Purpose: The continual search for new products for soft-tissue augmentation has in recent years led to the introduction of long lasting alternatives to hyaluronic acids and collagen that are composed of other polymers able to improve clinical persistence over time. This is the first report in which sodium carboxymethyl cellulose (CMC) has been chemically treated by the cross-linking process and thus used as a hydrogel for soft-tissue augmentation through injection with thin needles. The study evaluates, from a clinical point of view, the behavior of cross-linked carboxymethyl cellulose hydrogel used in the aesthetic field and its side effects so as to check the safety and performance of the polymer following intradermal injections.

Patients and methods: This work shows the preliminary results of an ongoing clinical study conducted between 2006 and 2009, performed on 84 healthy volunteers (62 females, 22 males) aged between 18 and 72 years, for the treatment of 168 nasolabial folds, 45 perioral wrinkles, and 39 lip volume.

Results: Study results show an excellent correction of facial defects. Tolerance and aesthetic quality of the correction obtained indicate considerable safety features and absence of side effects. From a clinical point of view, hydrogel is gradually absorbed into the injection site without migration issues.

Conclusion: Cross-linked CMC hydrogel proves to be an ideal agent for soft tissue augmentation with regard to safety and ease of application. It did not cause infection, extrusion, migration, or adverse reactions in the patients who have been followed for two years. Delayed aesthetic results on facial wrinkles were very satisfactory.

Keywords: dermal fillers, facial aging, cosmetic, hyaluronic acid, facial wrinkles, facial fold

Introduction

The first injectable heterologous implants date back to 1889 with the introduction of paraffin in humans. Because of the important side effects produced, such as pulmonary embolism, granulomas, and “paraffinoma”, paraffin was abandoned. The use of liquid silicone was evaluated from 1961 in the medical field and was successively extended to the area of aesthetics. At the beginning of 20th century, fat autologous implants and lipofilling started to be used. Since 1970, new technologies have allowed the reduction of the immunogenic potential of bovine collagen, used for the correction of wrinkles and scars. In 1985, different types of collagen were introduced to the market, followed by other substances, such as hyaluronic acid, known generically as dermal fillers.

Hyaluronic acid and collagen fillers are short-acting. Clinical results disappear quickly and may require subsequent applications in order to maintain the aesthetic
results. Therefore, long lasting alternative substances such as calcium hydroxypatite and poly-L-lactic acid have appeared with increasing results in recent years. However, these products have significant limitations. They often cause reactive fibrosis of tissues and are only indicated for filling into deep tissues. If injected in mid or superficial dermis they frequently produce ulcers and granulomas. Generally they prove less manageable than hyaluronic acids and collagen, which instead allow a wider range of use.

Carboxymethyl cellulose (CMC) is a biosynthetic substance neither animal nor human, already present in its native state in some dermal fillers with carrier or filling function associated with other polymers. This is the first report in which CMC has been chemically treated by the cross-linking process and thus used as a hydrogel for soft tissue augmentation through injection with thin needles.

This study evaluates, from a clinical point of view, the behavior of cross-linked carboxymethyl cellulose hydrogel used in the aesthetic field and its side effects so as to check the safety of the polymer following intradermal injections.

Material and methods
Preparation of cross-linked carboxymethyl cellulose hydrogel
The preparation of the polymer was carried out by using pharmacological grade sodium carboxymethyl cellulose, chemically treated with 1,4-Butanediol diglycidyl ether cross-linking and subjected to multiple stages of diafiltration. The purified polymer was therefore suspended in saline solution, put in 1 mL syringes and sterilized air-steam cycle at 121 degrees. The preparation of tests was performed in Italdevice Srl Laboratories (Pomezia, Italy), which are certified for the preparation of pharmaceutical and medical devices.

The tested product does not contain preservatives such as parabens and color additives or any substance prohibited by the FDA and EEC regulations. Substances contained in the formula are present in the amounts approved by the International Pharmacopoeia.

Specifications of cross-linked carboxymethyl cellulose hydrogel
Hydrogel, prepared according to this procedure and used for this experiment, showed pH of 7.4 and osmolarity of 318. CMC concentration was 20 mg/g and hydrogel particles were about 500 microns (485–519 microns) and allowed easy injection with 27½ G and 30½ G needles.

Rheometric tests for rheology realized at 25°, 1%, 1 Hz, were: a) oscillatory (25°; 1 Hz) vs deformation amplitude 0.1%–1000%; b) oscillatory (25°; 1%) vs frequency 0.1–40 Hz; c) flow (25°; 3 min) vs velocity 0.1–4 S⁻¹, and showed: phase angle (δ) of 28°, storage (elastic) modulus (G’ ) of 70 Pa, viscous (loss) modulus (G’’ ) of 35 Pa, viscosity (η) of 380 Pa·s. These tests determine: a) maximum load applied to the gel without loss of mechanical property, which was 30%; b) viscoelasticity, investigating the liquid–solid behavior of the hydrogel at various conditions, which showed a predominantly solid behavior at all frequencies investigated; c) phase angle, showed no change in the elastic and viscous properties, modifying the frequencies. These studies showed a material whose structure is very strong even at high deformation, with an identical variation of its elastic and viscous properties at different stress conditions applied (Figures 1 and 2).

Tests were repeated using cellulase enzyme to break the cross-linked network of the gel, after putting into gas chromatography on column injection, to assess the fraction of the cross-linking residual agent remaining in the hydrogel that was lower than one part per million.

All of tests were performed in Laboratories Italdevice Srl (Pomezia, Italy).

Clinical tests
This study was performed on 84 healthy volunteers (62 females, 22 males) aged between 18 and 72 years, (average 44.3), subjected to informed consent about the procedure, which was undertaken by four independent medical specialists in office-based surgery centers of São Paulo and Porto Alegre (Brazil). The study, conducted in accordance with the Declaration of Helsinki, was approved by respective ethic and research committees in
the participating research centers and lasted from June 2006 to March 2009.

People excluded from the tests were: pregnant women, patients younger than 18 years, patients with a tendency to develop hypertrophic and keloid scars, patients with burned skin or undergoing radiotherapy, patients taking aspirin and anticoagulants, patients with inflammation or infection of the area to be treated.

Protocol execution of tests

Two weeks before treatment, an intradermal skin test was performed by injecting 0.05 mL of cross-linked CMC hydrogel in the forearm of each patient in order to check local tolerance to the product. Only volunteers in good health with healthy and intact skin were chosen for the experiment. The application was preceded by asepsis with 70% alcohol solution.

According to the degree of wrinkle or defect to be corrected, the protocol included one or two treatment sessions, seven days apart, in which the maximum amount of the product used for each site of infiltration should not have exceeded 1 mL.

All tests were performed by injecting CMC into mid and deep dermis according to the end use of this device, as suggested by researchers. The effectiveness of treatment was evaluated on the basis of the double assessment of doctors and patients. The evaluation scale was organized as follows:

- Index of patients satisfaction in analogical scale:
  - dissatisfied > without visible changes > satisfied > very satisfied
- Degree of efficacy in doctors opinion:
  - A: aggravation after treatment; B: without visible changes; C: sufficient results; D: good results; E: excellent results.

The evaluation of results had been made on one or more defects per patient, before and after each treatment session. A subsequent assessment was performed four weeks after the last injection. The final evaluation was achieved after 6 months and after 9 months.

Evaluation of adverse reactions

Side effects were analyzed 15 minutes, 1 hour, and 24 hours after treatment in all patients, especially those showing redness of the treated area. Patients were examined by a retrospective analysis for signs of erythema and edema and assessed by scores 15 minutes, 1 hour, and 24 hours after injection. Reactions are recorded in Table 1. The scores of the adverse reactions were obtained by calculating the average value of erythema and edema. Results were compared with reactivity indices presented in Table 2.

Results

Eighty-four patients had been treated and followed for the injection of 168 nasolabial folds, 45 perioral wrinkles, and 39 lip volume, from June 2006 to March 2009. All patients were followed until March 2008 to verify the maintenance of the aesthetic result, but only 64 were further monitored over time until March 2009 (2 years follow-up) so as to check the occurrence of some unexpected event after the total absorption of the CMC. Twenty patients were re-injected after one year from the first treatment (from October 2007 and March 2009). For this group of patients long-term studies are still ongoing.

Patients through the analogical scale of results positively assessed acceptability of treatment. The satisfaction index exceeded 90% (see Table 3). After treatment, doctors found excellent results in 80% of cases (see Table 4). Patients considered the results very satisfactory in 85% of cases for nasolabial folds, perioral wrinkles, and lip volume. All treated cases showed the decrease of defect depth from the first infiltration, sometimes the complete resolution of wrinkles. Doctors and patients expressed similar opinions on the quality

Table 1 Intradermal reactivity scores from a clinical point of view

| Erythema         | Scores | Edema            | Scores |
|------------------|--------|------------------|--------|
| No erythema      | 0      | No edema         | 0      |
| Slight erythema  | 1      | Very slight edema| 1      |
| Clearly visible  | 2      | Slight edema     | 2      |
| erythema         |        |                  |        |
| Moderate erythema| 3      | Moderate edema about 1 mm raised skin | 3 |
| Marked erythema  | 4      | Strong extended edema | 4 |

of correction and stability over time, regardless of the type of treated wrinkles (Figures 3, 4 and 5). The results remained constant for 6 months in most patients. One patient in ten showed a more rapid decrease of the correction without returning to the initial condition. During this period the index of patient satisfaction, after six months, was between “satisfied” and “very satisfied, regardless of the type of corrected wrinkles.

Nine months after the first treatment the results were still good. The variations obtained with respect to the initial condition were judged positively in most cases. After one year results remain satisfactory for one third of patients.

**Observed adverse effects**

About one patient in ten underwent anesthesia. A nonspecific slight erythema was noted in less than 1/5 of treated patients (14 patients) on injection with spontaneous regression after 1–36 hours. No granulomas appeared early or late (0%). There was no infection (0%), extrusion (0%), or migration (0%) confirming the possibility of immediate and safe treatment without preliminary tests.

**Local and systemic tolerance**

The results of the observed data are presented in Table 5.

**Discussion**

Carboxymethyl cellulose (CMC) is a biosynthetic substance based on the b-(1–4)-D-glucopyranose polymer of the cellulose, neither animal nor human. The available literature shows that CMC is an inert substance extremely safe and free of mutagenic or carcinogenic outcomes. Some studies underline a bactericidal effect within the tissues, thus making the substance absolutely safe.

Presently, the growing success of hyaluronic acid for tissue filling is probably due to the possibility of direct injection without preliminary skin tests. Compared to old collagen it proves handy and easy to apply. However, hyaluronic acid have solution-like behavior at rheology low frequency and its properties help tissue repair. It also has anti-inflammatory functions but no filling function. Chemically treated by the cross-linking process, hyaluronic acid turns more pseudoplastic and suitable for dermal filling, although it does not conceptually present specific characteristics to that.

The choice of CMC for this study is based on the fact that this polymer has got, in its native state, specific characteristics for visco-supplementation, densification, and drug delivery. These properties have been received over the last 50 years by pharmaceutical companies that still use CMC as a high purity excipient for cortisone injections (dexamethasone) or an agent of delay (drug delivery) for the release of active principles (nifedipina).

Furthermore, CMC can produce tissue filling already in its native state. Some fillers (Radiesse®, BioForm Medical, Inc, USA; Sculptra®, Sanofi-Aventis Spa, IT; Laresse™, FzioMed, Inc, USA) use CMC with carrier or filling function.15,16,21

Despite having higher filling qualities than native hyaluronic acids, the native CMC (ie, non cross-linked), has got lower performance characteristics than cross-linked hyaluronic acids. Therefore the companies that until now have tried to use the native CMC for tissue filling...
Cross-linked carboxymethyl cellulose for soft-tissue augmentation

The re-injection performed on the same site of the first infiltration does not produce side effects in the short- and long-term. The re-injection aiming at additional correction of wrinkles requires a few days off after the first application.

The persistence of the hydrogel has been demonstrated within the tissue injected in dermal areas. From a clinical point of view, hydrogel is gradually absorbed into the injection site without migration issues. The polymer can be injected with very thin needles (30½ G) confirming the absolute flexibility and manageability of cross-linked CMC hydrogel.

Conclusion
In conclusion, cross-linked CMC hydrogel proves to be an ideal agent for facial wrinkles with regard to safety and ease of application. It did not cause infection, extrusion, migration, or adverse effects in the patients who have been followed for two years (some of them were monitored for a further 12 months after the total re-absorption of the polymer). A slight erythema visible as redness was noted only in few patients and disappeared within an acceptable term (1–36 hours). Delayed aesthetic results on facial wrinkles were very satisfactory.

Acknowledgments
Special thanks to Italdevice Srl (Pomezia, Italy) for preparation of the tests. Thanks to Professor Pedro DE Martins (Porto Alegre-RS, Brazil) and Dr Andè Muccini (Passo Fundo-RS, Brazil) for the advice and help to perform the treatments.
