MINIMAX POSTERIOR CONVERGENCE RATES AND
MODEL SELECTION CONSISTENCY IN
HIGH-DIMENSIONAL DAG MODELS BASED ON SPARSE
CHOLESKY FACTORS

BY KYOUNGJAE LEE* AND JAEYONG LEE† AND LIZHEN LIN*

The University of Notre Dame* and Seoul National University†

In this paper, we study the high-dimensional sparse directed acyclic graph (DAG) models under the empirical sparse Cholesky prior. Among our results, strong model selection consistency or graph selection consistency is obtained under more general conditions than those in the existing literature. Compared to Cao, Khare and Ghosh (2017), the required conditions are weakened in terms of the dimensionality, sparsity and lower bound of the nonzero elements in the Cholesky factor. Furthermore, our result does not require the irrepresentable condition, which is necessary for Lasso type methods. We also derive the posterior convergence rates for precision matrices and Cholesky factors with respect to various matrix norms. The obtained posterior convergence rates are the fastest among those of the existing Bayesian approaches. In particular, we prove that our posterior convergence rates for Cholesky factors are the minimax or at least nearly minimax depending on the relative size of true sparseness for the entire dimension. The simulation study confirms that the proposed method outperforms the competing methods.

1. Introduction. Detecting the dependence structure of multivariate data is one of important and challenging tasks, especially when the number of variables is much larger than the sample size. Due to advancements in technology, such data are routinely collected in a wide range of areas including genomics, climatology, proteomics and neuroimaging. The estimation of the covariance (or precision) matrix is crucial to reveal the dependence structure. Under the high-dimensional setting, however, the traditional sample covariance matrix is no longer a consistent estimator of the true covariance matrix (Johnstone and Lu, 2009). For the consistent estimation of the high-dimensional covariance or precision matrices, various restrictive matrix classes have been proposed to reduce the number of effective parameters. They include the bandable matrices (Bickel and Levina, 2008; Cai, Zhang and Zhou, 2010; Cai and Yuan, 2012; Banerjee and Ghosal, 2014),

MSC 2010 subject classifications: Primary 62C20; secondary 62F15, 62C12.
Keywords and phrases: DAG model, Precision matrix, Cholesky factor, Posterior convergence rate, Strong model selection consistency
sparse matrices (Cai and Zhou, 2012a,b; Banerjee and Ghosal, 2015) and low-dimensional structural matrices such as the sparse spiked covariance (Cai, Ma and Wu, 2015; Gao and Zhou, 2015) and sparse factor models (Fan, Fan and Lv, 2008; Pati et al., 2014). When the class of sparse matrices is of interest, the sparsity pattern can be encoded in many different ways. Sparsity can be imposed on the covariance matrix, precision matrix or Cholesky factor, which lead to different graph models. In this paper, we focus on imposing sparsity on the Cholesky factor of the precision matrix.

Consider a sample of data $X_1, \ldots, X_n \overset{i.i.d.}{\sim} N_p(0, \Sigma_n)$, where $N_p(\mu, \Sigma)$ is the $p$-dimensional normal distribution with the mean vector $\mu \in \mathbb{R}^p$ and covariance matrix $\Sigma \in \mathbb{R}^{p \times p}$. For every positive definite matrix $\Omega_n = \Sigma_n^{-1}$, the modified Cholesky decomposition (MCD) guarantees the existence of unique Cholesky factor $A_n$ and diagonal matrix $D_n$ such that $\Omega_n = (I_p - A_n)^T D_n^{-1} (I_p - A_n)$. The sparsity of a Gaussian directed acyclic graph (DAG) can be uniquely encoded by the Cholesky factor $A_n$ through the structure of the graph. In this paper, we assume that the parent ordering of the variables is known, which is a common assumption used in the literature such as in Ben-David et al. (2015), Khare et al. (2016), Yu and Bien (2017) and Cao, Khare and Ghosh (2017). The details on this concept will be provided in subsection 2.2. For the estimation of Cholesky factor $A_n$, the banded assumption and the sparsity assumption are two popular assumptions. Under the banded assumption, the elements of the matrix far from the diagonal are assumed to be all zero, while under the sparsity assumption, there is no constraint on the zero-pattern other than assuming most of the entries are zero. In recent years, various penalized likelihood estimators have been proposed with the sparsity assumption on $A_n$ (Huang et al., 2006; Rothman, Levina and Zhu, 2010; Shojaie and Michailidis, 2010; van de Geer and Bühlmann, 2013; Khare et al., 2016) and banded assumption on $A_n$ (Yu and Bien, 2017).

On the Bayesian side, relatively few works have dealt with asymptotic properties of the posteriors of high-dimensional Gaussian DAG models. Posterior convergence rates for the precision matrices with $G$-Wishart priors (Roverato, 2000) were derived by Banerjee and Ghosal (2014) and Xiang, Khare and Ghosh (2015), where $G$ is a decomposable graph. Note that a decomposable graph can be converted to a perfect DAG, a special case of the DAGs, by ignoring directions. Lee and Lee (2017) obtained the posterior convergence rates and minimax lower bounds for the precision matrices, but only bandable Cholesky factors were considered. Posterior convergence rates for the precision matrices as well as strong model selection consistency were recently derived by Cao, Khare and Ghosh (2017) for sparse DAG models.
However, their results are not adaptive to the unknown sparsity $s_0$, and the conditions required for obtaining such results are somewhat restrictive.

In this paper, we consider high-dimensional sparse Gaussian DAG models where sparsity is imposed via the sparse Cholesky factor. We adopt an empirical Bayes approach with a fractional likelihood. The empirical Bayes approach is justified by showing desirable asymptotic properties of the induced posterior such as strong model selection consistency and optimal posterior convergence rates. In addition, our theoretical results are adaptive to the unknown sparsity $s_0$.

There are four main contributions of this work. First, we show strong model selection consistency under much more general conditions than those in the literature. Specifically, the required conditions on the dimensionality, sparsity, structure of the Cholesky factor $A_n$ and the lower bound of the nonzero elements in $A_n$ (the beta-min condition, which will be described later) are significantly weakened. Second, we derive the minimax or nearly minimax posterior convergence rates for the Cholesky factors under two scenarios: with or without the beta-min condition for the true Cholesky factor. We show that at least one of the posterior convergence rates is minimax depending on the relative size of true sparseness for the entire dimension. To the best of our knowledge, this is the first result on minimax posterior convergence rates in high-dimensional DAG models. Third, we obtain the posterior convergence rates for precision matrices with respect to the spectral norm and matrix $\ell_\infty$ norm, which is the fastest among those of existing Bayesian approaches. Compared to Cao, Khare and Ghosh (2017), we achieve faster posterior convergence rate under more general conditions, except the bounded eigenvalue condition. Furthermore, their results depend on the unknown sparsity $s_0$, whereas ours do not. Fourth, our method significantly improves the model selection performance in practice. In particular, our method outperforms the other state-of-the-art methods in a simulation study. The theoretical choice of hyperparameters provided good guidelines for practical performance. Note that the choice of the hyperparameter, the individual edge probability $q_n$, in the hierarchical DAG-Wishart prior (Cao, Khare and Ghosh, 2017) can be problematic in practice, as the posterior with the theoretical choice of $q_n$ tends to be stuck at very small size models.

The rest of the paper is organized as follows. In section 2, we introduce notations, Gaussian DAG models, the empirical sparse Cholesky prior, the fractional posterior and the parameter class for the precision matrices. In section 3, strong model selection consistency, posterior convergence rates and minimax lower bounds for the Cholesky factor, and posterior convergence rates for the precision matrices are established. A simulation study...
focusing on the model selection property are represented in section 4. The proofs of the main results are provided in the supplemental article (Lee, Lee and Lin, 2018).

2. Preliminaries.

2.1. Norms and Notations. For any $a, b \in \mathbb{R}$, we denote $a \vee b$ and $a \wedge b$ as the maximum and minimum of $a$ and $b$, respectively. For any $a \in \mathbb{R}$, we denote $\lceil a \rceil$ as the largest integer strictly smaller than $a$. For any sequences $a_n$ and $b_n$, $a_n = o(b_n)$ denotes $a_n/b_n \to 0$ as $n \to \infty$. We denote $a_n = O(b_n)$, or equivalently $a_n \lesssim b_n$, if $a_n \leq Cb_n$ for some constant $C > 0$, where $C$ is an universal constant. We denote the indicator function for a set $A$ as $I(\cdot \in A)$ or $I_A(\cdot)$. For a given $p$-dimensional vector $u = (u_1, \ldots, u_p)^T$ and set $S \subseteq \{1, \ldots, p\}$, we define $u_S = (u_j)_{j \in S} \in \mathbb{R}^{|S|}$, where $|S|$ is the cardinality of $S$. For given index sets $S, S' \subseteq \{1, \ldots, p\}$ and real matrix $B \in \mathbb{R}^{p \times p}$, we denote $B_{(S, S')}$ as the $|S| \times |S'|$ submatrix consisting only of $S$th columns and $S'$th rows of $B$, and let $B_S = B_{(S,S)}$. For a real matrix $B$, we denote $S_B$ as the index set for nonzero elements of $B$ and call $S_B$ the support of $B$. We define $\mathcal{C}_p$ as the class of all $p \times p$ dimensional positive definite matrices. For any $p \times p$ symmetric matrix $B$, $\lambda_{\min}(B)$ and $\lambda_{\max}(B)$ are the minimum and maximum eigenvalues of $B$, respectively.

For any $p$-dimensional vector $u = (u_1, \ldots, u_p)^T$, we define vector norms $\|u\|_1 = \sum_{j=1}^p |u_j|$, $\|u\|_2 = (\sum_{j=1}^p u_j^2)^{1/2}$ and $\|u\|_{\max} = \max_{1 \leq j \leq p} |u_j|$. For any $p \times p$ matrix $B = (b_{ij})$, we define the spectral norm, matrix $\ell_1$ norm, matrix $\ell_\infty$ norm and Frobenius norm by

$$
\|B\| = \sup_{x \in \mathbb{R}^p, \|x\|_2 = 1} \|Bx\|_2 = (\lambda_{\max}(B^TB))^{1/2},
$$

$$
\|B\|_1 = \sup_{x \in \mathbb{R}^p, \|x\|_1 = 1} \|Bx\|_1 = \max_{1 \leq j \leq p} \sum_{i=1}^p |b_{ij}|,
$$

$$
\|B\|_\infty = \sup_{x \in \mathbb{R}^p, \|x\|_\infty = 1} \|Bx\|_{\max} = \max_{1 \leq i \leq p} \sum_{j=1}^p |b_{ij}|, \quad \text{and}
$$

$$
\|B\|_F = \left( \sum_{i=1}^p \sum_{j=1}^p b_{ij}^2 \right)^{1/2},
$$

respectively.

For a given positive integer $m$, we denote $\chi^2_m$ as the chi-square distribution with degrees of freedom $m$. For any random variables $Y_1, Y_2$ and $Y_3$, we
denote \( Y_1 \overset{d}{=} Y_2 \oplus Y_3 \) if the distribution of \( Y_1 \) is equal to that of \( Y_2 + Y_3 \), and \( Y_2 \) and \( Y_3 \) are independent. For given positive numbers \( a \) and \( b \), \( \text{Gamma}(a, b) \) and \( \text{IG}(a, b) \) are the gamma distribution and inverse-gamma distribution with shape parameter \( a \) and rate parameter \( b \), respectively. \( \text{Beta}(a, b) \) is the beta distribution whose density function at \( x \in (0, 1) \) is proportional to \( x^{a-1}(1-x)^{b-1} \). We denote \( N_p(X \mid \mu, \Sigma) \) as the density function of \( N_p(\mu, \Sigma) \) at \( X \in \mathbb{R}^p \). We denote the inverse-Wishart distribution by \( IW_p(\nu, \Phi) \), where the degree of freedom and scale matrix are \( \nu > p-1 \) and \( \Phi \in \mathcal{C}_p \), respectively.

2.2. Gaussian DAG Models. We consider the model

\[
X_1, \ldots, X_n \mid \Omega_n \overset{i.i.d.}{\sim} N_p(0, \Omega_n^{-1}),
\]

where \( \Omega_n = \Sigma_n^{-1} \) is a \( p \times p \) precision matrix and \( X_i = (X_{i1}, \ldots, X_{ip})^T \in \mathbb{R}^p \) for all \( i = 1, \ldots, n \). The MCD guarantees that there exists unique lower triangular matrix \( A_n = (a_{jl}) \) and diagonal matrix \( D_n = \text{diag}(d_j) \) such that

\[
\Omega_n = (I_p - A_n)^T D_n^{-1} (I_p - A_n),
\]

where \( a_{jj} = 0 \) and \( d_j > 0 \) for all \( j = 1, \ldots, p \). Let \( S_{A_n} \) be the support of the Cholesky factor \( A_n \), and \( S_j \) be the support of the \( j \)th row of \( A_n \). Let \( \mathbb{P}_{\Omega_n} \) and \( \mathbb{E}_{\Omega_n} \) be the probability measure and expectation corresponding to the model (1), respectively.

The model (1) can be interpreted as a Gaussian DAG model depending on the sparsity pattern of \( A_n \). For a set of vertices \( V = \{1, \ldots, p\} \) and a set of directed edges \( E \), a graph \( D = (V, E) \) is said to be a DAG if there is no directed cycles. It is also called the Bayesian network or belief network. In this paper, we assume that the variables have a known natural ordering in which no edges exist from larger vertices to smaller vertices. It has been commonly assumed in literature including Shojaie and Michailidis (2010), Ben-David et al. (2015), Khare et al. (2016), Yu and Bien (2017) and Cao, Khare and Ghosh (2017). There are relatively few works on DAG models when the ordering of variables is unknown (Kalisch and Bühlmann, 2007; Rütimann and Bühlmann, 2009; van de Geer and Bühlmann, 2013). As discussed in van de Geer and Bühlmann (2013), when the ordering is unknown, a very different technique is needed relative to the known ordering case.

For \( i \in V \), define the set of all \( i \)'s parents as the subset of \( V \) smaller than \( i \) and sharing an edge with \( i \) and denote it as \( \text{pa}_i(D) \). Any multivariate Gaussian distribution that obeys the directed Markov property with respect to a DAG \( D \) is said to be a Gaussian DAG model over \( D \). To be specific,
if \( X = (X_1, \ldots, X_p)^T \sim \mathcal{N}_p(0, \Omega^{-1}) \) and \( \mathcal{N}_p(0, \Omega^{-1}) \) belongs to a Gaussian DAG model over \( D \), then
\[
X_j \perp \{X_{j'}\}_{j' < j, j' \notin \text{pa}_j(D)} \mid (X)_{\text{pa}_j(D)},
\]
for each \( j = 1, \ldots, p \). Furthermore, if we adopt the MCD as in (2), with the known ordering of variables, \( \mathcal{N}_p(0, \Omega^{-1}) \) belongs to a Gaussian DAG model over \( D \) if and only if \( a_{jl} = 0 \) whenever \( l \notin \text{pa}_j(D) \) (Cao, Khare and Ghosh, 2017). In other words, the support of \( A \) uniquely determines a DAG \( D \) under the known ordering assumption. The model \( X = (X_1, \ldots, X_p)^T \sim \mathcal{N}_p(0, \Omega^{-1}) \) given \( S_A \) is equivalent to a Gaussian DAG model, and it can be represented as a linear autoregressive model,
\[
X_1 \mid d_1 \sim \mathcal{N}(0, d_1), \quad X_j \mid a_{S_j}, d_j, S_j \text{ ind } \mathcal{N}\left( \sum_{l \in S_j} X_l a_{jl}, d_j \right), \quad j = 2, \ldots, p,
\]
where \( a_{S_j} = a_{j,S_j} = (a_{j,j'})_{j' \in S_j}^T \). For more details on the expression (3), refer to BICKEL AND LEVINA (2008) and BEN-DAVID ET AL. (2015). The autoregressive model interpretation enables us to adopt the priors introduced in the linear regression literature. Since \( a_{S_j} \) corresponds to nonzero elements among \( a_j = (a_{j1}, \ldots, a_{jj-1})^T \), one can use a prior design for sparse regression coefficient vectors for \( a_j \), which is our strategy introduced in section 2.3.

In this paper, we consider the high-dimensional setting where \( p = p_n \) is a function of \( n \) increasing to infinity as \( n \to \infty \) and \( p \geq n \). We assume that the data were generated from a true precision matrix \( \Omega_{0n} \), where \( \Sigma_{0n} = \Omega_{0n}^{-1} \) is the true covariance matrix. Denote the MCD (2) of the true precision matrix by \( \Omega_{0n} = (I_p - A_{0n})^T D_{0n}^{-1} (I_p - A_{0n}) \), where \( A_{0n} = (a_{0,jl}), a_{0j} = (a_{0,j1}, \ldots, a_{0,jj-1})^T \) and \( D_{0n} = \text{diag}(d_{0j}) \). For notational convenience, let \( \Phi_0 = \Phi_{\Omega_{0n}} \) and \( \Psi_0 = \Psi_{\Omega_{0n}} \).

We now define some notations related to the data set. Let \( X_n = (X_1, \ldots, X_n)^T \in \mathbb{R}^{n \times p} \) be the data of size \( n \), and \( X_j = (X_{1j}, \ldots, X_{nj})^T \in \mathbb{R}^n \) be the \( j \)th column of \( X_n \). For a given index set \( S \subseteq \{1, \ldots, p\} \), let \( X_S = (X_j)_{j \in S} \in \mathbb{R}^{n \times |S|} \) be the data matrix consisting only of \( S \)th columns of \( X_n \). Let \( Z_{ij} = (X_{i1}, \ldots, X_{ij-1})^T \in \mathbb{R}^{j-1} \) and \( Z_j = (Z_{1j}, \ldots, Z_{nj})^T \in \mathbb{R}^{n \times (j-1)} \) for all \( j = 2, \ldots, p \).

For a given positive integer \( 1 \leq s \leq p \), we define \( \Psi_{\max}(s)^2 = \sup_{0 < |S| \leq s} \lambda_{\max}(X_S^T X_S) \) and \( \Psi_{\min}(s)^2 = \inf_{0 < |S| \leq s} \lambda_{\min}(X_S^T X_S) \), where the supremum and infimum are taken over all index sets \( S \subseteq \{1, \ldots, p\} \). We say that the restricted eigenvalue condition is met for some integer \( s \) if \( n^{-1} \Psi_{\min}(s)^2 \) is bounded away.
from zero uniformly for all large $n$. This condition has been used in the high-dimensional regression literature to control the behavior of the design matrix. The autoregressive model representation (3) connects the eigenvalues of the precision matrix $\Omega_0 n$ with those of the design matrix in (3) because the quantity $X_{S_j}$ corresponds to the design matrix based on the representation. Thus, the bounded eigenvalue assumption (A1) in section 2.5 essentially corresponds to the restricted eigenvalue condition.

### 2.3. Empirical Sparse Cholesky Prior

In this paper, we suggest the following prior distribution for our model:

$$a_{S_j} | d_j, S_j \sim \mathcal{N}_{|S_j|} \left( \hat{a}_{S_j}, \frac{d_j}{\gamma} (X_{S_j} \dot{X}_{S_j})^{-1} \right), \quad j = 2, \ldots, p,$$

$$\pi(d_j) \overset{i.i.d.}{\propto} d_j^{-\nu_0/2 - 1}, \quad j = 1, \ldots, p,$$

for some positive constants $\nu_0, c_1, c_2, R_2, \ldots, R_p$ and $\gamma$, where $f_{n_j}$ is a probability mass function on $\{0, 1, \ldots, R_j \land (j - 1)\}$ and $\hat{a}_{S_j} = (X_{S_j} \dot{X}_{S_j})^{-1} X_{S_j} \dot{X}_{j}$. The proposed prior is empirical in the sense that it depends on the data, so we call the prior (4) the empirical sparse Cholesky (ESC) prior. To obtain the desired asymptotic properties, appropriate conditions for hyperparameters in (4) will be introduced in section 3. Note that the prior for $d_j$ can be generalized to the proper prior $\text{IG}(\nu_0/2, \nu'_0)$ for some constant $\nu'_0 > 0$ and the results in section 3 also hold for this prior choice. However, for computational convenience, we describe and prove the main results with the improper prior $\pi(d_j) \propto d_j^{-\nu_0/2 - 1}$.

For the conditional prior of $a_j$ given $d_j$, we first introduce zero components through the prior $\pi_j$ and impose the Zellner’s g-prior (Zellner, 1986) on the nonzero components, $a_{S_j}$. The use of Zellner’s g-prior simplifies the calculation of the marginal posterior for $S_j$. Martin, Mess and Walker (2017) suggested a similar prior in the high-dimensional linear regression model. Also note that the ESC prior has a connection to the DAG-Wishart prior (Ben-David et al., 2015; Cao, Khare and Ghosh, 2017). Theorem 7.3 in Ben-David et al. (2015) shows that the DAG-Wishart prior on $(A_n, D_n)$ given a DAG implies the inverse-gamma distribution on $d_j$ and multivariate normal distribution on the nonzero elements of $a_j$ given $d_j$, where $(a_j, d_j)$ are mutually independent for all $j = 1, \ldots, p$. Thus, the ESC prior (4) is quite close to the DAG-Wishart prior when the support of $A_n$ is given.
Cao, Khare and Ghosh (2017) used the DAG-Wishart prior to recover the sparse DAG and estimate the precision matrix in high-dimensional settings. Thus, their prior on \((A_n, D_n)\) is quite close to ours, and can be viewed as a set of priors for autoregressive model (3) as discussed in the previous paragraph. For the support of DAGs, they imposed the element-wise sparsity using independent Bernoulli distributions with the hyperparameter \(q_n\), which has a nice interpretation as the individual edge probability. Based on the hierarchical DAG-Wishart prior, they obtained the strong model selection consistency for the DAG and the posterior convergence rate for the precision matrix with respect to the spectral norm. However, they did not directly adopt the autoregressive model interpretation as in (3), which is different from our approach. By using the ESC prior, we can adopt state-of-the-art techniques on selection consistency for the regression coefficient (Martin, Mess and Walker, 2017) and achieve the strong model selection consistency under much weaker conditions than those in Cao, Khare and Ghosh (2017). Furthermore, compared to the existing literature, we obtain faster posterior convergence rates for precision matrices and Cholesky factors under weaker conditions using the techniques introduced by Lee and Lee (2018, 2017) and Martin, Mess and Walker (2017). Indeed, the posterior convergence rates for Cholesky factors are nearly or exactly optimal depending on the relative size of true sparseness for the entire dimension.

2.4. \(\alpha\)-posterior Distribution. We suggest adopting the fractional likelihood with power \(\alpha \in (0, 1)\),

\[
(5) \quad L_n(A_n, D_n)^\alpha = \prod_{i=1}^{n} \left\{ N_p(X_i \mid 0, (I_p - A_n)^{-1} D_n ((I_p - A_n)^T)^{-1}) \right\}^\alpha.
\]

The use of fractional likelihood has received increased attention in recent years (Martin and Walker, 2014; Syring and Martin, 2016; Miller and Dunson, 2018). In this paper, we use the fractional likelihood mainly because of its appealing theoretical properties under relatively weaker conditions compared to the actual posterior (Bhattacharya, Pati and Yang, 2018). In the proof of the main results of this paper, the use of the fractional likelihood enables us to effectively deal with the ratio of estimated residual variances \(\hat{d}_{S_j}\) (the proof of Theorem 3.1) and the ratio of likelihood \(L_{nj}(a_j, d_j)\) (the proof of Lemma 10.2), where \(\hat{d}_{S_j}\) and \(L_{nj}(a_j, d_j)\) will be defined later.

Here we give a more detailed justification of using the fractional likelihood. The proposed conditional prior for \(a_{S_j}\) in (4) tracks the data closely because it is centered at the least square estimate. It may cause the unexpected inconsistency (Walker and Hjort, 2001). The fractional likelihood
approach can prohibit it by preventing the posterior from following the data too closely. To be more specific, the use of fractional likelihood can be interpreted as an empirical Bayes procedure by considering

\[ L_n(A_n, D_n)^\alpha \pi(A_n, D_n) = L_n(A_n, D_n) \frac{\pi(A_n, D_n)}{L_n(A_n, D_n)^{1-\alpha}}. \]

Hence, the resulting posterior consists of an ordinary likelihood function and a data-dependent prior \( \frac{\pi(A_n, D_n)}{L_n(A_n, D_n)^{1-\alpha}} \). Note that the power \( \alpha \) only appears in the prior. From this point of view, the prior is rescaled by a fractional likelihood which has an effect of penalizing parameter values that track the data too closely, while the penalty effect is controlled by the hyperparameter \( \alpha \).

The choice of \( \alpha \) can be important from a practitioner’s point of view even though theoretical results in this paper hold for any choice of \( 0 < \alpha < 1 \). In practice, we suggest using \( \alpha \) close to 1 to mimic the usual likelihood in finite sample scenario if there is no suspect of model failure, i.e. misspecification. As long as one chooses \( \alpha \) sufficiently close to 1, e.g. \( \alpha = 0.999 \) or \( \alpha = 0.9999 \), our experience confirms that the \( \alpha \)-posterior can be hardly distinguishable from the “usual” posterior even in a finite sample scenario.

**Remark 2.1.** Grünwald et al. (2017) suggested using I-log-SafeBayes (or R-log-SafeBayes) to determine \( \hat{\alpha} \), which gives the minimizer \( \hat{\alpha} \) of the posterior-expected posterior-randomized loss of prediction (or its variant). The induced posterior is robust to model misspecification in some cases (Grünwald et al., 2017).

The prior (4) and fractional likelihood (5) lead to the following joint posterior distribution,

\begin{align*}
\alpha_{S_j} | d_j, S_j, X_n & \overset{\text{iid}}{\sim} N_{|S_j|} \left( \tilde{\alpha}_{S_j}, \frac{d_j}{\alpha + \gamma} \left( X_{S_j}^T X_{S_j} \right)^{-1} \right), \quad j = 2, \ldots, p, \\
d_j | S_j, X_n & \overset{\text{iid}}{\sim} IG \left( \frac{\alpha n + \nu_0}{2}, \frac{\alpha n}{2} \tilde{d}_{S_j} \right), \quad j = 1, \ldots, p, \\
\pi_{\alpha}(S_j | X_n) & \propto \pi_j(S_j) \left( 1 + \frac{\alpha}{\gamma} \right)^{-|S_j|/2} \left( \tilde{d}_{S_j} \right)^{-\frac{\alpha n + \nu_0}{2}} \left( \tilde{d}_{S_j} \right)^{-\frac{\alpha n + \nu_0}{2}}, \quad j = 2, \ldots, p,
\end{align*}

where \( \tilde{d}_{S_j} = n^{-1} \tilde{X}_{S_j}^T (I_n - \tilde{P}_{S_j}) \tilde{X}_j \) and \( \tilde{P}_{S_j} = X_{S_j} (X_{S_j}^T X_{S_j})^{-1} X_{S_j}^T \). We refer to the posterior (6) as the \( \alpha \)-posterior and denote it by \( \pi_{\alpha}(\cdot | X_n) \) to clarify that we consider the \( \alpha \)-fractional likelihood. Throughout the paper, \( \alpha \in (0, 1) \) is a fixed constant.
2.5. Parameter Class. For given positive constants $0 < \alpha < 1$, $0 < \epsilon_0 < 1/2$, $C_{bm}$ and a sequence of positive integers $s_0$, we introduce conditions (A1)-(A4) for the true precision matrix:

(A1) $\epsilon_0 \leq \lambda_{\min}(\Omega_{0n}) \leq \lambda_{\max}(\Omega_{0n}) \leq \epsilon_0^{-1}$.

(A2) $\max_{1 \leq j \leq p} \sum_{l=1}^{p} I(a_{0,jl} \neq 0) \leq s_0$.

(A3) $\min_{(j,l): a_{0,jl} \neq 0} |a_{0,jl}|^2 \geq \frac{16}{\alpha(1-\alpha)\epsilon_0^2(1-2\epsilon_0)^2} C_{bm} \log p \frac{\log p}{n}$.

(A4) $\max_{1 \leq j \leq p} \sum_{j=2}^{p} I(a_{0,jl} \neq 0) \leq s_0$.

Condition (A1) ensures that the eigenvalues of $\Omega_{0n}$ are bounded by fixed constants, which has been commonly used for the estimation of the high-dimensional precision matrices (Ren et al., 2015; Cai, Liu and Zhou, 2016; Banerjee and Ghosal, 2015) as well as the high-dimensional DAGs (Yu and Bien, 2017; Khare et al., 2016). In this paper, condition (A1) is mainly used to get upper bounds of $d_{0j}$, $d_{ij}^{-1}$ and $\|A_{0n}\|$.

Condition (A2) restricts the number of nonzero elements in each row of $A_{0n}$ to be smaller than $s_0$. Note that $s_0$ may increase to infinity as $n$ gets larger. In our setting, it is equivalent to say that the cardinality of $pa_j(D_0)$ is less than $s_0$ for any $j = 2, \ldots, p$, where $D_0$ is the DAG corresponding to $A_{0n}$.

Condition (A3) is the well-known beta-min condition, which determines the lower bound for the nonzero signals. The beta-min condition has been used for the exact support recovery of the high-dimensional linear regression coefficients (Wainwright, 2009a; Bühlmann and van de Geer, 2011; Castillo, Schmidt-Hieber and van der Vaart, 2015; Yang, Wainwright and Jordan, 2016; Martin, Mess and Walker, 2017) as well as the high-dimensional DAGs (Khare et al., 2016; Yu and Bien, 2017; Cao, Khare and Ghosh, 2017).

Condition (A4) restricts the number of nonzero elements in each column of $A_{0n}$ to be smaller than $s_0$. In other words, the number of edges directed from any vertex is less than $s_0$. This assumption is required to deal with the posterior probability of $\|A_n - A_{0n}\|_1$. Note that if we consider only the banded structure for the Cholesky factor as in Yu and Bien (2017), conditions (A2) and (A4) automatically hold for some $s_0$.

Now, we define a class of precision matrices

$$\mathcal{U}_p = \mathcal{U}_p(\epsilon_0, s_0, \alpha, C_{bm}) = \left\{ \Omega \in \mathbb{C}_p : \Omega \text{ satisfies (A1)-(A3)} \right\}.$$ 

imsart-aos ver. 2014/10/16 file: sparse-cholcov.tex date: October 24, 2018
In section 3, we show that one can achieve the strong model selection consistency for any $\Omega_{0n} \in \mathcal{U}_p$. Furthermore, we derive the posterior convergence rates for $A_{0n}$ and show that these are optimal or nearly optimal for the class $\mathcal{U}_p$ (or $\mathcal{U}_p$ without condition (A3)).

REMARK 2.2. Cao, Khare and Ghosh (2017) weakened the bounded eigenvalue condition (A1) by replacing a constant $\epsilon_0$ with a sequence $\epsilon_{0,n}$, which can go to zero at certain rate. Our results also still hold under the similar weakened bounded eigenvalue condition with $\epsilon_{0,n}$, but it will sacrifice the other conditions. For example, by using a sequence $\epsilon_{0,n}$ in place of a fixed $\epsilon_0$ in the proof of Theorem 3.1, one can see that $s_0 \log p \leq C n \epsilon_{0,n}^2$ for some $C > 0$ and the beta-min condition (A3) with $\epsilon_{0,n}$ in place of $\epsilon_0$ are required.

3. Main Results. We introduce Condition (P) on the hyperparameters in the ESC prior (4), which is necessary for the results in this section. Note that this condition is for the hyperparameters of the prior distribution, which does not affect the true parameter space.

Condition (P) Assume that $\nu_0 = o(n)$, $c_1 = O(1)$, $c_2 \geq 2$ and $\gamma = O(1)$. For given positive constants $0 < \alpha < 1$ and $0 < \epsilon_0 < 1/2$ used in conditions (A1) and (A3), assume that $R_j = [n (\log p)^{-1} \{\log n\}^{-1} \vee c_3 \} ]$ for any $j = 2, \ldots, p$ and some small constant $0 < c_3 < (c')^2 \epsilon_0^2 / \{128(1 + 2 \epsilon_0)^2\}$, where $c' = \{(1 - \alpha)/10\}^2$.

The condition $c_2 \geq 2$ is similar to the condition $\kappa \geq 2$ in Yang, Wainwright and Jordan (2016). Note that the constants $c_1$ and $c_2$ in the ESC prior control the row-wise sparsity of the Cholesky factor $A_n$: large values of them make the posterior prefer small values for $|S_j|$. Thus, the above condition means that we need certain amount of penalty on $|S_j|$ to achieve desirable asymptotic properties. The condition on $R_j$ means that $R_j$ is of order $n (\log p)^{-1}$ and smaller than $n (\log p)^{-1} (c')^2 \epsilon_0^2 / \{128(1 + 2 \epsilon_0)^2\}$, so it can be replaced by the condition $R_j = [n (\log p)^{-1} (c')^2 \epsilon_0^2 / \{128(1 + 2 \epsilon_0)^2\}]$. To assure $s_0 \leq R_n$, we will assume that $s_0 \leq n (\log p)^{-1} c_3 / 2$ later. In general, assuming $s_0 = O(n (\log p)^{-1})$ or even $s_0 = o(n (\log p)^{-1})$ is essential to prove theoretical properties such as selection consistency and convergence rates. However, it can be unrealistically small for some finite sample size $n$. More importantly, the quantity $\epsilon_0$ is unknown in typical applications, so it is desirable to make the prior work for any choice of $\epsilon_0$. Condition (P) argues that there is such a prior. We suggest choosing a small enough $c_3$ so that $R_j$ can be regarded as $R_j = [n (\log p \cdot \log n)^{-1}]$ for finite samples.
Remark 3.1. Yang, Wainwright and Jordan (2016) suggested a prior for the linear model similar to the ESC prior but for the mean vector of the prior $\pi(a_{S_j} \mid d_j, S_j)$, they used zero mean vector while we used $\hat{a}_{S_j}$. There are two consequences from the use of the data-dependent mean $\hat{a}_{S_j}$. First, we do not need an upper bound condition for $\|X_{S_0j}a_{0,S_0j}\|_2$ or $\|a_{0,S_0j}\|_2$, while Yang, Wainwright and Jordan (2016) assumed $\|X_{S_0j}a_{0,S_0j}\|_2 \leq gd_{0j}\log p$, where $g = \gamma^{-1}$ in this paper. It is known that this type of condition is required if we use the Zellner’s $g$-prior with zero mean (Shang and Clayton, 2011). Second, to prove model selection consistency, Yang, Wainwright and Jordan (2016) assumed $g = p^{2c}$ for some $c \geq 1/2$ corresponding to $\gamma = p^{-2c}$ in our notation. This is the so-called information paradox of Zellner’s $g$-priors (Liang et al., 2008). We do not require this condition and just assume $\gamma = O(1)$.

3.1. Strong Model Selection Consistency. When the recovery of the DAG is of interest, it is desirable to use a Bayesian procedure that guarantees the strong model selection consistency. We show that the $\alpha$-posterior warrants this property under mild conditions. As mentioned earlier, the Gaussian DAG model has an interpretation as a sequence of autoregressive model (3), which enables us to adopt the state-of-the-art techniques for the selection consistency of the regression coefficient in Martin, Mess and Walker (2017).

To use the results in Martin, Mess and Walker (2017), there are two main issues that need to be addressed. The first is the restricted eigenvalue condition for the design matrix. In our setting, the design matrices consist of columns of data matrix $X_n$, thus each row follows a multivariate normal distribution. We show that under the bounded eigenvalue condition (A1), the restricted eigenvalue condition for any integer $R = o(n)$ automatically holds on some large set $N^c$ having $P_0$-probability tending to 1 (Lemma 9.1 in Supplementary Material). A similar result appears in Narisetty and He (2014).

The second issue is more challenging than the first. Martin, Mess and Walker (2017) considered only the known (fixed) residual variance case, which corresponds to the known $d_{0j}$ case in our setting. The assumption on the known residual variance results in a relatively straightforward proof for selection consistency. We extended their techniques to the unknown residual variance case by applying (non-central) chi-square concentration inequalities for the estimated residual variances $\hat{d}_{S_j}$ for some index set $S_j$, which is motivated by Shin, Bhattacharya and Johnson (2015). It reveals that the ratio of the marginal posteriors $\pi_{\alpha}(S_j \mid X_n)/\pi_{\alpha}(S_{0j} \mid X_n)$ actually behaves like the ratio of the conditional posteriors given $d_{0j}$, $\pi_{\alpha}(S_j \mid d_{0j}, X_n)/\pi_{\alpha}(S_{0j} \mid d_{0j}, X_n)$, with $P_0$-probability tending to 1, where $S_{0j}$ is the index set for the nonzero
elements in the $j$th row of $A_{0n}$.

We also note here that unlike the Lasso type (or its variants) of results with the random design matrix (Wainwright, 2009b), our theory does not require the irrepresentable condition on the true covariance matrix. For example, Yu and Bien (2017) and Khare et al. (2016) require the irrepresentable condition for the asymptotic properties of estimators in DAG models. See section IV of Wainwright (2009b) for more details on the irrepresentable condition.

Theorem 3.1 (Strong model selection consistency). For given positive constants $0 < \alpha < 1$, $0 < \epsilon_0 < 1/2$, $C_{bn} > c_2 + 2$ and an integer $s_0$, assume that $\Omega_{0n}$ satisfies conditions (A1), (A2) and (A3), i.e., $\Omega_{0n} \in \mathcal{U}_p$. Consider model (1) and the ESC prior (4) with Condition (P). If $s_0 \log p \leq nc_3/2$,

$$\sup_{\Omega_{0n} \in \mathcal{U}_p} \mathbb{E}_0 \left[ \pi_\alpha (S_{A_n} \neq S_{A_{0n}} \mid X_n) \right] = o(1).$$

The assumption $s_0 \log p = o(n)$ or $s_0 \log p \leq cn$ for some constant $c > 0$ is widely used in the high-dimensional sparse covariance or precision matrix estimation literature. In Theorem 3.1, we assume less restrictive condition $s_0 \log p \leq n c_3/2$, which automatically guarantees $s_0 \leq R_j$ for all $j = 2, \ldots, p$. Note that the constant $c_3$ is defined in Condition (P).

It is worthwhile to compare our result to those of Cao, Khare and Ghosh (2017), Yu and Bien (2017) and Khare et al. (2016). Note that in these works it is also assumed that the ordering of variables is known. Cao, Khare and Ghosh (2017) showed the strong model selection consistency using the hierarchical DAG-Wishart prior. They assumed variants of conditions (A1), (A2) and (A3). First, they relaxed condition (A1) by letting $\epsilon_{0,n} \to 0$ such that $(\log p/n)^{1/2 - 1/(2+k)} = o(\epsilon_{0,n}^4)$ for some $k > 0$, instead of a fixed $\epsilon_0 > 0$. Second, they assumed the same condition (A2) but further assumed $s_0^{2+k} \sqrt{\log p/n} = o(1)$ and $(\log p/n)^{k/(4k+8)} \log n = o(1)$ and considered only the DAGs with the total number of edges at most $8^{-1}s_0(n/\log p)^{(1+k)/(2+k)}$, which can be restrictive. Note that, when $p \geq n$, it does not include the banded Cholesky factor having $s_0$ nonzero elements for each row. Third, they assumed somewhat strong beta-min condition compared with (A3), which requires $\min_{j,l:a_{0,jl} \neq 0} |a_{0,jl}|^2 \geq M_n^2 \epsilon_{0,n}^{-1} (\log p/n)^{1/(2+k)}$ for some $k > 0$ and some sequence $M_n \to \infty$. Thus, their assumptions on the tuple $(n, p, s_0)$ as well as the parameter class are much more restrictive than ours, except for the bounded eigenvalue condition. Furthermore, the choice of hyperparameter in the hierarchical DAG-Wishart prior depends on the unknown sparsity parameter $s_0$, thus it is not adaptive to the unknown parameter.
More specifically, the hyperparameter $q_n$ in the hierarchical DAG-Wishart prior should be set at $q_n = s_0(\log p/n)^{1/(2+k)}$ for some $k > 0$ to achieve the strong model selection consistency.

Yu and Bien (2017) suggested a penalized maximum likelihood estimation for the Cholesky factor of the precision matrix and proved the exact signed support recovery under the condition $\rho^{-2}\|D_{0n}\|^{1} \left(12\pi^2 s_0 + 32\right)\log p < n$. They considered the class of precision matrices satisfying condition (A1) and having a banded structure with the row-specific bandwidths $s_{0j} = |S_{0j}|$ such that $a_{0lj} = 0$ for all $1 \leq l < j - s_{0j}$ and $2 \leq j \leq p$. Thus, by taking $s_0 = \max_j s_{0j}$, their class satisfies conditions (A2) and (A4). They also assumed the beta-min condition, $\min_{j:l:a_{0lj} \neq 0} |d_{0j}^{-1/2}a_{0lj}| \geq 8\rho^{-1}\sqrt{2}\|D_{0n}\|^{\log p/n}(4\max_j \|\Sigma_{0n,S_{0j}}^{-1}\|_{\infty} + 5\epsilon_0^{-1})$. In general, it holds that $\|\Sigma_{0n,S_{0j}}^{-1}\|_{\infty} = O(s_{0j}^{1/2})$ without further assumption, thus the above condition implies that the minimum nonzero $|d_{0j}^{-1/2}a_{0lj}|$ is bounded below by $\sqrt{s_0}\log p/n$ with respect to a constant multiple, thus stronger than condition (A3). Furthermore, they assumed the irrepresentable condition

$$\max_{2 \leq j \leq p} \max_{l:1 \leq l \leq j - s_{0j}} \|((\Sigma_{0n})_{l,S_{0j}})(\Sigma_{0n,S_{0j}})^{-1}\|_1 \leq \frac{6(1 - \rho)}{\pi^2}$$

for some constant $\rho \in (0, 1]$. Therefore, they only considered the banded Cholesky factor and used somewhat strong beta-min condition as well as the irrepresentable condition. However, the comparison with our result (Theorem 3.1) is not straightforward because their exact signed support recovery property is stronger than the selection consistency proved in Theorem 3.1.

Khare et al. (2016) proved the signed support recovery property of the convex sparse Cholesky selection (CSCS) method when the data vectors $X_1, \ldots, X_n$ are random sample from a sub-Gaussian distribution. They assumed condition (A1) as well as the (stronger) variants of conditions (A2) and (A3): they assumed $\sum_{j=2}^{p} s_{0j} = o(n/\log n)$ (which is stronger than $s_0 \log p \leq nc_3/2$) and $\min_{j:l:a_{0lj} \neq 0} |a_{0lj}|^2 \geq M_n s_0^2 \log n/n$ for some $M_n \to \infty$. Furthermore, they considered only the moderate high-dimensional setting, i.e. $p = O(nc)$ for some constant $c > 0$. They also required the irrepresentable condition similar to those in Yu and Bien (2017).

3.2. Posterior Convergence Rates for Cholesky Factors. In this subsection, we derive the posterior convergence rates for the Cholesky factors in two different scenarios depending on the existence of the beta-min condition (A3). At first, under the beta-min condition, we show the posterior convergence rates and minimax lower bounds with respect to the matrix $\ell_\infty$ norm.
CONVERGENCE RATE AND SELECTION CONSISTENCY FOR DAG MODEL

FIG 1. For a given $0 < \beta < 1$, it describes the range for $s_0$ in which the minimax rate for the Cholesky factor can be obtained. (A3) means the beta-min condition.

and Frobenius norm. The obtained posterior convergence rates are nearly minimax, and become exactly minimax if $\log p = O(s_0)$ and $\log j = O(s_{0j})$ for all $j = 2, \ldots, p$. We also derive the posterior convergence rate and minimax lower bound with respect to the matrix $\ell_\infty$ norm without the beta-min condition. The obtained posterior convergence rate turns out to be nearly minimax, and it will be exactly minimax if $s_0 \leq p^\beta$ for some $0 < \beta < 1$. Note that regardless of the relation between $s_0$ and $p$, at least one of the scenarios achieves the minimax rate. Especially, we attain the minimax rate for both scenarios if $C \log p \leq s_0 \leq p^\beta$ for some constant $C > 0$. Figure 1 describes the range for $s_0$ in which the minimax rate can be obtained.

3.2.1. Posterior Convergence Rates for Cholesky Factors under Beta-min Condition. Define $\hat{A}_n = (\hat{a}_{jl})$, where $(\hat{a}_{jl})_{l \in S_{0j}} = \hat{a}_{S_{0j}}$ and $(\hat{a}_{jl})_{l \in S_{0j}^c} = 0$. Thus, $\hat{A}_n$ is the empirical estimates of $A_{0n}$ with true support $S_{A_{0n}}$. To obtain the posterior convergence rate for the Cholesky factor, we use a divide and conquer strategy that is similar to Lee and Lee (2018, 2017). Specifically, we decompose the posterior contraction probability into two parts as follows:

$$
\pi_\alpha\left(\|A_n - A_{0n}\| \geq 2\epsilon_n' \mid X_n\right) \leq \pi_\alpha\left(\|A_n - \hat{A}_n\| \geq \epsilon_n' \mid X_n\right) + \pi_\alpha\left(\|\hat{A}_n - A_{0n}\| \geq \epsilon_n' \mid X_n\right)
$$

(7)

for some positive sequence $\epsilon_n'$. As in subsection 3.1, we concentrate on a large set $N^c$ allowing us to handle the posterior contraction probability easily. The first part of the right hand side of (7) describes how the posterior distribution concentrates around the empirical estimate $\hat{A}_n$. We use the selection consistency result in Theorem 3.1, and we focus only on the set $S_{A_n} = S_{A_{0n}}$. It enables us to deal with the posterior distribution for $A_n$ easily, but with a cost of the beta-min condition (A3) which is usually not essential for the convergence rate results. Through the posterior distribution (6) given $S_{A_n} = S_{A_{0n}}$, we can obtain the contraction probability for $\|A_n - \hat{A}_n\|$ using the concentration inequality for the chi-square random variables.
By taking expectation to the second part of the right hand side of (7), it gives the contraction probability of $\hat{A}_n$, $P_0[\|\hat{A}_n - A_{0n}\| \geq \epsilon'_n]$.

**Theorem 3.2 (Posterior convergence rates for $A_{0n}$ with beta-min condition).** For given positive constants $0 < \alpha < 1$, $0 < \epsilon_0 < 1/2$, $C_{bm} > c_2 + 2$ and an integer $s_0$, assume that $\Omega_{0n}$ satisfies conditions (A1), (A2) and (A3), i.e. $\Omega_{0n} \in \mathcal{U}_p$. Consider model (1) and the ESC prior (4) with Condition (P). If $s_0 \log p = o(n)$,

$$\sup_{\Omega_{0n} \in \mathcal{U}_p} E_0 \left[ \pi_\alpha(\|A_n - A_{0n}\|_\infty \geq K_{\text{chol}} \sqrt{s_0} \left( \frac{s_0 + \log p}{n} \right)^{1/2} | X_n) \right] = o(1),$$

$$\sup_{\Omega_{0n} \in \mathcal{U}_p} E_0 \left[ \pi_\alpha(\|A_n - A_{0n}\|_F^2 \geq K_{\text{chol}} \sum_{j=2}^{p} (s_{0j} + \log j) \left( \frac{s_0 + \log p}{n} \right) | X_n) \right] = o(1)$$

for some constant $K_{\text{chol}} > 0$.

Khare et al. (2016) obtained the convergence rate $\sum_{j=2}^{p} s_{0j} \lambda_n$ for estimating the Cholesky factor under the spectral norm in a moderately high-dimensional setting, i.e. $p = O(n^c)$ for some constant $c > 0$, where $\lambda_n$ is the tuning parameter in CSCS method. They also assumed condition (A1) as well as the (stronger) variants of conditions (A2) and (A3) as described in section 3.1. Because they assumed $\sqrt{\sum_{j=2}^{p} s_{0j} \log p/n} = o(\lambda_n)$, $\sum_{j=2}^{p} s_{0j} \lambda_n$ is strictly slower than $(\sum_{j=2}^{p} s_{0j})^{3/2} \sqrt{\log p/n}$ in term of the rate, which implies that their convergence rate is slower than the posterior convergence rate obtained in this paper.

In fact, it turns out that the posterior convergence rates in Theorem 3.2 are nearly optimal. Theorem 3.3 describes that the rates of the frequentist minimax lower bounds for the class $\mathcal{U}_p$, which are of independent interests. Note that the rates of Theorem 3.2 are exactly optimal if $\log p = O(s_0)$ and $\log j = O(s_{0j})$ for all $j = 2, \ldots, p$ matching the minimax rates of Theorem 3.3. The key idea for proving the minimax lower bounds is to break down the model (1) into a set of linear regression models.

**Theorem 3.3 (Minimax lower bounds for $A_{0n}$ with beta-min condition).** For given positive constants $0 < \alpha < 1$, $\epsilon_0$, $C_{bm}$ and an integer $s_0$, assume that $\Omega_{0n}$ satisfies conditions (A1), (A2) and (A3), i.e. $\Omega_{0n} \in \mathcal{U}_p$. Consider
CONVERGENCE RATE AND SELECTION CONSISTENCY FOR DAG MODEL

Then,

\[
\inf_{\hat{A}_n} \sup_{\Omega_0 \in U_p} \mathbb{E}_0 \|\hat{A}_n - A_0n\|_\infty \geq c \cdot \frac{s_0}{\sqrt{n}},
\]

\[
\inf_{\hat{A}_n} \sup_{\Omega_0 \in U_p} \mathbb{E}_0 \|\hat{A}_n - A_0n\|_F^2 \geq \frac{\sum_{j=2}^{p} s_0}{n}
\]

for some constant \(c > 0\), where the infimum is taken over all possible estimators \(\hat{A}_n\).

3.2.2. Posterior Convergence Rates for Cholesky Factors without Beta-min Condition. For a given positive constant \(\epsilon_0\) and a sequence of positive integers \(s_0\), we define a class of precision matrices,

\[
U_0^0 = U_0^0(\epsilon_0, s_0) = \left\{ \Omega \in C_p : \Omega \text{ satisfies (A1) and (A2)} \right\}.
\]

Note that in the definition of \(U_0^0\), we do not require the beta-min condition. Theorem 3.4 gives the posterior convergence rate for the class \(U_0^0\). For the Theorem 3.4, we use the ESC prior (4) but let \(d_j \sim IG(\nu_0/2, \nu'_0)\) for some constant \(\nu'_0 > 0\) instead of \(\pi(d_j) \propto d_j^{-\nu_0/2 - 1}\). We call this the modified ESC (MESC) prior. As mentioned before, Theorems 3.1, 3.2 and 3.6 in section 3 also hold for the MESC prior, but we describe Theorems 3.1, 3.2 and 3.6 with the ESC prior for the computational convenience.

We consider the denominator and numerator of the posterior probability \(\pi_\alpha(\|A_n - A_0n\|_\infty \geq \epsilon'_n)\) separately, for some positive sequence \(\epsilon'_n\). For any \(j = 2, \ldots, p\), let \(R_{nj}(a_j, d_j) = L_{nj}(a_j, d_j)/L_{nj}(a_0j, d_0j)\) be the likelihood ratio, where

\[
L_{nj}(a_j, d_j) = (2\pi d_j)^{-n/2} \exp \left\{ -\|\hat{X}_j - \hat{Z}_ja_j\|_2^2/(2d_j) \right\}.
\]

Dealing with the likelihood ratio \(R_{nj}(a_j, d_j)\) is one of the main tasks for proving Theorem 3.4. Lemma 10.1, Lemma 10.2 and Lemma 10.3 in Supplementary Material describe how we can deal with the likelihood ratio \(R_{nj}(a_j, d_j)\) in the denominator and numerator.

**Theorem 3.4 (Posterior convergence rate for \(A_0n\) without beta-min condition).** For a given positive constant \(0 < \alpha < 1\), \(0 < \epsilon_0 < 1/2\) and an integer \(s_0\), assume that \(\Omega_0n\) satisfies conditions (A1) and (A2), i.e. \(\Omega_0n \in U_0^0\). Consider model (1) with the MESC prior with Condition (P). If \(s_0\log p = o(n)\) and \(\nu_0 = O(1)\), then

\[
\sup_{\Omega_0n \in U_0^0} \mathbb{E}_0 \left[ \pi_\alpha(\|A_n - A_0n\|_\infty \geq K'_\text{chol} s_0 \left( \frac{\log p}{n} \right)^{1/2} | X_n \right] = o(1)
\]
for some constant $K'_{\text{chol}} > 0$.

Yu and Bien (2017) obtained the convergence rate
\[
\max_j \|\Sigma_{0n,S_0j}^{-1}\|_\infty \cdot \|A_{0n}\|_\infty s_0 \sqrt{\log p/n} + \max_j \|\Sigma_{0n,S_0j}^{-1}\|_2 s_0^2 \log p/n
\]
for the Cholesky factor with respect to the matrix $\ell_\infty$ norm. As stated before, they assumed condition (A1), the banded Cholesky factor structure (which corresponds to conditions (A2) and (A4) in this paper) and the irrepresentable condition. Note that their convergence rate coincides with ours only if $\|A_{0n}\|_\infty$ and $\max_j \|\Sigma_{0n,S_0j}^{-1}\|_\infty$ are bounded and $s_0^2 \log p = O(n)$.

To the best of our knowledge, it is the first result on the posterior convergence rate for the high-dimensional sparse Cholesky factor without the beta-min condition. Interestingly, the obtained posterior convergence rate is the same with the minimax convergence rate for the $s_0$-sparse coefficient vector in the regression models when $s_0 \leq p^\beta$ for some $0 < \beta < 1$. Note that the condition $s_0 \leq p^\beta$ is not restrictive in the high-dimensional setting, because this condition is met if $n \leq p^\beta$. Theorem 3.5 confirms that the above posterior convergence rate is nearly minimax for any $\Omega_{0n} = \mathcal{U}_p^0$. Similar to Theorem 3.3, the key idea for proving Theorem 3.5 is to break down the model into a set of linear regression models.

**Theorem 3.5** (Minimax lower bound for $A_{0n}$ without beta-min condition). For a given constant $\epsilon_0$ and an integer $s_0$, assume that $\Omega_{0n}$ satisfies conditions (A1) and (A2), i.e. $\Omega_{0n} \in \mathcal{U}_p^0$. Consider model (1). Then,
\[
\inf_{\hat{A}_n} \sup_{\Omega_{0n} \in \mathcal{U}_p^0} \mathbb{E}_{\Omega_0} \|\hat{A}_n - A_{0n}\|_\infty \geq c \cdot s_0 \left( \frac{\log(p/s_0)}{n} \right)^{1/2}
\]
for some constant $c > 0$.

**Remark 3.2.** If we assume $s_0 \leq p^\beta$ for some $0 < \beta < 1$, then $\log(p/s_0)$ has the same rate with $\log p$, and the rate of the minimax lower bound in Theorem 3.5 becomes $s_0 \sqrt{\log p/n}$. This assumption is reasonable in the high-dimensional setting.

### 3.3. Posterior Convergence Rates for Precision Matrices

In this subsection, we derive the posterior convergence rates for the precision matrices with respect to various matrix norms. Define $\hat{\Omega}_n = (I_p - \hat{A}_n)^T \hat{D}_n^{-1} (I_p - \hat{A}_n)$, where $\hat{A}_n$ and $\hat{D}_n = \text{diag}(d_{S_0})$ are the empirical estimates of $A_{0n}$ and $D_{0n}$ with the true support $S_{A_{0n}}$. Similar to the previous subsection, we use the divide and conquer strategy to deal with the posterior probability. For the recovery of $\hat{\Omega}_{0n} = (I_p - A_{0n})^T D_{0n}^{-1} (I_p - A_{0n})$, we further assume condition
CONVERGENCE RATE AND SELECTION CONSISTENCY FOR DAG MODEL

(A4). For given positive constants $\epsilon_0, C_{bm}$ and a sequence of positive integers $s_0$, define the parameter class as follows:

$$U^*_p = U^*_p(\epsilon_0, s_0, \alpha, C_{bm}) = \left\{ \Omega \in C_p : \Omega \text{ satisfies (A1)-(A4)} \right\}.$$ 

Theorem 3.6 shows the posterior convergence rates for the precision matrix with respect to the spectral norm and matrix $\ell_\infty$ norm.

**Theorem 3.6 (Posterior convergence rates for $\Omega_{0n}$).** For given positive constants $0 < \alpha < 1$, $0 < \epsilon_0 < 1/2$, $C_{bm} > c_2 + 2$ and an integer $s_0$, assume that $\Omega_{0n}$ satisfies conditions (A1)-(A4), i.e. $\Omega_{0n} \in U^*_p$. Consider model (1) and the ESC prior (4) with Condition (P) and $\nu_0^2 = O(n \log p)$. If $s_0^{3/2}(s_0 + \log p) = o(n)$, then

$$\sup_{\Omega_{0n} \in U^*_p} \mathbb{E}_0 \left[ \pi_\alpha(\|\Omega_n - \Omega_{0n}\| \geq K_{\text{conv}}s_0^{3/4} \left( \frac{s_0 + \log p}{n} \right)^{1/2} | X_n) \right] = o(1),$$

and, if $s_0(s_0 + \log p) = o(n)$, then

$$\sup_{\Omega_{0n} \in U^*_p} \mathbb{E}_0 \left[ \pi_\alpha(\|\Omega_n - \Omega_{0n}\|_\infty \geq K_{\text{conv}} \cdot \|I_p - A_{0n}\|_\infty s_0 \left( \frac{s_0 + \log p}{n} \right)^{1/2} | X_n) \right] = o(1)$$

for some constant $K_{\text{conv}} > 0$.

It is worthwhile to compare our result to other existing results. Cao, Khare and Ghosh (2017) obtained the posterior convergence rate, $s_0^2 \epsilon_0^{-2} \log p/n$, for the precision matrix with respect to the spectral norm. As discussed in section 3.1, they assumed variants of conditions (A1), (A2) and (A3). They further assumed the condition (A4). Although they did not state clearly that condition (A4) was used, this condition is necessary to use Lemma 3.1 of Xiang, Khare and Ghosh (2015) in their proof. If we assume the bounded eigenvalue condition (A1), their convergence rate becomes $s_0^2 \log p/n$, which is slower than the convergence rate in Theorem 3.6. Note that they assumed $s_0^{2+k} \sqrt{\log p/n} = o(1)$ for some constant $k > 0$, which is stronger than our assumption $s_0^{3/2}(s_0 + \log p) = o(n)$. Thus, we obtain the faster posterior convergence rates under more general condition on the tuple $(n, p, s_0)$ and parameter class, except for the bounded eigenvalue condition.

Yu and Bien (2017) considered the parameter class they used to prove the strong model selection consistency, but dropped the beta-min condition. They derived the convergence rate

$$\max_j \| (\Sigma_{0n}, S_0) \|^{-1} \| D_{0n}^{-1/2} (I_p - A_{0n}) \|_\infty s_0 \left( \frac{\log p}{n} \right)^{1/2}$$
for the precision matrix with respect to the matrix $\ell_\infty$ norm. Note that this convergence rate depends on the rate of $\max_j \| (\Sigma_{0n,S_0j})^{-1} \|_\infty D_{0n}^{-1/2} (I_p - A_{0n}) \|_\infty$. In general, it holds that $\max_j \| (\Sigma_{0n,S_0j})^{-1} \|_\infty = O(s_0^{1/2})$. Thus, their convergence rate is slower than the posterior convergence rate in Theorem 3.6, without a further assumption on $\Sigma_{0n}$ guaranteeing $\max_j \| (\Sigma_{0n,S_0j})^{-1} \|_\infty = O(\sqrt{s_0 / \log p} + 1)$.

4. Numerical Results. The use of the ESC prior not only guarantees optimal or near optimal asymptotic properties but also allows us to conduct the posterior inference easily. In this section, we carry out simulation studies to illustrate the model selection performance of our method. For the comparison, we chose state-of-the-art methods for high-dimensional sparse DAG models and measured the performance of each method. The simulation study confirms that our ESC prior outperforms the other existing methods.

4.1. Metropolis-Hastings Algorithm. Recall that, by (6), the marginal posterior distribution for $S_j \subseteq \{1, \ldots, j-1\}$ can be derived analytically as

$$
\pi_\alpha(S_j \mid X_n) \propto \pi_j(S_j) \left(1 + \frac{\alpha}{\gamma}\right)^{-\frac{|S_j|}{2}} \left(\hat{d}_{S_j}\right)^{-\frac{\alpha + p}{2}}
$$

for all $j = 2, \ldots, p$, up to some normalizing constants. Thus, we can run the Rao-Blackwellized Metropolis-Hastings algorithm for each $j = 2, \ldots, p$ in parallel. Here, we briefly summarize the algorithm used for the inference, where $L$ is the number of posterior samples:

Run the following steps for $j = 2, \ldots, p$.

(a) Set the initial value $S_j^{(1)}$.

(b) For each $l = 2, \ldots, L$,

i. sample $S_j^{new} \sim q(\cdot \mid S_j^{(l-1)})$;

ii. compute the acceptance probability

$$
p_{acc} = \min \left\{ 1, \frac{\pi_\alpha(S_j^{new} \mid X_n) q(S_j^{(l-1)} \mid S_j^{new})}{\pi_\alpha(S_j^{(l-1)} \mid X_n) q(S_j^{new} \mid S_j^{(l-1)})} \right\},
$$

and set $S_j^{(l)} = S_j^{new}$ with probability $p_{acc}$; otherwise, set $S_j^{(l)} = S_j^{(l-1)}$. 

We chose the kernel \( q(S' \mid S) \) which forms a new set \( S' \) by changing a randomly selected nonzero component to 0 with probability 0.5 or by changing a randomly selected zero component to 1 with probability 0.5.

The marginal posterior for \( S_j \) is controlled by the prior \( \pi_j(S_j) \), the penalty term \( (1 + \alpha/\gamma)^{-|S_j|/2} \) and the estimated residual variance \( \hat{d}_{S_j} \). The data favor to minimize the estimated residual while the prior and penalty term give more weight to the simpler models. The marginal posterior of \( S_j \) will find the model that balances data tracking and model complexity.

To use the Metropolis-Hastings algorithm, we need to choose the tuning parameters. Apart from the impact on theoretical results, the choice of tuning parameters also influences the practical performance. As Martin, Mess and Walker (2017) suggested, we set \( \alpha = 0.999 \) to mimic the Bayesian model with the ordinary likelihood. In the simulation study, as long as \( 1 - \alpha \) is close to zero, the performance was not dependent on the choice of \( \alpha \). The hyperparameters were chosen as \( \gamma = 0.1, \nu_0 = 0, c_1 = 0.0005 \) and \( c_2 = 2 \) to satisfy Condition (P).

4.2. Simulation Setting. For the simulation study, we considered the sparse Cholesky settings similar to those used in Khare et al. (2016). We randomly chose 3% or 4% of the lower triangular entries of the Cholesky factor \( A_{0n} \) and sampled their values from a uniform distribution on \([-0.7, -0.3] \cup [0.3, 0.7]\). The remaining entries were set to zero. The entries of the diagonal matrix \( D_{0n} \) were sampled from a uniform distribution on \([2, 5]\). Given the precision matrix \( \Omega_{0n} = (I_p - A_{0n})^T D_{0n}^{-1}(I_p - A_{0n}) \), the data sets were generated from the multivariate normal distribution \( N_p(0, \Omega_{0n}^{-1}) \) with \( (n = 100, p = 300) \) and \( (n = 200, p = 500) \).

4.3. Other Competing Methods. We compared the model selection performance of our method with those of other existing methods: the empirical Bayes (EB) procedure in Martin, Mess and Walker (2017), which we will denote as EB.M, hierarchical DAG-Wishart (DAG-W) prior (Cao, Khare and Ghosh, 2017) and convex sparse Cholesky selection (CSCS) (Khare et al., 2016).

1. (EB.M) : Because EB.M is originally proposed for the regression coefficient estimation, it can be applied independently to estimate each \( a_{0j} \) for \( j = 2, \ldots, p \). We set the hyperparameters \( \alpha, \gamma, c_1 \) and \( c_2 \) to be the same as those in our setting for a fair comparison. Note that Martin, Mess and Walker (2017) used \( \gamma = 0.001, c_1 = 1 \) and \( c_2 = 0.05 \) in their simulation study, but in our simulations, these choices did not yield better results: they tended to make unacceptably large FDR values.
The key difference between our method and EB.M is on how to infer the diagonal matrix $D_n$. Martin, Mess and Walker (2017) suggested plugging in the cross-validation based Lasso residual sum of squares estimate (Reid, Tibshirani and Friedman, 2016) of $d_{0j}$, while we impose a prior on $d_j$ and integrate it out to obtain the marginal posterior for $S_j$. Thus, EB.M ignores the uncertainty of $d_j$ and replaces it with a plug-in estimate.

2. (DAG-W) : The hierarchical DAG-Wishart prior (Cao, Khare and Ghosh, 2017) enables one to calculate the marginal posterior for the DAG analytically. Note that, in Cao, Khare and Ghosh (2017), they conducted log-posterior score search algorithm instead of Markov chain Monte Carlo (MCMC) algorithm. Basically, they generated sets of candidate graphs by using frequentist approaches and thresholding the modified Cholesky factor of $(n^{-1}X_n^T X_n + 0.5I_p)^{-1}$, and the graph which maximizes the log-posterior was chosen as the final estimate. In our simulation study, we implemented the log-posterior score search algorithm as well as Metropolis-Hastings algorithm, using the marginal posterior for the DAG, for a comprehensive comparison. For the implementation, we set the shape parameters at $\alpha_j(D) = S_j + 10$ and the scale matrix at $U_n = I_p$ as they suggested, where $D$ is the DAG corresponding to $\{S_j\}_{j=2}^p$. The critical part is the choice of the hyper-parameter $q_n$, which is the individual edge probability. It was shown that the choice of $q_n = e^{-\eta_n n}$ leads to strong model selection consistency, where $\eta_n = s_0 (\log p/n)^{1/(2+k)}$ for some $k > 0$. Thus, the theoretical choice of $q_n$ depends on the unknown parameter $s_0$ and constant $k > 0$. Furthermore, even with $s_0 = 1$ and $k = 0$, the resulting $q_n$ is too small, which does not allow the posterior to explore the model space efficiently. We observed that the choice $q_n = e^{-\eta_n n}$ makes the posterior stuck in very small size models and not able to detect the true model. For example, for the setting $(n = 100, p = 300)$ with the sparsity 3%, the corresponding posterior with $q_n = e^{-\eta_n n}$ concluded that the true Cholesky factor is a zero matrix, i.e. it never selected any nonzero variable. Thus, in our simulation study, we conducted the simulation only for two choices, $q_n = 0.01$ and $q_n = 0.001$, although they might not guarantee the strong model selection consistency. For the log-posterior score search, we chose $q_n = e^{-\eta_n n}$ as in Cao, Khare and Ghosh (2017).

3. (CSCS) : We chose the CSCS method (Khare et al., 2016) as a state-of-the-art frequentist competitor. The tuning parameter $\lambda_n$ in the CSCS method was selected by the Bayesian Information Criterion (BIC)-like
measure which is defined in section 2.3 of Khare et al. (2016). We calculated the values of BIC-like measure for $\lambda_n$ from 0.1 to 5.1 with an increment of 0.1. The value of $\lambda_n$ minimizing the BIC-like measure was chosen for the estimation.

4.4. Results. We ran the Metropolis-Hastings algorithm for each data set to conduct posterior inferences. Every MCMC chain ran for 24,000 iterations with a burn-in period of 4,000, so we obtained 20,000 posterior samples. We used the models selected by the CSCS method as the initial states for MCMC chains. We constructed the final model by collecting indices with inclusion probabilities, $\pi(a_{jl} \neq 0 \mid X_n)$, exceeding 0.5.

To measure the model selection performance, the number of errors, false discovery rate (FDR), true positive rate (TPR) and inclusion probabilities were reported. We calculated the mean inclusion probability for zero entries in $A_{0n}$ and denote it by $\bar{p}\_0$. Similarly, the mean inclusion probability for nonzero entries in $A_{0n}$ is denoted by $\bar{p}\_1$. More specifically, we calculated

$$\bar{p}_0 = \frac{1}{\sum_{j=2}^{p} (j - 1 - s_{0j})} \sum_{j=2}^{p} \sum_{l \notin S_{0j}} \pi(a_{jl} \neq 0 \mid X_n),$$

$$\bar{p}_1 = \frac{1}{\sum_{j=2}^{p} s_{0j}} \sum_{j=2}^{p} \sum_{l \in S_{0j}} \pi(a_{jl} \neq 0 \mid X_n).$$

The simulation results are summarized in Table 1. The ESC prior performs generally better than the other competing methods. The EB.M works reasonably well, but the overall performance is worse than that of ESC prior. The DAG-Wishart prior tends to have low TPR and mean inclusion probability $\bar{p}_1$ when $q_n = 0.001$. Note that when $q_n = 0.01$, which is chosen to be close to the unknown true sparsity level, the DAG-Wishart prior performs reasonably well, but the ESC prior still works better. However, the true sparsity is in general unknown, so fitting $q_n$ close to the true sparsity is a challenging task in practice. The log-posterior score search algorithm for DAG-Wishart is computationally efficient even for large $p$, but tends to have low FDR as well as TPR in our settings. The CSCS method has high TPR values, but at the same time, it has high FDR values. Thus, from the simulation study, we confirm that our ESC prior not only has nice theoretical properties but also practically outperforms the other existing methods.

5. Acknowledgement. We thank Ryan Martin for helpful discussions about the techniques for proving selection consistency. We would like to

Table 1
ESC, EB.M, DAG-W and CSCS denote our method (empirical sparse Cholesky prior), the empirical Bayes procedure proposed by Martin et al. (2017), the hierarchical Bayesian model using DAG-Wishart prior (Cao et al., 2016) and Convex Sparse Cholesky Selection (Khare et al., 2016), respectively. Sp: sparsity; FDR: false discovery rate; TPR: true positive rate; $\bar{p}_0$: the mean inclusion probability for zero entries in $A_{0n}$; $\bar{p}_1$: the mean inclusion probability for nonzero entries in $A_{0n}$.
