Multi-rate Control Design under Input Constraints via Fixed-Time Barrier Functions

Kunal Garg, Ryan K. Cosner, Ugo Rosolia, Aaron D. Ames and Dimitra Panagou

Abstract—In this paper, we introduce the notion of periodic safety, which requires that the system trajectories periodically visit a subset of a forward-invariant safe set, and utilize it in a multi-rate framework where a high-level planner generates a reference trajectory that is tracked by a low-level controller under input constraints. We introduce the notion of fixed-time barrier functions which is leveraged by the proposed low-level controller in a quadratic programming framework. Then, we design a model predictive control policy for high-level planning with a bound on the rate of change for the reference trajectory to guarantee that periodic safety is achieved. We demonstrate the effectiveness of the proposed strategy on a simulation example, where the proposed fixed-time stabilizing low-level controller shows successful satisfaction of control objectives, whereas an exponentially stabilizing low-level controller fails.

I. INTRODUCTION

Constraints requiring the system trajectories to evolve in some safe set at all times while visiting some goal set(s) are common in safety-critical applications. Constraints pertaining to the convergence of the trajectories to certain sets within a fixed time often appear in time-critical applications, e.g., when a task must be completed within a given time interval. Most popular approaches on the control synthesis under such specifications include quadratic programming techniques, where the safety requirements are encoded via control barrier functions (CBFs) and convergence requirements via control Lyapunov functions (CLFs), see e.g. [1], [2], or via one function that encodes both the safety and convergence requirements [3], [4].

Quadratic program (QP)-based approaches have gained popularity for control synthesis [1], [2], [4], [5] in real-time, since QPs can be solved efficiently. Most of the prior work, except [3], [4], deals with asymptotic or exponential convergence of the system trajectories to the desired goal set. Fixed-time stability (FxTS) [6] is a stronger notion of stability, where the time of convergence does not depend on the initial conditions. To address the problem of FxTS in the presence of input constraints, new Lyapunov conditions are proposed in [5], characterizing a domain of attraction for FxTS under input constraints.

As argued in the recent article [7], myopic control synthesis approaches relying solely on QPs are susceptible to infeasibility. To circumvent this issue, combining a high-level planner with a low-level controller has become a popular approach [8]–[12]. The underlying idea in these strategies is to design low-level controllers to track a reference trajectory, which is computed by a high-level planner using a simplified model. In [8] the authors presented the FaSTrack framework where the error bounds are computed using Hamilton-Jacobi (HJ) reachability analysis. This framework has been extended in [9], where the authors used Sum-Of-Squares (SOS) to compute the tracking error bounds. The constraint on the planner and the tracking error bounds may also be updated using an iterative procedure as suggested in [10]. A different approach that uses Model Predictive Controller (MPC) for high-level planning has been presented in [11] where the tracking controller is designed using control contraction metrics.

In this work, we introduce the notion of periodic safety where the system trajectories are required to remain in a safe set for all times and visit a subset of this safe set periodically. Inspired from [12], we use a multi-rate control framework where the low-level controller and the high-level planner operate at different frequencies. The high-level planner is used to generate a reference trajectory in the interior of a subset of the safe set, and the low-level controller to track this reference trajectory. The contribution of this paper is twofold. First, we combine the concepts of fixed-time stable Lyapunov functions [5] and control barrier functions [1] to define the notion of fixed-time barrier functions. We use it in a provably feasible QP, guaranteeing fixed-time convergence to a neighborhood of the reference trajectory from a region of attraction under input constraints. Second, we design the constraints of the MPC problem to consider this region of attraction of the low-level controller in the high-level planner. Compared to [12], we limit the rate of change for the planned trajectory so that the low-level controller is able to track the resulting reference trajectory within a predefined error bound. The limitation on rate change along with the tracking within the chosen error bound helps the system achieve periodic safety. Furthermore, we demonstrate that such constraints, which guarantee the correct operation of the low-level controller, do not jeopardize the feasibility of the MPC problem. Simulations demonstrate the fixed-time stabilizing low-level controller successfully satisfying the state constraints while an exponentially stabilizing controller [1] fails.

Notation: The Minkowski sum of two sets $\mathcal{X}, \mathcal{Y} \subset \mathbb{R}^n$ is denoted as $\mathcal{X} \oplus \mathcal{Y}$, and the Pontryagin difference as $\mathcal{X} \ominus \mathcal{Y}$. The set of positive integers, non-negative integers and non-negative reals is denoted as $\mathbb{N}$, $\mathbb{N}_0$, and $\mathbb{R}_0$, respectively.

II. PROBLEM FORMULATION

We first introduce the problem under study and then present some related background material.

System Model: We consider nonlinear control affine system of the following form:

$$\dot{x} = f(x) + g(x)u,$$

(1)
where $f : \mathbb{R}^{n_x} \to \mathbb{R}^{n_x}$ and $g : \mathbb{R}^{n_x} \to \mathbb{R}^{n_u \times n_u}$ are locally Lipschitz continuous functions with $f(0) = g(0) = 0$, $u \in \mathbb{R}^{n_u}$ is the input and $x \in \mathbb{R}^{n_x}$ is the system state. The control objective is to design a controller $u : \mathbb{R}_{0+} \times \mathbb{R}^{n_x} \to \mathcal{U} \subset \mathbb{R}^{n_u}$ such that solutions to the closed-loop system:

$$\dot{x} = f_a(t, x) \triangleq f(x) + g(x)u(t, x), \quad t_0 = 0, \quad t \geq 0 \tag{2}$$

satisfy the state constraints:

$$x(t) \in \mathcal{X}, \quad \forall t \in \mathbb{R}_{0+}, \quad x(T) \in \mathcal{X}_T, \quad \forall i \in \mathbb{N}_0, \quad \forall T > 0 \tag{3}$$

where $\mathcal{X} \subset \mathbb{R}^{n_x}$ and $\mathcal{X}_T \subset \mathcal{X} \cap \mathcal{D}$ with $\mathcal{D} = \{x | \|x\| \leq d\}$ for some $d > 0$. We assume that the input constraint set is given as $\mathcal{U} = \{u | A_u u \leq b_u\}$ for some $A_u \in \mathbb{R}^{m \times n_u}, b_u \in \mathbb{R}^m$. The time constant $T$ is a user-specific parameter that defines the update frequency of the planned trajectory, as will be further clarified in Section III-A. The control objectives as described in (3) require safety of the system in terms of forward invariance of the set $\mathcal{X}$, and periodic fixed-time stability of the set $\mathcal{X}_T$, which means that the system trajectories need to visit the set at each discrete time $iT$, $i \in \mathbb{N}_0$. To capture these objectives, we introduce the notion of periodic safety.

**Definition 1 (Periodic safety).** Given the sets $\mathcal{X}_T, \mathcal{X} \subset \mathbb{R}^{n_x}$, with $\mathcal{X}_T \subset \mathcal{X}$ and a time period $T > 0$, the set $\mathcal{X}_T$ is said to be periodically safe w.r.t. the safe set $\mathcal{X}$ for the closed-loop system (2) if for all $x(0) \in \mathcal{X}_T$, the following holds:

$$x(iT) \in \mathcal{X}_T, \quad x(t) \in \mathcal{X}, \quad \forall i \in \mathbb{N}, \quad \forall t \geq 0 \tag{4}$$

**Fig. 1.** Illustration of periodic safety of the set $\mathcal{X}_T$ w.r.t. the set $\mathcal{X}$.

Figure 1 illustrates the periodic safety where the system trajectories visit the set $\mathcal{X}_T$ periodically, while remaining inside the safe set $\mathcal{X}$. Note that this notion is stronger than that of conditional invariance as defined in [13], where the set $\mathcal{X}$ is called conditionally flow-invariant for the closed-loop system (2) if for all $x(0) \in \mathcal{X}_T \subset \mathcal{X}$, it holds that $x(t) \in \mathcal{X}$ for all $t \geq 0$. In particular, periodic safety of $\mathcal{X}_T$ w.r.t. $\mathcal{X}$ implies that $\mathcal{X}$ is conditionally flow-invariant. Next, we define the notion of fixed-time domain of attraction:

**Definition 2.** Given a set $\mathcal{C} \subset \mathbb{R}^{n_x}$ and a time $T > 0$, a set $D_C \subset \mathbb{R}^{n_x}$ is a Fixed-Time Domain of Attraction (FxT-DoA) of the set $\mathcal{C}$ for the closed-loop system (2), if

i) for all $x(0) \in D_C$, $x(t) \in D_C$ for all $t \in [0, T]$, and

ii) there exists $0 \leq T_C \leq T$ such that $\lim_{t \to T_C} x(t) \in \mathcal{C}$.

The concept of FxT-DoA is important under a constrained input $u \in \mathcal{U}$, as it is not possible to guarantee that fixed-time convergence can be achieved for arbitrary initial conditions. To characterize this FxT-DoA, inspired from [4], we introduce a class of barrier functions termed fixed-time barrier functions.

**Definition 3.** A continuously differentiable function $h : \mathbb{R}^{n_x} \to \mathbb{R}$ is a FxT barrier function for the set $\mathcal{S} = \{x | h(x) \geq 0\}$ with time $T_S > 0$ for the closed-loop system (2) if there exist parameters $\delta \in \mathbb{R}$, $\alpha > 0$, $\gamma_1 = 1 + \frac{1}{\mu}$ and $\gamma_2 = 1 - \frac{1}{\mu}$ such that the following holds:

$$\dot{h}(x) \geq -\delta h(x) + \alpha \min\{0, h(x)\}^{\gamma_1} + \alpha \min\{0, h(x)\}^{\gamma_2} \tag{5}$$

for all $x \in \mathcal{D}_S \subset \mathbb{R}^{n_x}$ where $T_S$ and $D_S$ are functions of $\delta, \alpha$.

Using (5), it follows from [5, Theorem 1] that the set $\mathcal{D}_S$ is a FxT-DoA of the set $\mathcal{S}$ with time $T_S$, where

$$\mathcal{D}_S = \left\{ \mathbb{R}^{n_x} : \left\{ x : h(x) \geq -k^u \left( r - \sqrt{\tau^2 - 1} \right)^\mu \right\}; \quad r < 1, \right\}$$

$$\mathcal{T}_S = \left\{ \frac{\alpha_\mu}{\mu_{k^u}^{1-\mu}}; \quad r < r_\tau, \right\}$$

$$\mathcal{S} = \left\{ \frac{\alpha_\mu}{\mu_{k^u}^{1-\mu}}; \quad r \geq r_\tau, \right\}$$

with $r = \frac{\delta}{2\alpha}$ and $0 < r, k < 1$. In particular, existence of a FxT barrier function $h$ implies: 1) forward invariance of the set $\mathcal{D}_S$ and 2) convergence to the set $\mathcal{S}$ within time $T_S$.

### III. Multi-Rate Control

In this section, we present a hierarchical strategy where we first design a high-level planner that generates a reference trajectory $z(t)$, and then, a low-level controller that tracks this reference trajectory to guarantee that the closed-loop trajectory $x(t)$ satisfies (3). The control input is defined as

$$u(t) = u_i(t) + u_m(t), \tag{6}$$

where $u_i$ and $u_m$ are defined using the policy II defined as:

$$\mathcal{II} : \left\{ u_i(t) = \pi_i(x(t), u_m(t), i), \quad u_m(t) = 0, \quad t \in \mathcal{T}_i \right\}$$

$$\mathcal{III} : \left\{ u_i(t) = u_{i+1}(t), \quad u_m(t) = \pi_m(x(t)), \quad t/T \in \mathbb{N} \right\} \tag{7}$$

where $\mathcal{T}_i = \{(i-1)T, iT\}$. Here, $\pi_m : \mathbb{R}^{n_x} \to \mathcal{U}_M \subset \mathcal{U}$ is the control policy from the high-level planner, to be designed in Section III-A, that generates a reference trajectory using a Linear Time-Invariant (LTI) model of system (1), and $\pi_i : \mathbb{R}^{n_x} \times \mathbb{R}^{n_u} \times \mathbb{N} \to \mathcal{U}$ is the low-level control policy, to be designed in Section III-B, that helps track this reference trajectory. The constraint set $\mathcal{U}_M \subset \mathcal{U}$ dictates how much of the control authority is reserved individually for the high-level planner and the low-level controller, and is a design parameter.

#### A. High-level planning

In this section we describe the high-level planning strategy.

**Reference Model:*** We assume that the reference trajectory $z(t)$ is generated using the following piecewise LTI model:

$$\dot{z} = A(z(t) + B u_m(t)), \quad t \in \cup_{i=0}^{\infty} \{ iT, (i+1)T \}$$

$$\dot{z}^+ = \Delta z(x^-(t)), \quad t \in \cup_{i=0}^{\infty} \{ iT \} \tag{8}$$

where $T$ from (3) is specified by the user and $z^-(t) = \lim_{\tau \to +} z(\tau)$ and $z^+(t) = \lim_{\tau \to -} z(\tau)$ denote the right and

\*The closed-loop solutions of a sampled-data system are uniquely determined under piecewise continuous, bounded control inputs [14, Section 2.2]
left limits of the reference trajectory \( z(t) \in \mathbb{R}^n \), which is assumed right continuous. The matrices \((A, B)\) are known and, in practice, may be computed by linearizing the system dynamics (1) about the equilibrium point, i.e., the origin. Finally, the reference input \( u_m(t) \in \mathbb{R}^d \) and the reset map \( A_\varepsilon \), which depends on the state of the nonlinear system (1), are given by the higher layer as discussed next.

**Model Predictive Control**: We design a Model Predictive Controller (MPC) to compute the high-level input \( u_m(t) \) that defines the evolution of the reference trajectory in (8), and to define the reset map \( A_\varepsilon \) for the LTI model (8). The MPC problem is solved at 1/T Hertz and therefore the reference high-level input is piecewise constant, i.e., \( u_m(t) = 0 \) \( \forall t \in T \) where \( T = \bigcup_{i=0}^{\infty} (i, (i+1)T) \). First, we introduce the following discrete-time linear model:

\[
 z_{i+1}^d = \tilde{A} z_i^d + \tilde{B} v_i,
\]

where the transition matrices are \( \tilde{A} = e^{A T} \) and \( \tilde{B} = \int_0^T e^{A(T-\eta)} B d\eta \). Now notice that, as the high-level input \( u_m \) is piecewise constant, if at time \( t_i = iT \) the state \( z(iT) = z_i^d \) and \( u_m(iT) = v_i \), then at time \( t_{i+1} = (i+1)T \) we have that

\[
 z^-(i+1)T) = z_{i+1}^d - 1.
\]

Given the discrete-time model (9) and the state of the nonlinear system (1) \( x(iT) \), we solve the following finite-time optimal control problem at time \( t_i = iT \in T_c \):

\[
 \begin{align*}
 \min_{v_i: z_{i}^d} & \sum_{k=i}^{i+N-1} \left( \|z_{k+1}^d - z_{k}^d\|_Q + \|v_{k}^d\|_R \right) \\
 \text{s.t.} & \quad z_{k+1}^d = A z_{k+1}^d + B v_{k}^d, \\
 & \quad z_{i+1}^d = x(iT) \\
 & \quad z_{k}^d \in \mathcal{X}_F \cap \mathcal{C}, v_{k}^d \in \mathcal{U} \\
 & \quad \|z_{k}^d\|_Q + \|v_{k}^d\|_R \leq d - c \\
 & \quad z_{i}^d \in \mathcal{X}_T \cap \mathcal{C} \forall k = i, \ldots, i+N-1
\end{align*}
\]

We define the sets \( D_i \) and \( C_i \) as

\[
 D_i = \{ x \mid \|x - z^-(iT)\| \leq d \}, \\
 C_i = \{ x \mid \|x - z^-(iT)\| \leq c \}.
\]

We show in Section IV that \( C_i \subset D_{i+1} \) (guaranteed by bound on the rate change of the reference trajectory \( z(t) \)) along with \( D_i \subset \mathcal{X} \) and \( C_i \subset \mathcal{X} \) (guaranteed by \( \delta \)) guarantees that closed-loop trajectories meet the objectives in (3). Under these considerations, the low-level control objective for \( t \in \mathcal{T}_i = [(i-1)T, iT) \) is to design the policy \( \pi_i \) such that the set \( D_i \) is FxT-DoA for the set \( C_i \). To this end, for the time interval \( T_i \) with \( i \in \mathbb{N}_0 \), consider the candidate FxT barrier function \( h_i : \mathbb{R}^n_x \rightarrow \mathbb{R} \) defined as

\[
 h_i(x(t)) = \frac{1}{2} \delta^2 - \frac{1}{2} \|x(t) - z^-(iT)\|^2, \quad t \in T_i.
\]

and define the following QP:

\[
 \begin{align*}
 \min & \quad \frac{1}{2} u_i^T u_i + 1 + \frac{1}{2} \delta^2 + c \delta \\
 \text{s.t.} & \quad A u_i + u_m \leq b, \\
 & \quad L_f h_i(x) + L_q h_i(x) (u_m + u_i) \geq -\delta h_i(x) \\
 & \quad \alpha \min(0, h_i(x)) \leq \alpha h_i(x) \leq \alpha \min(0, h_i(x)) \\
 & \quad x(iT) \in \mathcal{X}_F \cap \mathcal{T}_i \forall k = i, \ldots, i+N-1
\end{align*}
\]

where \( c > 0 \) and \( u_m = \pi_m(x(i-1)T) \). We denote the optimal solution of the QP (19) as \( (u_i^*, x_m, i, \delta^*, x_m, i, i) \) and define the low-level policy as

\[
 \pi_i(x(t), u_m(t), i) = u_i^*(x(t), u_m(t), i).
\]

The constraint (19b) guarantees that \( u = u_i^* + u_m \in \mathcal{U} \). The parameters \( \mu, \alpha, \gamma_1, \gamma_2 \) in (19c) are fixed, and are chosen as \( \alpha = \max \left\{ \frac{k}{T}, \frac{\mu}{T} \right\} \), \( \gamma_1 = 1 + \frac{1}{\mu} \) and \( \gamma_2 = 1 - \frac{1}{\mu} \) with \( \mu > 1 \) and \( 0 < \frac{1}{\mu} \), so that the closed-loop trajectories reach the zero super-level set of the FxT barrier function \( h_i \) within the time step \( T \).

**IV. CLOSED-LOOP PROPERTIES**

In this section we show the properties of the proposed multirate control architecture. Consider the closed-loop system (15) under the control input (7) with policies \( \pi_m \) and \( \pi_i \) defined in (13) and (20), respectively. Below, we explain how we show that the closed-loop trajectories satisfy (3):

A. First, we show in Lemma 1 that under the low-level control \( u_i \), the set \( \mathcal{D}_i \) is FxT-DoA for the set \( \mathcal{C}_i \), so that starting from any \( x((i-1)T) \in \mathcal{D}_i \), the closed-loop trajectories reach the set \( \mathcal{C}_i \) within time \( T \).

B. Next, in Theorem 1 we show recursive feasibility of the MPC so that the closed-loop trajectories satisfy \( x((i-1)T) \in \mathcal{D}_i \) for all \( i \in \mathbb{N} \), which along with item A, implies that the closed-loop trajectories satisfy (3).

**A. Fixed Time Domain of Attraction**

In this section, we show that under the low-level controller defined as the optimal solution of the QP (19), the set \( \mathcal{D}_i \) is a FxT-DoA for the set \( \mathcal{C}_i \). To this end, it is essential that the QP (19) is feasible for all \( x \) so that the low-level controller is well-defined. The slack term \( \delta \) ensures the feasibility of the
For the feasibility of the assumption, which is a standard assumption in the literature for guaranteeing forward invariance (see [15] for more details).

**Assumption 1.** For all \( x \in \partial C_i, \ i \in \mathbb{Z}_+, \) and \( u_m \in U_M, \) there exists \( u_t \in U_t \) such that the following holds:

\[
L_fh_i(x) + L_g h_i(x)(u_m + u_t) \geq 0.
\]

From Definition 3, we know that FxT-DoA depends on the ratio \( \frac{r}{r} \). We make the following assumption on the maximum value of \( s^*(x) \) as the solution of the QP (19) so that \( h_i \) is a FxT barrier function for \( C_i \) and \( D_i \) is its FxT-DoA.

**Assumption 2.** For each interval \( T_i, \) the solution \((u^*(x(t), u_m, i), s^*(x(t), u_m, i))\) of the QP (19) is continuous for all \( t \in T_i \) and the following holds

\[
\sup_{t \in T_i} \frac{s^*(x(t), u_m, i)}{2\alpha} \leq \frac{d^2}{2k} + \frac{k}{2(d^2 + c^2)} + \pi, \tag{21}
\]

where \( \alpha = \max\{\frac{\mu}{(1-k^{2})}, \frac{\mu}{\tau}\}, \gamma_1 = 1 + \frac{1}{\mu} \) and \( \gamma_2 = 1 - \frac{1}{\mu} \) for some \( \mu > 1 \) and \( 0 < k < 1. \)

**Remark 1.** As argued in [5], for given input bounds (dictated by the set \( U \)), the value of the slack term \( s \) in QP (19) depends on the time of convergence \( T \). Furthermore, the upper-bound in (21) depends on the parameters \( c, k, \) where \( 0 < c < d \) is such that \( \mathcal{X}_T \cap C_i \) is non-empty and \( 0 < k < 1. \) Thus, in practice, numerical simulations can guide the choice of the parameters \( c, k, \) and the time \( T, \) so that (21) can be satisfied.

**Lemma 1.** Suppose that Assumptions 1-2 hold. Then, for each time interval \( T_i \) with \( i \in \mathbb{N}, \) under the control policy (20), it holds that for all \( x((i-1)T) \in D_i, \) the closed-loop trajectory \( x(t) \) satisfies \( x(t) \in D_i \) for all \( t \in T_i \) and \( x^{-}(iT) \in C_i. \)

**Proof:** Under Assumption 1, it follows from [2, Lemma 2] that the QP (19) is feasible for all \( x \). Denote \( D_{C_i} \), as a FxT-DoA for the set \( C_i \), for the time \( T \). Note that by definition, \( C_i = \{x | h_i(x) \geq 0\}. \) We first compute an expression for \( D_{C_i} \) and then, we show that under Assumption 2, \( D_i \subseteq D_{C_i}. \) From [5, Theorem 1], we know that the FxT-DoA \( D_{C_i} \) is given as a function of \( r_M = \sup r^* = \frac{d^2}{2k}, \) i.e., the maximum value of the ratio \( r^*. \) We consider the two cases, namely \( r_M < 1 \) and \( r_M \geq 1 \) separately.

For \( r_M < 1, \) it follows from [5, Theorem 1] that \( D_{C_i} = \mathbb{R}^{n_x} \) is the FxT-DoA for \( C_i \). Thus, \( D_i \) is also a FxT-DoA of the set \( C_i. \)

For \( r_M \geq 1, \) it follows from [5, Theorem 1] that a FxT-DoA (i.e., the set \( D_{C_i} \)) is given as

\[
D_{C_i} = \left\{ x | h_i(x) \geq -\inf_{t \in T_i} k^{\mu} \left( r^*(x(t)) - \sqrt{r^*(x(t))^2 - 1}\right)^{\mu} \right\}.
\]

Note that

\[
\inf_{t \in T_i} r^*(x(t)) - \sqrt{r^*(x(t))^2 - 1} = r_M - \sqrt{r_M^2 - 1}, \tag{22}
\]

where the equality follows from the fact that \( r - \sqrt{r^2 - 1} \) is a monotonically decreasing function for \( r \geq 1. \) Thus, it follows that \( D_{C_i} = \left\{ x | h_i(x) \geq -k^{\mu} \left( r_M - \sqrt{r_M^2 - 1}\right)^{\mu} \right\}. \)

With the FxT barrier function \( h_i(x) \) defined in (18), the set \( D_{C_i} \) reads

\[
D_{C_i} = \left\{ x | \frac{1}{2}\|x - z^{-}(iT)\|^2 \leq k^\mu \left( r_M - \sqrt{r_M^2 - 1}\right)^\mu + \frac{1}{2}c^2 \right\}. \tag{23}
\]

Now, under Assumption 2, it holds that \( r_M \leq \frac{d^2}{2k} + \frac{k}{2(d^2 + c^2)} + \pi. \) By re-arranging this inequality, we obtain that under Assumption 2, it holds that

\[
\frac{1}{2}d^2 \leq k^\mu \left( r_M - \sqrt{r_M^2 - 1}\right)^\mu + \frac{1}{2}c^2. \tag{24}
\]

Now, for any \( x((i-1)T) \in D_i, \) it holds that \( \|x((i-1)T) - z^{-}(iT)\| \leq d. \) Thus, it follows from (24) that

\[
\frac{1}{2}\|x((i-1)T) - z^{-}(iT)\|^2 \leq k^\mu \left( r_M - \sqrt{r_M^2 - 1}\right)^\mu + \frac{1}{2}c^2,
\]

for all \( x((i-1)T) \in D_i. \) Using this, and (23), it follows that for any \( x((i-1)T) \in D_i, \) within a fixed time \( T_i \) that \( T_i \leq T, \) it follows that \( T_i \leq T. \) Thus, the system trajectories reach the set \( C_i \) on or before \( t = (i-1)T + T = iT. \)

Finally, we show that the closed-loop trajectories remain in the set \( C_i \) till \( t = iT, \) i.e., the set \( C_i \) is forward invariant for the closed-loop trajectories of (2). Let \( t_i = t_i \triangleq (i-1)T + T_i \) denote the first time instant when the closed-loop trajectories of (2) reach the boundary of the set \( C_i, \) i.e., \( h_i(x(t_i)) = 0. \) From the analysis in the first part of the lemma, it holds that \( t_i \leq iT. \) From (19), it follows that \( h_i(x) \geq \delta^*(x, u_m, i)h_i(x) \geq \delta_M h_i(x) \) for all \( x \in C_i, \) where \( \delta_M = \sup_{t \in T_i} \delta^*(x(t), u_m, i). \) The proof can be completed using [1, Proposition 1].

**Thus, satisfaction of (19) implies that system trajectories reach the set \( C_i \) on or before \( t = iT, \) and stay there till \( t = iT. \) Now, in order for the closed-loop trajectories to reach the set \( C_i \) on or before \( t = (i+1)T, \) it is required that \( x(iT) \in D_{i+1}, \) which is shown in the following lemma.

**Lemma 2.** If the MPC problem (11) is feasible at time \( t_i = iT, \) then \( x(iT) \in D_{i+1}. \)

**Proof:** By assumption of the lemma, the MPC problem (11) is feasible at time \( t_i = iT. \) Now consider the optimal MPC solution (12) at time \( t_i = iT. \) By definition, we have that \( x(iT) - z_{i,1}^{*,d} \in C, \) which implies that \( ||x(iT) - z_{i,1}^{*,d}|| \leq d. \) Furthermore, by feasibility of the optimal MPC solution (12) for problem (11), we have that \( ||z_{i+1,1}^{*,d} - z_{i+1,1}^{*,d}|| \leq d - c. \) This implies that

\[
||x(iT) - z_{i+1,1}^{*,d}|| = ||x(iT) - z_{i,1}^{*,d} + z_{i,1}^{*,d} - z_{i+1,1}^{*,d}||
\leq ||x(iT) - z_{i,1}^{*,d}|| + ||z_{i,1}^{*,d} - z_{i+1,1}^{*,d}|| \leq d.
\]

Finally, from (10) we have that \( z_{i+1,1}^{*,d} = z^{-}((i+1)T). \) Thus, from the above equation we conclude that \( ||x(iT) - z^{-}((i+1)T)|| \leq d, \) which implies that \( x(iT) \in D_{i+1}. \)
B. MPC Recursive Feasibility and Closed-Loop Constraint Satisfaction

So far, we have shown that feasibility of the MPC guarantees that \( x(iT) \in D_{i+1} \), which, under the low-level control policy (20), guarantees that \( x((i+1)T) \in C_{i+1} \). Thus, what is remaining to be shown is that the MPC (11) is recursively feasible, i.e., if (11) is feasible at \( t = 0T \), then it is feasible at \( t = iT \) for all \( i \in \mathbb{N} \). This would guarantee that \( x(iT) \in C_i \) and therefore, by Assumption 3, the following sequences of recursive feasibility of the MPC (11).

Assumption 3. The set \( X_T \) is invariant for the autonomous discrete time model \( z^d((i+1)T) = Az^d(iT) \) for all \( i \in \mathbb{N} \). Furthermore, for all \( i \in \mathbb{N} \), it holds that \( \|z^d(iT) - Az^d(iT)|| \leq d - c \).

Remark 2. The above assumption is standard in the MPC literature [16], [17] and it allows us to guarantee that the MPC problem is feasible at all time instances. In practice, the set \( X_T \) can be chosen as a small neighborhood of the origin.

Now we are ready to state the main result that shows that the MPC problem is recursively feasible for all \( t \in [iT, (i+1)T) \) and for all \( i \in \mathbb{N} \).

Theorem 1. Let Assumptions 1-3 hold and consider the closed-loop system (15) under the control policy (7), where \( \pi_m \) is defined in (13) and \( \pi_1 \) is defined in (20). If at time \( t = 0 \) problem (11) is feasible, then the closed-loop trajectories under the control policy (7) satisfy (3), i.e., the set \( X_T \) is periodically safe w.r.t. the set \( X \) with period \( T \).

Proof: The proof proceeds by induction. First, we show that if at time \( t_i = iT \) the MPC problem (11) is feasible, then at time \( t_{i+1} = (i+1)T \) the MPC problem (11) is feasible. Let \( \lfloor i \rfloor, \ldots, \lfloor i+N \rfloor \) be the optimal state input sequence to the MPC problem (11) at time \( t_i = iT \). Then from the feasibility of the MPC problem and Proposition 2 we have that \( x(iT) \in D_{i+1} \), which together with Lemma 1 implies that

\[ x((i+1)T) \in C_{i+1} = \{x \mid \|x - z^*((i+1)T)|| \leq c\}. \]

Now notice that from equation (10) we have \( z^*_{(i+1)T} = z^*((i+1)T) \), which in turn implies that

\[ x((i+1)T) - z^*_{(i+1)T} = x((i+1)T) - z^*((i+1)T) \in C \] (25)

and, therefore, by Assumption 3, the following sequences of states and inputs

\[ \lfloor u^*_i \rfloor, \ldots, \lfloor u^*_i \rfloor, \ldots, \lfloor u^*_{i+N-1} \rfloor \] (26)

are feasible at time \( t_{i+1} = (i+1)T \) for the MPC problem (11).

Next, we show that the feasibility of the MPC problem implies that state and input constraints are satisfied for the closed-loop system. Notice that by definition \( u_m(t) = \lfloor u^*_i \rfloor \in U_m \) for all \( t \in [iT, (i+1)T) \) and from Lemma 1, we have the low-level controller returns a feasible control action \( u_i(t) \), therefore we have that

\[ u(t) = u_i(t) + u_m(t) \in U, \forall t \in \mathbb{R}_{0^+}. \] (27)

Finally, from the feasibility of the state-input sequences in (26) for the MPC problem (11), we have that \( x^d_{(i+1)T} \in X_T \cap C \) and \( x((i+1)T) - x^d_{(i+1)T} \in C, \forall i \in \mathbb{N}_{0^+}. \) (28)

From the above equation we conclude that \( x(iT) \in X_T \) for all \( i \in \mathbb{N}_{0^+} \). Note that since \( z^*((i)T) \in X_T \cap C, C \subseteq D, \) and \( X_T = \mathcal{X} \cap D \), it follows that \( D_i = \{z^*((iT)) \} + D \subseteq \mathcal{X} \) for all \( i \in \mathbb{N} \). Hence, that \( x(t) \in \mathcal{X} \) for all \( t \geq 0 \). Thus, the closed-loop trajectories under the control policy (7) satisfy (3), i.e., the set \( X_T \) is periodically safe w.r.t. the set \( \mathcal{X} \) with period \( T \).

V. Simulations

In this section, we present a simulation case study where we use the proposed strategy to steer a Segway to the origin\(^2\). The state of the system are the position \( p \), the velocity \( v \), the rod angle \( \theta \) and the angular velocity \( \omega \) (see Figure 2). The control action is the voltage commanded to the motor and the equations of motion used to simulate the system can be found in [18, Section IV.B]. In this simulation, we run the high-level MPC planner at 5Hz and the low-level controller at 10kHz with parameters \( d = 0.6 \) and \( c = 0.005 \). We choose the set \( X_T = \{x = [p, v, \theta, \omega]^T \mid |p| \leq 10, |v| \leq 5, |\theta| \leq 0.3, |\omega| \leq 10\pi \}, X = \{0\}, \) input bounds \( \|u\| \leq 25 \) and \( \|u_m\| \leq 15 \). In the first scenario, the initial conditions are \([-1.0, 0.1, 0.3]^T \) and \( T = 0.2 \). Figure 2 shows the evolution of the FXT barrier functions \( h_i \) and the control input \( u \). It can be seen that the input constraints are always satisfied, and the FXT barrier functions reach zero at each time step \( T \), leading to periodic safety of the underlying set \( X \).

Periodic safety is also evident from the left figure in Figure 3, where the closed-loop trajectories are shown to converge to the set \( C_i \) by end of each interval \( T_i \). The middle plot in

\( h_i \)

\( u_m + u_l \)

Fig. 2. Plots that depict the system and the values of the barrier function \( h_i \) and total input \( u_m + u_l \).

\(^2\)Code available at https://github.com/kunalgarg42/fxts_multi_rate
cases where exponentially stabilizing controllers might fail. Therefore, leading to infeasibility of the MPC in (11) at \( t = 1T \), whereas the trajectory \( x(t) \) generated by the proposed method enters \( C_1 \), before \( t = 1T \).

Figure 3 shows the projection of the closed-loop trajectories on the \( p - \theta \) plane. It can be seen from the inset plot that the closed-loop trajectory leaves the set \( X_T \) in the interval \( 1T \) and returns to the set before the next time step. It can be observed (as discussed in Section III) that the sets \( C_i, D_i \) satisfy \( C_i \subseteq X_T \) and \( D_i \subseteq X \), respectively, guaranteeing \( x(iT) \in X_T \) and \( x(t) \in X \), i.e., periodic safety of the set \( X_T \) w.r.t. the set \( X \).

To compare the performance of the fixed-time stabilizing controller with an exponentially stabilizing one at the low level, we performed a simulation with initial conditions very close to the boundary of the set \( X_T \). In this case, we chose \( X_T = \{ x = [p, v, \theta, \omega]^T \mid |p| \leq 10, |v| \leq 5, |\theta| \leq 0.5, |\omega| \leq 10\pi \} \) and initialized the system with \( \theta(0) = 0.495 \). In this case, the parameters are chosen as \( d = 1, c = 0.04 \) and \( T = 0.25 \). The right plot on Figure 3 shows the trajectory \( x(t) \) generated by the proposed controller, and the trajectory \( \tilde{x}(t) \) generated by an exponentially stabilizing controller [1]. The inset plot on the right plot of Figure 3 shows that both \( x(t) \) and \( \tilde{x}(t) \) leave the set \( X_T \). The closed-loop trajectory \( x(t) \) returns back to the set \( X_T \) before \( t = 1T \), while \( \tilde{x}(t) \) fails to do so, leading to infeasibility of the MPC in (11) at \( t = 1T \). This demonstrates the efficacy of the proposed framework over the existing methods that use exponentially stabilizing controllers.

VI. CONCLUSIONS

In this paper, we introduced the notion of periodic safety requiring system trajectories to visit a subset of a safe set periodically. We defined the notion of fixed-time barrier function and used it in a multi-rate control framework, with MPC as a high-level planner, for control synthesis. We demonstrated that the proposed framework is capable of solving corner cases where exponentially stabilizing controllers might fail. Future work includes studying the robustness properties of the proposed framework by considering model uncertainties.
