This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the Information for Authors.

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal’s standard Terms & Conditions and the Ethical guidelines still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.
Plasma assisted designing of biocompatible 3D printed PCL/silver nanoparticle scaffolds: In vitro and in vivo analysis

Neethu Ninan1,a,b,*, Blessy Joseph1, Rahul Madathiparambil Visalakshan1,b, Richard Bright2,b, Clement Denoual2, Peter Zilm2, Yogesh Bharat Dalvi2, Priya P.V1, Aji Mathew2, Yves Grohens2, Nandakumar Kalarikkal2, Krasimir Vasilev2,a,b,*, Sabu Thomas1,a,c

3D printing presents numerous opportunities for designing tissue engineering constructs with intricate porosity, geometry and favourable mechanical properties that has the potential to revolutionize medical treatments. However, an often-encountered restriction is the selection of materials suitable for utilization in 3D printing, not all of which have appropriate biocompatibility properties. In this work, fused deposition modeling was employed to fabricate 3D PCL constructs without the use of any solvent. Plasma deposition was used to modify the surface of the scaffolds followed by immobilization of silver nanoparticles. The physico-chemical and mechanical analysis demonstrated that the scaffolds retained their porosity and mechanical integrity. The mechanical properties evaluated by nanoindentation technique demonstrated an increase in reduced modulus to 1.87±0.012 GPa for PCL scaffolds functionalized with silver nanoparticles for 24 hours. We also showed complete prevention of colonization by medically relevant pathogens. The modified scaffolds had good biocompatibility. The immune response studies in the culture of macrophages confirmed a reduction in the level of expression of pro-inflammatory cytokines which is a key requirement for successful wound healing. The in vivo studies on Sprague Dawley rats indicated enhanced angiogenesis and absence of foreign body reaction for scaffolds functionalized with silver nanoparticles for 6 hours. The 3D printing approach presented in this study provides new sustainable opportunities that can be adopted for designing biomaterial constructs having enhanced biological properties.

**Introduction**

The extracellular matrix (ECM) is a 3-dimensional (3D) network with hierarchical topographical features, providing support and aiding cellular adhesion, differentiation and migration.1 ECM is a non-cellular component present in all tissues which when disrupted can lead to inflammatory responses that aggravate the wound healing process.2,3 To address the necessity for a better ECM substitute, several biofabrication techniques have evolved in the past decade.4-6 The goal is to generate tissue engineering scaffolds that create a microenvironment which resembles natural ECM and promote tissue reconstruction and replacement. Among the various biofabrication techniques, 3D printing is a technology with high process versatility and flexibility which permits spatiotemporal control of the communication between cells and ECM.2 It is a bottom-up approach that consists of bio-ink (polymers or cell-laden hydrogels) deposition in a layer-by-layer fashion to produce scaffolds with intricate porosity and geometry.4 The technique carries great promise in tissue modeling, pharmaceutics, replacing complex anatomical structures, tissue regeneration and other areas.4

Several synthetic polymers can be used in 3D printing because of their photochemical and thermal processability. However, their poor bioactivity leads to reduced cell anchorage and unfavourable protein adsorption.7 Polycaprolactone (PCL) is one such synthetic polymer approved by the Food and Drug Administration (FDA) for biomedical applications.8,9 It is an ideal material for 3D printing due to its low melting point. Nonetheless, the low surface energy and hydrophobicity of PCL makes the polymer unfavourable for cell adhesion leading to reduced biological performance.10,11,12 Attempts have been made to modify the surface of PCL using alkaline hydrolysis which often had a negative impact on material bulk property and altered its morphology.12 The surface modification of PCL using polyethylene glycol has resulted in the production of
oxides and free radicals that could impact the polarity of the surface. Application of functional coatings to PCL is an approach to mitigate these problems. Surface functionalization can be carried out via a physical or chemical attachment of ligands or biomolecules. The disadvantage of physical adsorption is the possibility of desorption from the surface. On the other hand, covalent immobilization overcomes the fundamental problem of instability and leaching of bioactive motifs attached on the surface. However, the chemistry underlying this immobilizing technique is often substrate-dependent, complex, multistep and involves the use of a large amount of solvents.

Plasma polymerization is a substrate independent technology used to deposit a nano-thin layer of polymer on any type of material providing targeted and versatile surface engineering without changing bulk properties. In contrast, other techniques for thin layer fabrication such as Layer-by-Layer and Self Assembled Monolayers require a specific substrate. Thin layers deposited by plasma polymerization can be used to introduce reactive functional groups onto biomaterial surfaces that can effectively bind bioactive molecules and nanoparticles. The unique features of this facile method are the absence of solvents or initiators, minimal requirement of precursors and lack of liquid organic waste, making it environmentally friendly. Plasma technology has been already demonstrated to be a useful utility to modify 3D printed scaffolds. For example, acrylic acid-coated 3D printed PCL has resulted in enhanced growth of osteoblasts and mesenchymal stem cells.

An issue with all medical devices and constructs, including those generated via 3D printing, is colonization by bacteria and subsequent infections. Infections with medical devices can be devastating to patients causing mortality and morbidity and add substantial costs to the healthcare systems worldwide. AgNPs are now well accepted for their antibacterial properties and have been applied to a range of medical devices. AgNPs are mixed with synthetic or bio polymers to yield scaffolds with antibacterial properties. PCL wound dressings impregnated with ionic silver, zinc oxide and copper exhibited antibacterial properties. However, the study did not provide any evidence on their impact on biocompatibility or immune response. PCL/AgNPs composite scaffolds prepared by electrospinning and solvent casting displayed antibacterial activity but exhibited poor control over pore size and architecture compared to 3D printing technique. Very recently, Radhakrishnan et al. reported 3D printing of PCL/AgNPs using fused deposition modeling. Here, PCL/AgNPs scaffolds were fabricated using tetrahydrofuran and dimethylformamide as solvents which was further extruded. The main goal of our work was to avoid toxic solvents and maintain a sustainable approach. Gao et al., has prepared PCL nanocomposites containing octahedral AgNPs for bone tissue engineering. Ho et al., has synthesised PCL/carbon nanotube nanocomposites for cardiac tissue engineering. Both these articles focus on nanocomposites where the bulk property of PCL is significantly changed unlike plasma surface engineering technique employed in this work.

Plasma methods were integrated with traditional tools of nanotechnology to confer antibacterial properties to PCL 3D printed scaffolds without compromising their mechanical integrity. To achieve that, we applied plasma polymer coatings engineered with silver nanoparticles (AgNPs) to the surface of 3D porous scaffolds. We hypothesized that the potent antimicrobial properties of AgNPs can be transferred to 3D printed constructs and this will make them resistant to bacterial colonization. However, a challenge remains to preserve the biocompatibility of the material after the application of an antibacterial coating and prevent cells and tissue cytotoxicity. Thus, in this study, we not only demonstrate high antibacterial efficacy of the surface modified scaffolds, but we also evaluate whether there may be any negative impact on primary human fibroblast cells viability. Furthermore, the evaluation of nanomechanical attributes of immobilized silver nanoparticles would provide insight to the biomechanical properties of modified scaffolds. Important for applications, we also studied the innate immune responses of the new material in a culture of macrophages and evaluated their performance in vivo on male Sprague Dawley rats.

## Experimental

### Materials

PCL Capa™ 6800 (molecular weight = 80 000 g/mol) was purchased from Perstorp. Allyl amine (98%), 2-mercaptopropionic acid, sodium borohydride (NaBH₄), phosphate-buffered saline (PBS), Dulbecco’s Modified Eagle’s Medium (DMEM), Rosewell Park Memorial Institute (RPMI) medium were purchased from Sigma Aldrich. Silver nitrate was procured from Pro Sci-Tech. Penicillin and Streptomycin were bought from Life Technologies. Fetal bovine serum (FBS) was obtained from Thermo Scientific. Tryptone Soy Broth (TSB) was purchased from Oxoid. For all experiments, ultra-pure MilliQ water was used. *Staphylococcus epidermidis* (ATCC 35984) and *Pseudomonas aeruginosa* (NCTC 6749) were chosen for antibacterial experiments based on their ability to cause chronic wound infections. Primary human foreskin fibroblasts (HFF2) and monocyte cell lines (THP-1) were used in the experiments. HFF2 were grown in DMEM consisting of 5% heat inactivated FBS and 1% (v/v) Penicillin / Streptomycin in 5% CO₂ incubator maintained at 37°C. THP-1 was incubated in RPMI containing 5% heat-inactivated FBS and 1% (v/v) Penicillin / Streptomycin at 37°C in a humidified atmosphere at 5% CO₂.

Ketamine Hydrochloride Injection (Aneket ®) and Xylazine Injection (Xylaxin *) were used for the in vivo studies.

### Methods

#### Fabrication of scaffolds via 3D printing

3D printed scaffolds were fabricated using Markerbot Replicator 2X 3D printer with a 0.4 mm diameter nozzle. Before extrusion, PCL pellets were dried in a vacuum oven set at 45 °C for 24 h. The dried pellets were extruded using a SCAMEX single-
The diameter of the cylindrical die was 2 mm, and the filament thickness were adjusted to 1.75 mm. The extruder was set at a temperature of 80°C and the printing bed was at room temperature (~25°C). The velocity of printing was 12.5 mm/s for the first layer and 25 mm/s for the second layer. To obtain well-defined pores, an extrusion flow of 75% and a gap of 0.65 mm was maintained between the rods. Using a Simplify 3D software, 3D models were converted into optimized instructions to the printer to fabricate 3D printed PCL scaffolds.

**Plasma coating of 3D printed scaffolds**

3D printed PCL scaffolds were cleaned in ethanol, dried with a nitrogen stream and placed in a custom-built plasma reactor chamber operated at 13.56 MHz. The scaffolds were then further cleaned using air plasma (50 W, 5 minutes, 1x10⁻¹ mbar) to remove unwanted organic materials. Plasma polymer coatings were applied in the presence of allylamine at 40 W for 2 minutes and at a precursor pressure of 1.3 x 10⁻¹ mbar. Before any further modification, the scaffolds were kept overnight at room temperature in vacuum-sealed containers to stabilize the plasma coating.

**Synthesis of AgNPs and subsequent immobilization**

AgNPs were synthesized using an established protocol by reducing silver nitrate with sodium borohydride. 12 ml of AgNO3 (2 mM) was added to 5 ml of mercapto succinic acid (2 mM) under ice-cold conditions. Drops of 0.5 ml of NaBH₄ (0.5 M) were added slowly to the above mixture under vigorous stirring. The whole set up was protected from light and allowed to stir overnight until a stable reddish-brown solution of AgNPs was formed. The nanoparticle solution was stable for at least 6 months when stored in the refrigerator at 4°C. Immobilizations of AgNPs to the plasma polymer coated PCL scaffolds was carried out from solution for 6 hours (pPCL-Ag6) and 24 hours (pPCL-Ag24). After the immobilization period, scaffolds were rinsed thrice in Milli Q water and dried with a nitrogen stream. The scaffolds were placed in vacuum-sealed containers until further use.

**Scanning electron microscope (SEM)**

The morphology of the control and test scaffolds were observed using a scanning electron microscope (Zeiss Merlin FEG-SEM, Zeiss, Jena, Germany) at 2 kV. The samples were mounted on aluminium stubs with double-sided tape and sputter-coated with platinum. From the images obtained, the average pore size was determined using ImageJ software.

**Ellipsometer**

The thickness of the plasma polymer was measured using Variable Angle Spectroscopic Ellipsometer (AJA Woollam Co. Inc.) fitted with a VB-400 control module and HS-190 high-speed monochromator. WVASE32 software was used for data analysis. Three silicon wafers from each plasma deposition were used for thickness measurements and their average was recorded.

**Water contact angle analysis**

Sessile drop water contact angle measurements were carried out using a contact angle measurement instrument connected to a CCD camera (RD-SDMO2). The samples were placed on a plane solid support at room temperature. Measurements were taken by carefully adding 2 µL of Milli-Q-water on the surface of the scaffold at different positions and images of the droplet shape were captured after every 30s. The contact angle was measured using DropSnake plugin toolbar in Image J software. Triplicates of samples were analysed, and the mean of these values was tabulated.

**X-ray Photoelectron Spectroscopy (XPS)**

The chemical composition of the modified and unmodified scaffolds was determined using SPECS SAGE XPS equipped with Mg radiation source that operates at 10 kV and 20 mA. For all the scaffolds, survey spectra were recorded over the binding energy range of 0-1000 eV with 0.5 eV resolution and pass energy of 100 eV. The obtained spectra were processed, and curve fitted using Casa XPS software.

**Thermal analysis**

The thermal behaviour of the 3D printed samples was studied using a Differential Scanning Calorimeter (DSC, Q-20, TA instruments). 5 mg of each sample was weighed in aluminium pans and heated at 10°C/min under nitrogen flow at 50 mL/min, over a temperature range of 10 to 80°C. The melting and crystallization temperatures were estimated from the DSC graphs using the first heating scan. All the experiments were repeated thrice.

**Mechanical analysis**

The mechanical properties of the scaffolds were analyzed using a nano-indenter (Nano Guru, NG50, Instron) with a Berkovich diamond probe. The samples were fixed on the flat sample holder disc using glue and random test locations were chosen under an optical microscope by moving the translation stage. Displacement-controlled nanoin dentation experiments were conducted using a trapezoidal loading curve with a loading rate of 30nm/s for 5s at a peak displacement of 150 nm. All the experiments were repeated thrice.

**Antibacterial assay**

The anti-bacterial properties of AgNPs loaded 3D printed scaffolds were investigated against Staphylococcus epidermidis (ATCC 35984) and Pseudomonas aeruginosa (NCTC 6749). These bacterial strains were chosen based on their ability to cause wound infections. Each scaffold was placed in the sterile well...
plate to which 1ml of Tryptone Soy Broth (TSB) was added and incubated at 37°C on a shaker for 2 hours. To these wells, 105 CFU/ml of either S. epidermidis or P. aeruginosa were added and incubated overnight at 37°C on a shaker. The control wells contained 1ml of TSB containing bacteria, without any scaffolds. After incubation, TSB from each well was serially diluted and 10 µl was plated onto agar plates and incubated overnight at 37°C. Duplicates of samples were done and colony-forming units (CFU) were counted and plotted for each sample. All the experiments were repeated thrice.

**Cell viability**

The biocompatibility of the prepared scaffolds was evaluated using resazurin assay, a fluorometric assay that measures the metabolic capacity of live cells. HFF cells were seeded at a density of 5×10⁴ cells/well in 24 well plates and incubated overnight at 37°C. The cell culture medium (DMEM) was then removed, and cells were washed with PBS. Fresh DMEM was added to the wells along with PCL, pPCL, pPCL-Ag6 and pPCL-Ag24 and cells were allowed to grow for another 24 hours after which DMEM was replaced with media containing 10% FBS. Then, 100µl of media was transferred to 96 well plates and the fluorescent intensity was recorded using a microplate spectrophotometer set at an excitation wavelength of 544 nm and an emission wavelength of 590 nm. Triplicates of samples were analysed, and data were plotted as mean ± SD. The cell viability was calculated according to the following equation:

\[
\text{Cell viability (\%)} = \left( \frac{\text{Fluorescence intensity of test scaffold}}{\text{Fluorescence intensity of control scaffold}} \right) \times 100
\]

**Cell attachment**

For fixing HFF cells, 1.25% glutaraldehyde was used along with 4% paraformaldehyde and 4% sucrose in PBS. The fixative was removed, and cells were washed with PBS, dehydrated in 50% (v/v) ethanol and then completely dried using Hexamethyldisilazane (HMDS). The fixed cells were sputter coated in platinum and imaged using Scanning electron microscope Zeiss Merlin FEG-SEM, Zeiss, Jena, Germany.

**Immune studies**

The monocyte cell lines (THP-1) were differentiated into macrophages using phorbol-12-myristate 13-acetate (PMA) and grown on 24 well plates at a density of 5×10⁴ cells/well as reported previously. After overnight incubation, the cell culture medium (RPMI) was removed and cells were washed with PBS. Fresh RPMI was added to the wells along with PCL, pPCL, pPCL-Ag6 and pPCL-Ag24. 1 µg/ml of LPS was added to the wells to activate macrophages and create an inflammatory environment and incubated for 6 hours after which conditioned media was collected and centrifuged to remove cell debris. The supernatant was then tested for IL-8, IL-1β and TNFa using ELISA kits (BioLegend, San Diego, CA, USA) following instructions from the manufacturer.

**In vivo studies**

Male Sprague Dawley rats (180–260 g) were selected from the inbred animals for the in vivo studies. The rats were obtained from Kerala Veterinary and Animal Sciences University, Mannuthy, India. All the animal procedures were performed with the approval of institutional animal ethics committee (No.602/PO/Re/S/2002/CPCSEA), strictly adhering to the guidelines of CPCSEA constituted by the Ministry of Environment, Forests and Climate Change, Animal Welfare Division of Government of India in Pushpagiri Institute of Medical Sciences and Research Centre, Tiruvalla, Kerala, India. The animal breeds were housed in sterile cages under aseptic conditions making provision for sterile food and water. The animals were anesthetized with a mixture of Ketamine hydrochloride and Xylazine injection, dorsal region of the rats was shaved, sterilized with alcohol and two 1.5 × 1.5 cm full thickness skin excision wounds were created and a skin flap was reflected to expose the subcutaneous tissue. The 3D scaffolds with 1.5 × 1.5 cm dimensions were sutured on the wound. The membranes were implanted subcutaneously, and the skin flap was sutured back to retain the polymer membranes within the subcutaneous pouch. The skin pouch was reopened on day 7 and day 21 to evaluate the tissue response to the polymer membranes. Visual observation was done to find any signs of local inflammation caused by the surgical implantation. Hematoxylin and Eosin, stained sections were investigated for overall morphology, adhesion, and tissue response to the biomaterial. The stained sections (a minimum of 10 sections obtained from different layers of each tissue) were examined. Inflammatory cells (macrophages, polymorphonuclear leukocytes, lymphocytes, and plasma cells) locations, presence of giant cells, and the blood vessels were separately evaluated.

**Results and discussion**

To develop surface engineered PCL scaffolds, a combination of 3D printing and plasma polymerisation was employed. In the current study, the 3D printed scaffolds (18× 18× 0.4 mm) were fabricated using fused deposition modelling in which PCL was extruded as a thin filament through a heated nozzle and deposited via a 3D printer facilitated by the Computer-Aided Design (Simplify3D) software. The scaffolds were prepared via layer-by-layer assembly in which the first layer of extruded PCL was fused with a second layer to form a porous structure for tissue regeneration. The resultant PCL scaffolds had an organised architecture achieved by 45° shift of the horizontal printing angle between successive layers. The obtained porous 3D constructs were then surface modified by depositing a nanometer-thin layer from the plasma phase of vapour of allylamine (pPCL). The surface coatings had a thickness of 24.01 ± 0.3 nm as evaluated by spectroscopic ellipsometry. Subsequently, AgNPs capped with MSA were immobilized to the plasma polymer layer. The AgNPs had an average particle diameter of 12 ± 3 nm, which is consistent with our previous
the pristine PCL scaffold showed two peaks corresponding to Cls at 285 eV and O1s at 532 eV (Fig. 3A), consistent with the chemical structure of the polymer. When the scaffolds were coated with allylamine based plasma polymer, a distinct peak corresponding to N1s at about 400 eV appeared in the survey spectrum confirming the successful surface modification of the 3D printed PCL structures. After immobilization of AgNPs, an intense peak at 368 eV corresponding to Ag3d was detectable (Fig. 3A). The atomic percent of silver on the surface of the pPCL-Ag6, pPCL-Ag24 was 7.87 ± 1% and 13.9 ± 1.5%, respectively (Fig.3B).

Surface wettability is an influential factor that controls cell adhesion. The change in water contact angle and surface chemistry is due to the presence of hydrophobic surfaces for attachment and proliferation. Wettability is dependent on surface topographical features and chemical structure. Here, the static water contact angle was calculated as an indicator of scaffold’s wettability. The pristine PCL printed scaffold is hydrophobic with a water contact angle of WCA = 90 ± 0.2° (Fig.3C). Hydrophobicity of PCL is due to the presence of hydrocarbon chains as PCL is mainly a saturated aliphatic polyester with many repeating units of hexanoate. As shown in Fig.3C, after surface modification, the hydrophilicity of the surface significantly increased leading to lower WCA in the range of 30-40°. The calculated WCA is a complex function of

![Fig. 1 Schematic representation of (a) the components involved in fabricating plasma polymer-modified PCL scaffolds containing AgNPs (pPCL-Ag) and their chemistry of immobilisation; (b) equipment and processes involved; and (c) targeted outcomes.](image)

**Surface morphology analysis**

The surface morphology of the fabricated scaffolds was evaluated using SEM. Fig. 2 showed hierarchical structures composed of well-ordered and interconnected pores. Pore interconnectivity has a positive impact on the rate of cell growth, depth of cell infiltration and migration. These pores are intended to facilitate efficient diffusion of nutrients and removal of waste products from cells. The average pore diameters of PCL, pPCL, pPCL-Ag6 and pPCL-Ag24 were 336 ± 20 μm, 345 ± 36 μm, 329 ± 17 μm and 327 ± 20 μm, respectively. The SEM images indicate that neither the plasma polymerisation process nor the subsequent immobilization of AgNPs did not cause any critical changes to the bulk morphological property or pore size of the original PCL scaffold (Fig. 2a-d). The pore sizes remained in the range required for promotion of cell proliferation, angiogenesis and penetration of tissues into the scaffolds. The high magnification SEM images (Fig. 2e-f) also revealed the smooth surface of the pristine PCL and pPCL scaffolds. Silver nanoparticles could be also visualized (Fig. 2g-h) pointing to an increase in nanoparticles surface density with increasing immobilization time. The average number of nanoparticles on pPCL-Ag6 and pPCL-Ag24 was 27 ± 2 and 82 ± 1.5 per μm², respectively.

**Surface chemistry and wettability**

Biomaterial surface chemistry plays a critical role in governing subsequent biological responses. The surface chemical composition of the modified and pristine PCL was evaluated by X-ray photoelectron spectroscopy (XPS). The survey spectra of
change in surface chemistry due to the introduction of polar amine groups on the surface by plasma coating and variation of surface topography by nanoparticle immobilization.

Thermal and mechanical properties

The thermal behaviour of the modified and unmodified PCL scaffolds was investigated using DSC analysis (Fig.4A-B). The exothermic peak during cooling (Fig.4B) corresponds to crystallization while the endothermic peak (Fig.4A) is due to melting. The melting (Tm) and crystallization temperature (Tc) obtained from the DSC thermograms are listed in Table S1. PCL is a semi-crystalline polymer having both amorphous and crystalline regions. The characteristic Tc and Tm of pristine PCL were 40.26 and 62.94°C, respectively. No significant difference in the Tc was determined for the scaffolds before and after surface modification. However, there was a slight increase in Tm of the plasma coated scaffolds (pPCL, pPCL-6, pPCL-24) compared to pristine PCL. Tm is the temperature at which the molecular chains of PCL lose their regular well-defined orientation and become disordered. The small increase in Tm could be attributed to the surface modification which restricted the motion of molecular chains at the surface of the material, requiring more heat to melt the crystalline regions in scaffolds.\(^5,\)\(^5,\)\(^6\)

The mechanical properties of PCL, pPCL, pPCL-Ag6 and pPCL-Ag24 were evaluated using nano-indentation at a displacement of 150 nm (Fig.4C-D). During the nano-indentation test, the nano-indenter tip penetrates through the surface of the test material and records force and displacement during loading and unloading regime. The resulting load-displacement curve is the response of interest from which nano-mechanical properties such as hardness and modulus are elucidated. The Oliver-Pharr method was used to calculate displacement controlled reduced modulus and hardness of the samples. The reduced modulus was calculated from equation (1).

\[
\frac{1}{E_r} = \left(1 - \frac{\nu_1}{E_1}\right)/E_1 + \left(1 - \nu_t\right)/E_t \tag{2}
\]

where \(S\) is the unloading stiffness and \(A_p\) is the projected area. Modulus of elasticity (Et) can be deduced from Er using equation (2).

\[
E_t = S\left(\sqrt{\pi/(2\sqrt{A_p})}\right) \tag{1}
\]

In equation (2), \(E_1\) and \(\nu_1\) are modulus and Poisson ratio of the diamond indenter, \(E_t\) and \(\nu_t\) are modulus and Poisson ratio of the test material. For a diamond indenter probe, values for \(E_1\) is 1140 GPa and \(\nu_1\) is presumed to be 0.4 from a rough estimation.\(^5\)\(^7\) Using equation (2), Et for PCL, pPCL, pPCL-Ag6 and pPCL-Ag24 were calculated and plotted in Fig.4D.

As it can be seen from the load-displacement curves, there was a substantial increase in the required load to obtain the same displacement in case of the surface modified scaffolds compared to the pristine material (Fig.4C). Both hardness and modulus of the scaffolds increased for plasma polymer-modified scaffolds (Fig.4D). This was because when indented, both plasma polymer and underlying substrate contribute to the deformation process. After immobilization of AgNPs onto the plasma coated scaffolds, the indenter experienced more resistance as it penetrated the surface to a depth of 150 nm. The nano-mechanical evaluation demonstrates that the pPCL-Ag scaffolds show higher reduced modulus and hardness compared to the pristine PCL scaffolds. The reduced modulus of unmodified PCL was 0.889 ± 0.017 GPa, and that of plasma modified PCL was 1.48 ± 0.021 GPa. 3D scaffolds immobilized with silver nanoparticles had a reduced modulus of 1.51 ± 0.03 GPa. With an increase in immobilisation time of silver nanoparticles to 24h, there was an increase in reduced modulus to 1.87 ± 0.012 GPa. This may be because more nanoparticles were attached onto the surface after 24 hours as quantified by XPS, which offered more resistance to the indenter.

Antibacterial properties

The antibacterial efficacy of the prepared scaffolds was evaluated against S. epidermidis (SE) ATCC 35984 (Gram-positive) and P. aeruginosa (PA) NCTC 6749 (Gram-negative) as these bacteria are often associated with wound infections and are representatives of Gram-positive and Gram-negative species.\(^5\)\(^8,\)\(^9\) Antibacterial testing was carried out by first incubating the scaffolds in 10^7 CFU/ml of bacteria for 24h at 37°C. The resulting bacterial suspensions were plated on agar plates, and the colonies counted to evaluate the number of viable bacteria. The average colonies counted on SE and PA control plates were 6.2 x 10^{12} CFU/ml and 1.95 x 10^{13} CFU/ml, respectively (Fig.5). However, no bacterial colony growth was observed when both bacterial species were incubated with pPCL-Ag6 and pPCL-Ag24 modified scaffolds. This indicates that modification of the PCL scaffolds with silver nanoparticles can provide effective protection against infection. Our results were consistent with a body of knowledge on the antibacterial
properties of silver nanoparticles, a topic that generated tremendous interest over the last two decades. Upon exposure to an aqueous medium, AgNPs oxidises which leads to the release of silver ions that bind to bacterial DNA, block replication and cell metabolism and cause bacterial lysis.\(^{35,60}\)

### Biocompatibility and immune responses

The biocompatibility of the nanocomposite scaffolds was tested with primary human foreskin fibroblasts via the resazurin assay. Fibroblasts were selected for evaluating biocompatibility as these cells play a principal role in wound healing and tissue regeneration.\(^{61}\) In this assay, the metabolic activity of the cells is quantified in terms of fluorescence intensity of resorufin. Resazurin is converted to irreversible fluorescent pink coloured resorufin by viable cells. The results are presented in Fig. 6B and showed that functionalised PCL scaffolds exhibited negligible cytotoxicity. A small reduction in metabolic activity was observed for pPCL-Ag24 scaffolds. However, even in the case of the highest silver nanoparticle surface concentration (pPCL-Ag24) the cell metabolic activity was well within 80% of control which is accepted as satisfactory by ISO 109993-5 standards.\(^{62}\)

The morphology of the cells attached on the scaffold surface was assessed using scanning electron microscopy after 48 hours of cell culture (Fig. 6A). The results conveyed that the distribution and spreading of cells are more homogenous in the composite scaffolds compared to native PCL scaffolds. Hydrophobicity and low surface energy could be the possible reasons that attributed to poor cell infiltration on native PCL scaffolds.\(^{13,14,15,16}\)

Cell bridging was evident in pPCL, pPCL-Ag6 and pPCL-Ag24 scaffolds exhibiting strong cell-cell communications. Most of the cells were found to strongly anchor to the fist layer of functionalised scaffolds and gradually migrate to the top layer in 48 hours. In pPCL and pPCL-Ag6, cells showed a spread morphology, indicating the active physiological state of the cells (inlet figures). This was supported by the presence of protrusions called lamellipodia seen in active cells showing the well-established attachment of cells. Cell proliferation was comparatively less on pPCL-Ag24 scaffolds, in agreement with viability results discussed above. The results of the test suggested that modification of PCL scaffold with AgNPs is a viable pathway to reduce the risk of infection while retaining the biocompatibility of the material.

In the next step, we evaluated the innate immune response of the modified and unmodified PCL scaffolds. The immune system plays a pivotal role in wound healing and repair, thus, it is important to assess whether the modified scaffolds may elicit an undesired immunological response.\(^{63,64}\)

Impaired healing of wounds is often associated with raised levels of pro-inflammatory cytokines and prolonged inflammatory phase.\(^{65,66}\)

A good dermal tissue engineering scaffold is expected to reduce inflammation and promote skin regeneration. In this study, we differentiated monocyte like cell lines (THP-1) into macrophages which were used as model cells to investigate the immune responses. The modified and unmodified scaffolds were incubated in the culture of these cells overnight at 37°C to determine the level of expression of pro-inflammatory markers as a function of surface modification and the presence of AgNPs. The results from ELISA analysis (Fig. 7) showed that there was little difference in the expression of IL-8 (a neutrophil recruitment mediator) in all groups, only a small (but a statistically significant) reduction in the case of pPCL-Ag6 and pPCL-Ag24. The expression of IL-1β was very similar for the modified and unmodified scaffolds, the small differences in the cases of pPCL-Ag6 and pPCL-Ag24 not being statistically significant. However, there was a major reduction in the expression of TNF-α in the silver nanoparticle coated groups. TNF-α is a proinflammatory cytokine and a major driver of many signalling events leading to the recruitment of inflammatory cells and amplification of inflammatory response. While inflammation is an important part of the defence response to invading pathogens, many studies demonstrate that the process delays wound healing. For example, Ritsu et al. demonstrated that suppression of TNF-α expression led to faster healing wounds.\(^{67}\) Thus, we speculate that the reduc
pro-inflammatory cytokines expression observed in the case of scaffolds containing silver nanoparticles, and in particular TNF-α, may facilitate faster-wound healing.

Fig. 7 Evaluation of the immune response. Pro-inflammatory cytokine expression (A) IL-8 (B) TNF-α and (C) IL-1β from differentiated THP-1 cells for (a) control (b) PCL (c) pPCL (d) pPCL-Ag6 and (e) pPCL-Ag24. (Statistical significance was estimated using one-way ANOVA. ****p < 0.0001, ***p < 0.001, **p < 0.01.)

In vivo implantation studies

Normally a foreign body implanted in vivo can elicit a strong inflammatory response. A moderate pro-inflammatory response encourages wound healing, but an excessive inflammatory response leads to organ damage and dysfunction. Hence it is important to analyze the in vivo performance of the scaffolds after implantation (Fig. 8C). No evident adverse inflammatory reaction (infection, fistula, or fibrous capsule) was observed at either the implantation sites or adjacent sites during post transplantation follow up period of 21 days (Fig. 8A). The formation of new blood vessels (angiogenesis) is visible in all samples (Fig. 8B).

From the histological images, it is evident that the PCL scaffolds containing AgNPs enhanced the proliferation of fibroblasts compared to PCL and pPCL (Fig. 9). During wound healing, the fibroblasts proliferate and secrete various extracellular matrix...
(ECM) proteins including fibrin, fibronectin, collagen, and other ECM proteins that provide a provisional matrix for angiogenesis and tissue remodelling. This leads to the development of granulation tissue, which is imperative for proper wound healing. You et al. reported that AgNPs accelerated the migration of fibroblasts with an increased expression of α-smooth muscle actin (α-SMA).68 Neat PCL was characterized by a large number of giant cells and plasma cells (chronic inflammatory cells) which indicates inflammation. Numerous plasma cells (chronic inflammatory cells) were observed in neat PCL after seven days which shows inflammation. On the 21st day, fibroblast proliferation and angiogenesis were seen in the PCL group along with foreign body reaction. In the plasma modified group, edema was more pronounced on the 7th-day. This indicates that vascular proliferation is yet to start and is predominated by early vessels having leaky nature. Overall response is delayed in the amine-modified group. Even on the 21st day, the edema continued along with plasma cells and no evident fibroblast proliferation could be seen. A large number of fibroblasts could proliferate through pPCL-Ag6 with a few giant cells which shows that incorporation of silver nanoparticles did not induce much inflammation when compared to PCL and pPCL. On the 7th day, collagen formation was seen with vessel proliferation and no edema was observed. In pPCL-Ag6 group, collagen deposition was seen and the vessels were also matured on the 21st day. Fibroblast cells were also observed with minimum inflammation. In pPCL-Ag24 group, foreign body reaction was observed along with minimum angiogenesis and collagen deposition was also low on the 7th day. Fibroblast proliferation and collagen deposition are seen on 21st day. However inflammatory reaction is still predominant which delays wound healing. This could be due to the increased concentration of silver nanoparticles in 3D printed PCL incubated in silver nanoparticles for 24hrs. Samberg et al. reported increased edema and focal inflammation with increased silver nanoparticle concentration.69 Hence, we propose pPCL-Ag6 scaffold as a suitable material for tissue engineering applications.

Conclusions

In the present study, we demonstrate a plasma nanoengineering approach to fabricate 3D PCL printed scaffolds having improved mechanical and antibacterial properties. The surface properties of the PCL scaffolds were successfully tailored via a thin plasma polymer film deposited from the vapour of allylamine. The positive charge of the protonated amine groups available in the plasma polymer coating was utilised for the electrostatic immobilization of silver nanoparticles in a concentration-controlled manner. The scaffolds demonstrated an increase in mechanical properties after AgNPs immobilization. The AgNPs functionalised scaffolds showed complete inhibition of the growth of Gram-positive and Gram-negative pathogens often associated with wound infections. Studies with primary human dermal fibroblasts showed no apparent cytotoxicity caused by the plasma polymer coating or the incorporated AgNPs. We also examined the immune responses in a culture of macrophages obtained from differentiated THP-1 human monocyte cell line. We found a reduction of proinflammatory cytokines expression by the scaffolds containing AgNPs. The most significant reduction was in the secretion of TNF-α, a cytokine associated with amplification of inflammation and delayed wound healing. The scaffolds that were incubated in AgNPs for 6 hours were more biocompatible than scaffolds incubated for 24 hours. Matured blood vessels were also seen in 6 hours incubated scaffolds in our in vivo experiments. Thus, the surface plasma polymer nanoengineering approach provides new opportunities for refining the properties of biomaterial constructs.
