\rho) \) there is at least one \( \rho' \in R \) and a position \( i \in \text{dom}(\rho') \) such that \( \psi(\rho', i) = k \), or, informally, \( R \) “covers” \( \rho \).)
- If \( i < j \), then \( \psi(\rho', i) < \psi(\rho', j) \). (So \( \psi(\rho', 1) \psi(\rho', 2) \cdots \) is a scattered subword of \( \rho \).)

When all the above properties are satisfied, we call the pair \( R, \psi \) a distribution of \( \rho \) or simply distribution when \( \rho \) is clear from the context.

**Example 5** Let \( \rho \) be a run of a PDM \( P \). Below are two distributions \( R, \psi \) and \( S, \psi' \) of \( \rho = r_a r_b r_c r_a r_b r_c r_c r_c \). On the left we have the runs of \( P \) given by \( R = \{ \rho_1', \rho_2', \rho_3' \} \), and its embedding function \( \psi \); on the right the runs \( S = \{ \sigma_1', \sigma_2', \sigma_3' \} \), and its function \( \psi' \).

| \( \psi \) | 1 2 3 | \( \rho = r_a r_b r_c r_c r_c r_a r_b r_c r_c r_c r_a r_b r_c r_c r_c \) | \( \psi' \) | 1 2 3 4 5 6 | \( \rho = r_a r_b r_c r_c r_c r_a r_b r_c r_c r_c r_a r_b r_c r_c r_c \) |
|---|---|---|---|---|
| \( \rho_1' \) | 1 6 | \( r_a r_b r_c r_c r_c \) | \( \sigma_1' \) | 1 4 | \( r_a r_b r_c r_c r_c \) |
| \( \rho_2' \) | 1 2 5 | \( r_a r_a r_c r_c \) | \( \sigma_2' \) | 1 2 4 5 | \( r_a r_a r_c r_c \) |
| \( \rho_3' \) | 1 3 4 | \( r_a r_b r_c r_c \) | \( \sigma_3' \) | 1 3 5 6 | \( r_a r_a r_b r_c r_c \) |

**Lemma 5** (Distributing lemma) Let \( u \in L(D) \), and let \( M \) be a multiset of words of \( L(C) \) compatible with \( u \). Let \( v \in M \) and let \( \rho \) an accepting run of \( v \) in \( C \) that distributes to a multiset \( R \) of runs of \( C \), and let \( M_R \) the corresponding multiset of words. Then \( M \oplus \{ v \} \oplus M_R \) is also compatible with \( u \).

---

\(^5\) See Theorem 4 for a definition of \( N \).
Proof Since $u$ is compatible with $M$, there exists a witness $s \in L(S)$ such that $s \in (u \parallel \bigcup_{w \in M} w)$. Since $\Sigma_C \cap \Sigma_D = \emptyset$, we have $(u \parallel \bigcup_{w \in M} w) = (u \parallel \bigcup_{w \in M} u \parallel w)$, and so $s \in (u \parallel \bigcup_{w \in M} w)$. Therefore there exists an interleaving function, i.e. a bijection $I : [\bigcup_{w \in \{u\} \cup M} \text{dom}(w) \to \text{dom}(s)$, that assigns to each position in each word $w$ in $\{u\} \cup M$ a corresponding position in $s$ with the same action. Further, the interleaving function satisfies $i < j \in \text{dom}(w)$ iff $I(w, i) < I(w, j)$ for each $w \in \{u\} \cup M$.

For example, if $u = w_d(1)$ and $M = \{w_1, w_2\}$, where $w_1 = r_c(1)w_c(2)r_c(1)$ and $w_2 = r_c(2)w_c(1)$, then we can take $s = w_d(1)r_c(1)w_c(2)r_c(2)w_c(1)r_c(1)$, with $I(w_1, 1) = 2$, $I(w_1, 2) = 3$, $I(w_2, 1) = 4$, $I(w_2, 2) = 5$ and $I(u, 1) = 1$.

We have to show that, given $v \in M$, a run $\rho$ of $C$ accepting a word $v$, and a distribution $R$ of $\rho$ accepting a multiset $M_R$ of words, then $M \cup \{v\} \cup M_R$ is compatible with $u$.

Let $R, \psi$ be the distribution $R$ of $\rho$. We construct a word $s'$ witnessing that $u$ and $M \cup \{v\} \cup M_R$ are compatible. The word $s'$ is a stuttering of $s$, that is, it is obtained from $s$ by repeating some letters of $s$; since, by definition of the store, $S$ is closed under stuttering, we have $s' \in S$. Let $s = a_1a_2 \ldots$ and let $i$ be such that $I(v, j) = i$ for some $j \in \text{dom}(v)$. Further, let $k$ be the number of runs in $R$ such that some position in them is mapped to position $j$ by the embedding function $\psi$ (intuitively, $k$ is the number of runs in $R$ executing the action at position $j$). Then we replace $a_i$ by $a_i^k$ (that is, by the word $a_1 a_2 \ldots a_t$ of length $k$).

For example, if we distribute $w_1$ above to $\{r_c(1)w_c(2), w_c(2)r_c(1), w_c(2)\}$, then we get $s' = w_d(1)r_c(1)(w_c(2)r_c(2)w_c(2))r_c(2)w_c(2)r_c(1)$.

We clearly have a one-to-one correspondence between positions in $s'$ and positions in $u \cup \{v\} \cup M_R$. \hfill $\square$

5.3.2 The boundedness lemma

We are interested in distributing a multiset of runs of $C$ into another multiset with, loosely speaking, “better” effective stack height.

Fix a run $\rho$ of $C$ and a distribution $R$ of $\rho$ with embedding function $\psi$. In Example 5, $(\rho)_{1..4}$ is distributed into $(\rho')_{1..1}, (\rho')_{1..2}$ and $(\rho')_{1..3}$. Assume $\rho$ is executed by one contributor. We can replace it by $3$ contributors executing $\rho'_1, \rho'_2, \rho'_3$, without the rest of the network noticing any difference. Indeed, the three processes can execute $r_a$ immediately after each other, which for the rest of the network is equivalent to the old contributor executing one $r_a$.

Then we replace the execution of $(\rho)_{2..4}$ by $(\rho')_2(\rho')_2(\rho')_2$.

We introduce some definitions allowing us to formally describe such facts. Given $k \in \text{dom}(\rho)$, we denote by $c(\rho, k)$ the configuration reached by $\rho$ after $k$ steps. We naturally extend this notion to define $c(\rho, 0)$ as the initial configuration. We denote by $\text{last}_\psi(\rho', i)$ the greatest position $p \in \text{dom}(\rho')$ such that $\psi(\rho', p) \leq i$ (similarly if none exists, we fix $\text{last}_\psi(\rho', i) = 0$). Further, we denote by $c(\rho', k)$ the configuration reached by $\rho'$ after $k$ steps of $\rho$, that is, the configuration reached by $\rho'$ after the execution of $\text{last}_\psi(\rho', k)$ transitions; formally, $c(\rho', k) = c(\rho', \text{last}_\psi(\rho', k))$.

Example 6 Let $\rho$, $R$, and $\psi$ as in Example 5. Assuming that the PDM $P$ has one single state $p$, stack symbols $\{\bot, a\}$ such that the three rules $r_a, r_b$ and $r_c$ are given by $r_a : p \bot \to p a \bot$, $r_b : p a \to p a a$, and $r_c : p a \to p$, then we have $c(\rho, 5) = p a a \bot$. Further, $\text{last}_\psi(\rho'_1, 5) = 1$, $\text{last}_\psi(\rho'_2, 5) = 3$, and $\text{last}_\psi(\rho'_3, 5) = 3$. Finally, $c(\rho'_1, 5) = p a \bot$, $c(\rho'_2, 5) = p a \bot$, and $c(\rho'_3, 5) = p a \bot$.

Definition 7 ($(Z, K)$-bounded distribution) Given $Z \in \text{dom}(\rho)$ and $K \in \mathbb{N}$, we say that a distribution $R$ of $\rho$ is $(Z, K)$-bounded if for every $\rho' \in R$ and for every $i \leq Z$, the effective stack height of $c(\rho', i)$ is bounded by $K$. 

\[ \text{Springer} \]
We want to show a boundedness lemma that allows us to distribute a single run into bounded runs of many contributors. An initial attempt at the lemma would show that there is a constant $N$, depending only on $C$, such that for every run $\rho$ of $C$ and for every $Z \in \text{dom}(\rho)$ there is a $(Z, N)$-bounded $R_Z$ of $\rho$.

However, this statement alone is not enough. To see the problem, imagine we have a way to build such a distribution $R_Z$ but with the property that the greater the value of $Z$ the more contributors must be involved. In turn, this would imply that infinitely many contributors would have to be involved to simulate an infinite run. This is a problem since we want finitely many contributors. Thus, our boundedness lemma below requires a further property, called synchronization, on $R_Z$. Synchronization will allow us escape the use of unboundedly many contributors.

**Definition 8** (Synchronized distribution) A distribution $R$ is synchronized if for every configuration $c(\rho, i)$ with effective stack height 1 and for every $\rho' \in R$, we have $c(\psi(\rho', i)) = c(\rho, i)$ (same control state and same stack content) and, moreover, $c(\psi(\rho', i))$ also has effective stack height 1.6

**Example 7** We now give an example of two distributions of a finite run that decrease the effective stack height, one of them being synchronized. Consider the two distributions $R$ and $S$ of $\rho = \text{rarbrbrcrcrc}$ in Example 5. Further assume that the PDM $P$ has one single state $p$, stack symbols $\{\bot, \alpha\}$ such that the three rules $r_a$, $r_b$, and $r_c$ are given by $r_a : p\bot \rightarrow p\alpha\bot$, $r_b : p\alpha \rightarrow p\alpha\alpha$, and $r_c : p\alpha \rightarrow p$. Figure 2 graphically depicts the stack contents of the configurations of the runs (the control state is always $p$), and their respective effective stack heights.

We observe that $\rho$ is effectively 4-bounded. The distribution $R$ is $(Z, 2)$-bounded for every $1 \leq Z \leq 6$, because the configurations $c(\rho_j, i)$ have effective stack height at most 2 for every $1 \leq j \leq 3$ and every $1 \leq i \leq 6$. The distribution is not synchronized. Indeed, the configuration $c(\rho, 6) = p\bot$ has effective stack height 1, but $c(\psi(\rho', 6)) = p\alpha\bot \neq c(\rho, 6)$.

The distribution $S$ is $(Z, 3)$-bounded for every $1 \leq Z \leq 6$ and synchronized. Note that in each of $\{\sigma'_i\}_{i=1,2,3}$ at positions $\text{last}_\psi(\sigma'_i, 0)$ and $\text{last}_\psi(\sigma'_i, 6)$ (the only two positions at which $\rho$ has effective stack height 1), the stack content is $\bot$, and thus the effective stack height is also 1.

We can now state the boundedness lemma. Notice that the constant $N$ in the lemma depends only on $C$.

---

6 Notice that the effective stack height of a configuration depends on the run it belongs to, and so $c(\rho, i) = c(\rho', i)$ does not necessarily imply that they have the same effective stack height.
Lemma 6 (Boundedness lemma) Let \(N = 2|Q_C|^2|\Gamma_C| + 1\), and let \(\rho\) be a run of \(C\). For every \(Z \in \text{dom}(\rho)\) there is an \((Z, N)\)-bounded and synchronized distribution \(R_Z\) of \(\rho\).

We will prove the lemma by induction on \(Z \in \text{dom}(\rho)\). In order to do this, we need two ingredients. The first ingredient (Lemma 7 below) allows us to distribute the first position whose stack height goes beyond \(N\). The second ingredient (Definition 9 and Lemma 8 will allow us to compose distributions for the induction step.

Lemma 7 Let \(N = 2|Q_C|^2|\Gamma_C| + 1\). Let \(\rho\) be a run of \(C\) and \(Z \in \text{dom}(\rho)\) be the first position of \(\rho\) such that \(c(\rho, Z)\) is not \(N\)-bounded. Then there is a \((Z, N)\)-bounded and synchronized distribution of \(\rho\).

Proof For convenience, when we want to denote that, in a run \(\rho\), the configurations reached after \((\rho)_{1,i}\) and \((\rho)_{1,j}\) are \(c\) and \(c'\), we write

\[
\rho = (\rho)_{1,i} [c] (\rho)_{i+1,j} [c'] (\rho)_{j+1,\infty}.
\]

We construct a \((Z, N)\)-bounded and synchronized distribution \(\{\rho_a, \rho_b\}\) of \(\rho\). We denote by

\[
\alpha_{N+1} \alpha_N \cdots \alpha_1 w_0,
\]

the stack content of \(c(\rho, Z)\) where the \(\alpha_i\) are stack symbols and \(w_0\) is a stack word. Because \(c(\rho, Z)\) is not \(N\)-bounded \(\rho\), the active prefix of \(c(\rho, Z)\) starts with \(\alpha_{N+1} \alpha_N \cdots \alpha_1\). Define \(\{\overrightarrow{p_1}, \overrightarrow{p_2}, \overrightarrow{p_2}, \ldots, \overrightarrow{p_k}, \overrightarrow{p_N}\} \subseteq \text{dom}(\rho)\) such that for each \(i, 1 \leq i \leq N\) we have \(c(\rho, \overrightarrow{p_i})\) and \(c(\rho, \overrightarrow{p_i})\) are the configurations immediately after the symbol \(\alpha_i\) in \(c(\rho, Z)\) is pushed, respectively popped and such that each configuration between \(\overrightarrow{p_i}\) (included) and \(\overrightarrow{p_i}\) (excluded) has \(\alpha_i \overrightarrow{\alpha_{i-1}} \cdots \alpha_1 w_0\) as a suffix. We get \(c(\rho, \overrightarrow{p_i}) = q_i \alpha_i \overrightarrow{\alpha_{i-1}} \cdots \alpha_0 w_0\) and \(c(\rho, \overrightarrow{p_i}) = q'_i \alpha_i \overrightarrow{\alpha_{i-1}} \cdots \alpha_0 w_0\) for some \(q_i, q'_i \in Q_C\). Observe that the following holds:

\[
\overrightarrow{p_1} < \cdots < \overrightarrow{p_N} < \overrightarrow{p_i} < Z < \overrightarrow{p_{N-1}} < \cdots < \overrightarrow{p_1}.
\]

Since \(N = 2|Q_C|^2|\Gamma_C| + 1\), by the pigeonhole principle we find \(q, \alpha, q'\) and three indices \(1 \leq j_1 < j_2 < j_3 \leq N\) such that by letting

\[
\alpha_{j_3-1} \cdots \alpha_{j_2} \alpha_{j_2-1} \cdots \alpha_{j_1} \alpha_{j_1-1} \cdots \alpha_1
\]

we have

\[
\rho = (\rho)_{1,\overrightarrow{p_{j_1}}} [q \alpha w_1 w_0] (\rho)_{\overrightarrow{p_{j_1+1}} \cdots \overrightarrow{p_{j_2}}} [q \alpha w_2 w_1 w_0] (\rho)_{\overrightarrow{p_{j_2+1}} \cdots \overrightarrow{p_{j_3}}} [q \alpha w_3 w_2 w_1 w_0]
\]

\[
(\rho)_{\overrightarrow{p_{j_3+1}} \cdots \overrightarrow{p_{j_1}}} [q' w_3 w_2 w_1 w_0] (\rho)_{\overrightarrow{p_{j_3+1}} \cdots \overrightarrow{p_{j_1}}} [q' w_2 w_1 w_0] (\rho)_{\overrightarrow{p_{j_1+1}} \cdots \overrightarrow{p_{j_3}}} [q' w_1 w_0] (\rho)_{\overrightarrow{p_{j_1+1}} \cdots \overrightarrow{p_{j_3}}}.\]

Now define \(\rho_a\) from \(\rho\) by simultaneously deleting \(w_2\) (actually, the two following parts of the run \((\rho)_{\overrightarrow{p_{j_3+1}} \cdots \overrightarrow{p_{j_1}}} (\rho)_{\overrightarrow{p_{j_2+1}} \cdots \overrightarrow{p_{j_3}}}\) ), we similarly define \(\rho_b\) by deleting \(w_3\) (actually, \((\rho)_{\overrightarrow{p_{j_3+1}} \cdots \overrightarrow{p_{j_1}}} (\rho)_{\overrightarrow{p_{j_2+1}} \cdots \overrightarrow{p_{j_3}}}\) ). The following shows that \(\rho_a\) defines a legal run since it is given by

\[
(\rho)_{1,\overrightarrow{p_{j_1}}} [q \alpha w_1 w_0] (\rho)_{\overrightarrow{p_{j_2+1}} \cdots \overrightarrow{p_{j_3}}} [q \alpha w_2 w_1 w_0]
\]

\[
(\rho)_{\overrightarrow{p_{j_3+1}} \cdots \overrightarrow{p_{j_1}}} [q' w_3 w_2 w_1 w_0] (\rho)_{\overrightarrow{p_{j_3+1}} \cdots \overrightarrow{p_{j_1}}} [q' w_2 w_1 w_0] (\rho)_{\overrightarrow{p_{j_1+1}} \cdots \overrightarrow{p_{j_3}}}.\]

A similar reasoning holds for \(\rho_b\). We conclude by proving two claims.
\( \rho \) distributes to \( \{ \rho_a, \rho_b \} \). The embedding function \( \psi \) for \( \rho_a \) (again, the case of \( \rho_b \) is analogous) is given by

\[
\psi(\rho_a, i) = \begin{cases} 
  i & \text{for } 1 \leq i \leq \overrightarrow{p}_{j_1} \\
  i + (\overrightarrow{p}_{j_2} - \overrightarrow{p}_{j_1}) & \text{for } \overrightarrow{p}_{j_1} + 1 \leq i \leq \overrightarrow{p}_{j_2} - (\overrightarrow{p}_{j_2} - \overrightarrow{p}_{j_1}) \\
  i + (\overrightarrow{p}_{j_1} - \overrightarrow{p}_{j_2}) + (\overrightarrow{p}_{j_2} - \overrightarrow{p}_{j_1}) & \text{for } \overrightarrow{p}_{j_2} - (\overrightarrow{p}_{j_2} - \overrightarrow{p}_{j_1}) + 1 \leq i 
\end{cases}
\]

Hence, we have a distribution \( \{ \rho_a, \rho_b \} \), \( \psi \) of \( \rho \).

\( \{ \rho_a, \rho_b \} \), \( \psi \) is a \((Z, N)\)-bounded and synchronized distribution of \( \rho \). Since the effective stack height of every configuration of \( \rho_a \) (resp. \( \rho_b \)) up to position last(\( \rho_a \), \( Z \)) (resp. last(\( \rho_b \), \( Z \))) is at most \( N \), the distribution is \((Z, N)\)-bounded. Finally, observe that we have \( c(\rho, i) = c_\psi(\rho_a, i) = c_\psi(\rho_b, i) \) for every \( i \leq \overrightarrow{p}_{j_1} \) and every \( i \geq \overrightarrow{p}_{j_1} \). Since all configurations of \( \rho \) of effective stack height 1 are in these two areas, the distribution is synchronized. \( \square \)

We now introduce the second ingredient for the proof of the Boundedness Lemma: a notion of composition of distributions that allows us to “nest” distributions (that is, to distribute a run into several runs, and then distribute one of these runs again into several runs), while preserving the properties of synchronization and boundedness. We then show, in Lemma 8, that the composition of distributions is well-defined, that is, that the composition of distributions is indeed a distribution of \( \rho \).

**Definition 9** Let \( R, \psi \) be a distribution of \( \rho \). Let \( \rho' \in R \), and let \( R', \psi' \) be a distribution of \( \rho' \). The composition of \( R, \psi \) and \( R', \psi' \) is given by \((R \ominus \{ \rho' \}) \oplus R', \psi'' \), where the embedding function \( \psi'' \) is defined as follows:

- \( \psi''(r, i) = \psi(r, i) \) for every \( r \in R \ominus \{ \rho' \} \), and
- \( \psi''(r, i) = \psi'(r, \psi''(r, i)) \) for every \( r \in R' \).

**Lemma 8** Let \( R, \psi \) be a distribution of \( \rho \). Let \( \rho' \in R \) and let \( R', \psi' \) be a distribution of \( \rho' \). The composition \((R \ominus \{ \rho' \}) \oplus R', \psi'' \) is a distribution of \( \rho \).

**Proof** We need to show that \( \psi'' \) satisfies the three properties of an embedding function.

- **Surjectivity** If \( k \in \text{dom}(\rho) \), we first exploit the surjectivity of \( \psi \): either there exists \( \rho'' \in R \ominus \{ \rho' \} \), and some \( i \in \text{dom}(\rho'') \) such that \( \psi(\rho'', i) = k \) (which means that \( \psi''(\rho'', i) = k \)) or there is some \( j \in \text{dom}(\rho') \) such that \( \psi'(\rho', j) = k \). In the latter case, we then exploit the fact that \( R', \psi' \) is a distribution of \( \rho' \), and deduce that there exists \( \rho'' \in R' \) and \( i \in \text{dom}(\rho'') \) such that \( \psi'(\rho'', i) = j \); hence we have \( \psi(\rho', \psi'(\rho'', i)) = k \), and so \( \psi''(\rho'', i) = k \).

- **Monotonicity** For every \( \rho'' \in R \ominus \{ \rho' \} \), from the monotonicity of \( \psi \) we obtain that \( \psi''(\rho'', i) < \psi''(\rho'', j) \) for every \( i < j \). If \( \rho'' \in R' \), first we derive from the monotonicity of \( \psi' \) that \( \psi'(\rho'', i) < \psi'(\rho'', j) \) holds for every \( i < j \). Then, by monotonicity of \( \psi \), we obtain \( \psi(\rho', \psi'(\rho'', i)) < \psi(\rho', \psi'(\rho'', j)), \) and so \( \psi''(\rho'', i) < \psi''(\rho'', j) \).

**Proof (of boundedness lemma, Lemma 6)** The proof is by induction on \( Z \). If \( Z = 1 \), then we claim \( R_1 = \{ \rho \} \). This is because the first configuration of a run has effective stack height at
most 2 (if the first rule was a push, and that symbol will be later popped). Since by definition
\( N \geq 3 \), we get that \( \rho \) is \((1, N)\)-bounded and trivially synchronized.

For the induction step, assume that some distribution \( R_{Z-1} \), \( \psi \) of \( \rho \) is \((Z-1, N)\)-bounded
and synchronized. If \( R_{Z-1} \) is also \((Z, N)\)-bounded, we take \( R_Z = R_{Z-1} \), and we are done.
Otherwise, there is \( \rho' \in R_{Z-1} \) such that \( c_\psi(\rho', 0), \ldots, c_\psi(\rho', Z - 1) \) are effectively \( N \)-
bounded, but \( c_\psi(\rho', Z) \) is not.

Informally, this means that the \( Z \)-th transition of \( \rho \) was distributed to \( \rho' \). Let \( Z_{\rho'} \) be that
position in \( \rho' \); formally \( Z = \psi(\rho', Z_{\rho'}) \) (if no such \( Z_{\rho'} \) exists, \( c_\psi(\rho', Z - 1) = c_\psi(\rho, Z) \)).
Since \( Z_{\rho'} \) is the first position of \( \rho' \) whose configuration is not \( N \)-bounded, we have that
\( c(\rho', 0), \ldots, c(\rho', Z_{\rho'} - 1) \) are \( N \)-bounded, but \( c(\rho', Z_{\rho'}) \) is not. We apply Lemma 7 to
each such \( \rho' \) and \( Z_{\rho'} \), and get \((Z_{\rho'}, N)\)-bounded and synchronized distributions for those \( \rho' \):
\( R_{\rho'} = \{ \rho'_1, \rho'_2 \} \). Let \( R_Z \) be the distribution obtained by replacing in \( R_{Z-1} \) every bad run \( \rho' \)
by \( R_{\rho'} \). Then \( R_Z \) is an \((Z, N)\)-bounded and synchronized distribution of \( \rho \). □

Example 8
With this example, we make the following two claims: the first claim is about
the bound \( (2|Q|^2|\Gamma| + 1) \). We claim this bound is tight as the minimal value of \( N \) for
the boundedness lemma (Lemma 6) and also the reduction theorem (Theorem 4) to hold
is \( \Theta(\Omega(2|Q|^2|\Gamma|)) \). We do not prove \( (2|Q|^2|\Gamma| + 1) \) to be exact, we prove it to be (linearly) tight.

The second claim is that if we consider a network admitting an infinite run, we may
need more instances of the \((2|Q|^2|\Gamma| + 1)\)-restriction of the PDM contributor to produce an
infinite run. Intuitively, this means bounded memory for contributors comes at the price
of witnesses involving more contributors. Below we give an example where with unbounded
memory there is a witness with one contributor whereas with bounded memory a witness
requires at least two contributors.

We build a PDM with \( k_1 + k_2 + 2 \) states and with stack alphabet \( \{\perp\} \cup [1, k_3] \), where
\( k_1, k_2, k_3 \) are distinct prime numbers. Conceptually, the PDM has two cycles. The first cycle
has \( k_1 \) states, and each traversal of the cycle pushes the word \((1 \ldots k_3)^{k_1}\) on to the stack. The
cycle can be left non-deterministically. We use an additional state, the only initial one, to
ensure that the cycle is traversed at least once.

On leaving the first cycle, the PDM enters a second cycle. The second cycle has \( k_2 \) states
and each state pops a stack symbol. Thus, each traversal of the cycle pops \( k_2 \) symbols from
the stack. The PDM can only leave this cycle from its first state, and only when \( \perp \) is the
topmost stack symbol. On leaving the second cycle, the PDM moves to the last state, from
where it writes victory in the store.

In order to reach the last state, the stack of the PDM must reach a height of at least
\((1 + k_1 k_2 k_3)\) symbols. This is because, at the end of the first cycle, the stack has some
multiple of \( k_1 k_2 k_3 \) symbols which is also a multiple of \( k_2 \). By relative primality of \( k_1, k_2, \)
and \( k_3 \), the stack must have at least \( k_1 k_2 k_3 \) symbols in addition to \( \perp \). Therefore, no run
reaching the last state can be distributed into runs exhibiting effective stack height smaller
than \((1 + k_1 k_2 k_3) = \Theta(|Q|^2|\Gamma|) \), which proves claim 1.

To address claim 2, we further improve this example so as to show that a single instance
of the contributor run in parallel with a special leader may reach the last state, but at least two
instances of its \( N \)-restriction are required, so that at least one of them may reach that state.

It is possible for the leader to be informed whenever a contributor takes a loop (once in
each loop the contributor informs the leader through the store and pauses until it receives
acknowledgment through the store). Then the contributor asks permission before entering
in the last state. The leader only grants permission if he was informed exactly a multiple of \( k_4 \)
times of the entrance of some contributor in some loop (the leader is simply a loop with \( 1 + k_4 \)
states), where \( k_4 \) is a prime number different from the others. If there is only one contributor,
the contributor may reach the victory state by growing a $1 + k_1k_2k_3k_4$-sized stack, which is too large for its $N$-restriction. Therefore a single instance of the $N$-restricted contributor does not suffice. At least two are required for an accepting run.

5.3.3 The proof of the Reduction Theorem

Proof (of Theorem 4) Theorem 4 states the non-emptiness is equivalent to the non-emptiness using $N$-restricted contributors. By Theorem 3, the non-restricted contributors capture all behaviours of the restricted ones. Thus one implication is trivial. For the other direction, we show that from an infinite run (with unrestricted contributors), we can $(Z, N)$-distribute each contributor with $Z$ sufficiently large, which allows us, using the pigeonhole principle, to deduce an infinite run using the $N$-restricted contributors.

Let $w$ be a word of $L(D)$ and let $M$ be a multiset of words of $C$ compatible with $w$. Let $s$ be a witness of compatibility, and let $I$ be the corresponding interleaving function (as introduced in the proof of the Distributing lemma). Recall that $s$ is an interleaving of $w$ and $M$, that $I(w, i)$ is the position of $s$ at which we find the $i$-th letter of $w$, and that $I(v, j)$ is the position of $s$ at which we find the $j$-th letter of $v$, for every $v \in M$.

In the sequel of the proof we consider that $M$ only contains infinite words. Remark that if $M$ contains some finite words, we can apply the distribution lemma over those runs and deduce (a possibly larger) multiset of words that yield $N$-bounded runs while still preserving compatibility. Without further formalization, we only consider the case where $M$ contains only infinite words.

Let $\sigma$ be an accepting run of $w$, and let $R$ be a multiset of runs accepting each element of the multiset $M$. The proof follows three steps:

1. We find a sequence of positions of $s$ corresponding to actions of the leader, such that both the run of the leader and $s$ can be pumped between any two such positions.
2. We take a position far enough in this sequence, say $Z$, and distribute all the runs of $R$ into a multiset $R_Z$, such that every run of $R_Z$ is $N$-bounded up to position $Z$. We show the existence of two positions, say $X, Y$, both smaller than $Z$, satisfying the following condition. Take the multisets of configurations of the runs of $R_Z$ at positions $X$ and $Y$, and “prune” them by removing their dark suffixes. Let $C_X$ and $C_Y$ be the resulting multisets of pruned configurations. Then $C_X$ and $C_Y$ have the same support (that is, they contain the same elements, although not necessarily the same number of times).
3. We show that by adding more runs to $R_Z$, we can obtain a new distribution for which the multisets $C_X$ and $C_Y$ not only have the same support, but are equal. We then show that the runs executed by the leader and by the contributors of this new distribution between positions $X$ and $Y$ can be pumped. This yields a word $w_1w_2^\omega \in L(D)$ (where $w_2$ is the word executed by the leader between positions $X$ and $Y$) compatible with a multiset of words of the form $\{v_11v_2^\omega, \ldots, v_1n v_2^\omega\}$ (where $v_21, \ldots, v_2n$ are the runs executed by the contributors between positions $X$ and $Y$), and for which we can find a witness of compatibility of the form $s_1s_2^\omega$, where $s_1$ is an interleaving of $w_1$ and $\{v_11, \ldots, v_1n\}$, and $s_2$ is an interleaving of $w_2$ and $\{v_21, \ldots, v_2n\}$.

Step (1) Since $\sigma$ is an infinite accepting run of $D$, by Proposition 2 it contains infinitely many positions of effective stack height 1. By the pigeonhole principle, from this sequence of positions we can extract an infinite subsequence of configurations with the same control state and topmost stack symbol. Since $\sigma$ is also an accepting run, we can further extract from this sequence an infinite subsequence such that between any two positions an accepting state
of $D$ is visited. Let $(b_i)_{i \in \mathbb{N}}$ denote the image of this last infinite sequence by $\mathcal{I}$. That is, $(b_i)_{i \in \mathbb{N}}$ denotes the infinite sequence of positions of $s$ obtained by the procedure above.

Now from $(b_i)_{i \in \mathbb{N}}$ we extract a subsequence $(c_i)_{i \in \mathbb{N}}$ such that between any two elements of it, every run of $R$ reaches a configuration with effective stack height 1. More formally, for every $i$ and for every $\rho \in R$, there exists $p_{i,\rho} \in \text{dom}(\rho)$ such that $c(\rho, p_{i,\rho})$ has effective stack height 1 and $c_i < \mathcal{I}(\rho, p_{i,\rho}) < c_{i+1}$. Since, by Proposition 2, every run of $R$ reaches infinitely often such configurations, $(c_i)_{i \in \mathbb{N}}$ exists. This gives us our sequence of positions in $s$.

Step (2) Let $t = |M|^{|Q_{\mathcal{C}}||\Gamma_{\mathcal{C}}|^2|\Gamma_{\mathcal{C}}|^1| + 1$, and let $Z = c_i$ (that is, position $Z$ in $s$) is the $t$-th element of the sequence $(c_i)_{i \in \mathbb{N}}$, and is likely much further than $t$-th position of $s$). For each run $\rho \in R$, let $Z_\rho$ denote an element of $\text{dom}(\rho)$ such that $\mathcal{I}(\rho, Z_\rho) = Z$. By Lemma 6, we can distribute each run $\rho \in R$ into a $(Z_\rho, N)$—bounded multiset $R_\rho$ (with embedding function $\psi_\rho$).

For every $i \geq 1$, let $q_{\rho,i}$ be the largest position of $\text{dom}(\rho)$ such that $\mathcal{I}(\rho, q_{\rho,i}) = c_i$, and let $R_\rho(q_{\rho,i}) = \{c_{\psi_\rho}(\tau, q_{\rho,i}) | \tau \in R_\rho\}$ be the multiset of configurations of $R_\rho$ at the position corresponding to $q_{\rho,i}$. We denote by $\alpha_\rho(i)$ the result of removing the dark suffixes of the configurations of $R_\rho(q_{\rho,i})$. We call the result pruned configurations.

If $i \leq t$, then, by the definition of $R_\rho$, all the active prefixes of $R_\rho(q_{\rho,i})$ are $N$-bounded. So the pruned configurations of $\alpha_\rho(i)$ consist of a control state and a stack content of length at most $N$, and therefore the number of possible pruned configurations is bounded by $|Q_{\mathcal{C}}||\Gamma_{\mathcal{C}}|^2|\Gamma_{\mathcal{C}}|^1|^1$. It follows that the number of possible sets (not multisets!) of pruned configurations is strictly smaller than $t$. So by the pigeonhole principle we find two elements $c_l$ and $c_r$ of the sequence $(c_i)_{i \in \mathbb{N}}$, where $l < r \leq t$, such that $\alpha_\rho(l)$ and $\alpha_\rho(r)$ have the same support for every $\rho$, (i.e. the sets are equal though the multisets may not be).

Step (3) We show how to modify the distributions $R_\rho$ so that the multisets $\alpha_\rho(l)$ and $\alpha_\rho(r)$ not only have same support, but are equal. Observe that, even though the multisets are not equal, they have the same cardinality. We introduce new runs in the distribution to “balance” these multisets. Denote by $\alpha$ the common support of $\alpha_\rho(l)$ and $\alpha_\rho(r)$. For every $\alpha \in \alpha$, we find two runs $\rho_a'$ and $\rho_a''$ in $R_\rho$ such that $c_{\psi_\rho}(\rho_a', q_{\rho, l})$ and $c_{\psi_\rho}(\rho_a'', q_{\rho, r})$ have pruned configuration $\alpha$.

Now we define a new distribution of $\rho$ to a multiset $R'_{\rho} \oplus \{\rho_a'a'| \alpha \in \alpha\}$ with embedding function $\psi_\rho'$. The run $\rho_a'a'$ is such that the pruned configuration $c_{\psi_\rho}(\rho_a'a', q_{\rho, l})$ is $\rho_a'$ and $c_{\psi_\rho}(\rho_a'a', q_{\rho, r})$ is $\rho_a''$: informally $\rho_a'a'$ does as $\rho_a'$ up to position $\psi_\rho(\rho_a', p_{i,\rho})$, and then as $\rho_a''$ from $\psi_\rho(\rho_a'', p_{i,\rho})$. (Remark that building these “multiset balancing runs” crucially relies on synchrony by requiring the existence of a position where the runs reach a position with effective stack height 1). Formally, $\psi_\rho'$ is the same as $\psi_\rho$ over each $\tau \in R_\rho$, and $\psi_\rho'(\rho_a'a', i) = \psi_\rho(\rho_a', i)$ when $i \leq \psi_\rho(\rho_a', p_{i,\rho})$ and $\psi_\rho'(\rho_a'a', i) = \psi_\rho(\rho_a', i) - \psi_\rho(\rho_a', p_{i,\rho})$ when $i > \psi_\rho(\rho_a', p_{i,\rho})$. Observe that since $c(\rho, p_{i,\rho})$ has effective stack height 1, it is exactly the same configuration as $c_{\psi_\rho}(\rho_a', p_{i,\rho})$ and $c_{\psi_\rho}(\rho_a'', p_{i,\rho})$. It is also the same configuration as $c_{\psi_\rho}(\rho_a'a', p_{i,\rho})$. So $\rho_a'a'$ is a run of $C$, and $R_\rho \oplus \{\rho_a'a'| \alpha \in \alpha\}$, $\psi_\rho'$ is a synchronized $(Z_\rho, N)$—bounded distribution of $\rho$.

By adding to $R_\rho$ sufficiently many instances of the appropriate $\rho_a'a'$, we obtain a new distribution $R'_{\rho}$ of $\rho$, such that the two multisets $\alpha_\rho(l)$ and $\alpha_\rho(r)$ are the same.

By the Distribution Lemma, the word $w$ of $L(D)$ is compatible with the words of the runs $\bigoplus_{\rho \in R} R'_{\rho}$. Let $\pi$ be a witness of compatibility. Consider the fragment of $\pi$ between the positions corresponding to $c_l$ and $c_r$ in $\pi$. The content of the store is the same at these two positions. Also, recall that we chose the $(c_i)_{i \in \mathbb{N}}$ so that the projection of the fragment onto the actions of the leader can be repeated infinitely often. Denote by $w^\omega$ the run of

 Springer
the leader consisting of repeating the subrun between positions corresponding to $c_l$ and $c_r$. Finally, for each $R'_\rho$, the multiset of pruned configurations of $R'_\rho$ at positions $c_l$ and $c_r$ is the same, each run in $R'_\rho$ is $N$-bounded between $c_l$ and $c_r$, and has effective stack height 1 at some point on that fragment. This does not mean that for every run $\tau \in R_\rho$ the pruned configuration will be the same at those positions, but that there exists a permutation $\mu$ of $R_\rho$ such that the pruned configuration of $\tau$ at position $c_l$ is the same as $\mu(\tau)$ at position $c_r$. Let us briefly mention that we once again rely on synchronization for the correctness of the construction: it is crucial that there is a position with effective stack height 1 between $c_l$ and $c_r$ so that concatenating successive fragments of runs does not modify the effective stack height. Denoting $\ell_\tau = (\tau)c_{\phi'_\rho}(\tau,p_\rho,l)+1..c_{\phi'_\rho}(\tau,p_\rho,r)$, we get that the multiset $\{ (\tau)_{1..c_{\phi'_\rho}(\tau,p_\rho,l)}\ell_\mu(\tau)\ell_{\mu^2(\tau)} .. | \tau \in R'_\rho, \rho \in R \}$ is a multiset of $N$-bounded runs of $C$, that is compatible with $w^{\otimes}$. Finally Theorem 3 shows those $N$-bounded runs are captured by the $N$-restricted contributors which concludes the proof. $\square$

6 Conclusion

Together with [10], our results complete the complexity picture for safety and liveness verification for parameterized systems consisting of a leader process and arbitrarily many anonymous and identical contributor processes communicating through a shared, bounded-value, register through reads and writes. When processes are modeled by finite-state machines, the complexity of both safety and liveness verification is NP-complete. Surprisingly, this complexity is lower than the non-parameterized case where a system consists of a leader and a fixed number of contributors. For pushdown processes, safety verification is PSPACE-complete, and our results show an NEXPTIME upper bound for liveness verification. Again, contrast the result with the undecidability of safety verification for a fixed number (two or more) of pushdown processes.
