Abstract

A finite-element approach based on the first-order FE\textsuperscript{2} homogenisation technique is formulated to analyse the alkali-silica reaction-induced damage in concrete structures, by linking the concrete degradation at the macro-scale to the reaction extent at the meso-scale. At the meso-scale level, concrete is considered as a heterogeneous material consisting of aggregates embedded in a mortar matrix. The mechanical effects of the Alkali-Silica Reaction (ASR) are modelled through the application of temperature-dependent eigenstrains in several localised spots inside the aggregates, and the mechanical degradation of concrete is modelled using continuous damage model, which is capable of reproducing the complex ASR crack networks. Then, the effective stiffness tensor and the effective stress tensor for each macroscopic finite element are computed by homogenising the mechanical response of the corresponding representative volume element (RVE), thus avoiding the use of phenomenological constitutive laws at the macro-scale. Convergence between macro- and meso-scales is achieved via an iterative procedure. A 2D model of an ASR laboratory specimen is analysed as a proof of concept. The model is able to account for the loading applied at the macro-scale and the ASR-product expansion at the meso-scale. The results demonstrate that the macroscopic stress state influences the orientation of damage inside the underlying RVEs. The effective stiffness becomes anisotropic in cases where damage is aligned inside the RVE.

1. Introduction

The alkali-silica reaction (ASR) is the most common type of alkali-aggregate reaction, which is the generic term for reactions between the alkaline concrete pore solution and certain mineral phases within the aggregates. At the scale of the aggregates and cement paste, ASR manifests itself in the form of local silica dissolution, growth of micro-cracks, their filling with the ASR products, and the overall expansion of aggregates and eventually paste. Micro-cracks are homogeneously distributed within the mesostructure. Their orientation shows dependence on the stress state [Dunant and Scrivener 2012a]; typical crack patterns vary from randomly oriented to echelons of co-directional cracks. Damage development results in a loss of stiffness and tensile strength (see Fig. [1]). The nature of the ASR expansion is subject of debating. Significant alkali-aggregate expansions are only observed, when the relative humidity exceeds 80% [Stark 1991]. The most popular hypothesis regarding the expansion of concrete is swelling of the ASR product after water absorption [Swamy 1992]. The problem is further complicated by the presence of two types of ASR product: amorphous and crystalline. Shi and co-workers [Shi et al. 2019] recently showed that the synthesised crystalline ASR product has relatively low water uptake capacity, thereby reducing swelling to negligible amounts.

Figure 1: Stages of concrete damaging due to ASR: (a)alkalis from cement paste diffuse into aggregates and react with amorphous silica; (b) resulting ASR products exert internal pressure on aggregates; (c) tensile cracking advance into aggregates and cement paste.

In order to study the physical correlation between the gel formation and cracking, several meso- and micro-scale models have been developed [Bazant and Zi 2000, Multon et al. 2009, Comby-Peyrot et al. 2009, Alnaggar et al. 2013, Esposito and]
These models have proven to be useful in the analysis of laboratory experiments of ASR, because a systematic variation of single input parameters is possible. Since ASR is most commonly detected in large concrete structures exposed to water, such as sea walls, bridge piers and dams, several macro-models that can address the consequences of ASR directly at the structural scale of concrete have also been proposed. These models aim at predicting when and how an affected structure should be repaired. Such predictions are important in order to avoid a significant reduction in service life of the structure and hence help alleviate the economical effects of ASR. In macro-scale models, concrete is considered as a homogeneous material and the underlying mesostructure consisting of aggregates and the cement paste is not resolved. This simplified material description is necessary because an explicit representation of the aggregates and the cement paste at this scale would yield to computational models of unacceptable size.

One large subgroup of these macro-scale models is based on a phenomenological approach [Larive, 1998, Capra and Bournazel, 1998, Ulm et al., 2000, Saouma and Perotti, 2006, Martin et al., 2012, Omikrine Metalssi et al., 2014, etc.]. These models compute directly the macroscopic ASR strain by extrapolating results from laboratory experimental measurements to field conditions. Phenomenological models require extensive experimental studies to determine all the input parameters needed for the simulations.

Another group of macro-scale ASR models incorporates poromechanics, in which concrete is considered as a solid skeleton permeated by open porosity [Capra and Sellier, 2003, Bangert et al., 2004, Comi et al., 2009, Grimal et al., 2010, Pignatelli et al., 2013, Multon and Sellier, 2016, Esposito and Hendriks, 2016, etc.]. Constitutive laws for macro-scale simulations are derived from homogenisation principles. The ASR-induced damage is typically assumed to be isotropic. The solid phase does not distinguish between aggregates and cement paste, which causes a uniform damage distribution inside the concrete skeleton.

Recently, due to the advancement of high-performance computing, the first numerical multi-scale models have been proposed for ASR [Puatatsananon and Saouma, 2013, Wu et al., 2014, Rezakhani et al., 2019]. These models couple numerical computations at the micro- and meso-scales in a single simulation. The multi-scale approach is advantageous because the consequences of ASR at a larger scale can be computed.
directly from the reaction advancement inside an underlying representative volume element (RVE). The RVE represents the heterogeneous structure of concrete at a smaller length scale.

In order to study the consequences of ASR in large structures such as concrete dams, multi-scale models that establish a link between the meso- and the macro-scale are required. The development of such a multi-scale model for concrete with slow-reacting aggregates, i.e. aggregates with a non-uniform amorphous silica distribution, is the objective of the present work. In the course of this study, special attention is paid to the development of a realistic material constitutive behaviour allowing for the crack growth, opening and closure.

The remainder of the paper is organised as follows: in Section 2 the novel ASR multi-scale model is described in detail, including parallel implementation. Section 3 introduces the constitutive law used at the meso-scale. Calibration of the proposed meso-scale model is described in Section 4. Subsequently, in Section 5 the multi-scale model is applied to study the mechanical consequences of ASR in a 2D cross-section of laboratory concrete specimens in order to verify the method and to highlight the capabilities of the proposed approach. We discuss how the orientation of damage inside the RVE and the anisotropy of the effective stiffness at the macro-scale are a natural consequence of the interaction between the meso- and the macro-scale.

2. The ASR multi-scale model

Our objective is the modelling of ASR at the macro-scale by incorporating the results of meso-scale simulations. Compared to a purely phenomenological model, this approach has the advantage that the material behaviour at the macro-scale is based on the underlying physical processes. In this work, we use a first-order FE2 homogenisation scheme to couple the macro- and the meso-scale. This method consists of two coupled finite element (FE) problems, one for the macro- and the other for the micro-scale, i.e. the scale of the underlying RVE, which determines the effective material behaviour. Note that in this work, the micro-scale of the FE2 problem is the meso-scale of concrete. In the remainder of this article, the terms meso-scale and micro-scale are, thus, used interchangeably. The FE2 method is based on the principle of separation of scales, which has been formulated as "The microscopic length scale is assumed to be much smaller than the characteristic length over which the macroscopic loading varies"
in space” by Geers et al. [2010]. This assumption is valid for the multi-scale modelling of ASR, since large concrete structures have several tens of meters of width and height, and the meso-scale RVE is in the centimetre range. The concept of a first-order FE² homogenisation scheme for small deformations is illustrated in Fig. 2.

![Figure 2: Schematic illustration of the numerical homogenisation scheme for ASR simulations. Every macroscopic computational point is coupled to an underlying RVE. The boundary conditions for the RVE are defined through the macroscopic deformation gradient $F_M$. Macroscopic temperature $T_M$ is passed to the meso-scale for predicting the ASR product expansion rate. After solving the RVE problem, the macroscopic stress $\sigma_M$ and the effective stiffness tensor $C_M$ are computed.](image)

Note that in the following, the subscripts $M$ and $m$ will be used to denote physical quantities at the macro- and the micro-scale, respectively. For instance, $\sigma_M$ is the macroscopic stress for which the microscopic counterpart is $\sigma_m$. Every Gauss integration point of the macro-scale FE problem is coupled to a meso-structural RVE of concrete. Quasi-static conditions are assumed at both scales because the advancement of ASR is slow. The two scales are coupled through the macroscopic deformation gradient $F_M$, the effective stiffness tensor $C_M$, and the macroscopic stress $\sigma_M$. The boundary conditions of the meso-scale boundary value problem (BVP) are a function of $F_M$. The BVP is solved for the given boundary conditions, and the effective stiffness
tensor $C_M$ and the homogenised mesoscopic stress $\sigma_M$ are then computed and passed back to the macro-scale. The balance between the internal and external forces at the macro-scale is verified. In the case of imbalance, the whole procedure is repeated in the next iteration. As a convergence criterion, we use the norm of the difference between the internal and external forces, also known as residual.

In the course of ASR development within RVEs, cracks may coalesce and therefore violate the separation of scales’ principle. The strain localisation limits the concept of homogenisation [Coenen et al., 2012]. We test the validity of homogenisation for a problem where cracks are homogeneously distributed over the micro-scale volume. The following major developments are called to extend the applicability of the classical homogenisation concept to the ASR case:

- A realistic constitutive model of concrete. The material model adopted in this study is the continuous orthotropic damage with stiffness recovery upon crack closure, which will be described in Section 3.
- A robust stiffness homogenisation procedure. This measure is called to overcome the ill-posedness of the macro-scale boundary value problem. This is done by an adaptive homogenisation of stiffness either by tension or by compression tests, which produce a non-singular stiffness tensor. The resulting tensors are better suited for the macroscopic stress state, which also improves the convergence rate of the iterative scheme. The homogenisation procedure is described in Subsection 2.4.

One distinctive feature of the current model is the fact that the external loading is not only coming from the macro-scale, but also from the micro-scale in the form of expanding ASR product. The interplay between these two load scales is interesting both from the physical and the numerical point of view.

2.1. Macro-scale problem

Let $\Omega_M$ denote a body of ASR-affected concrete at the macro-scale. The domain is bounded by $\Gamma_M$, which can be decomposed into the Neumann boundary $\Gamma_{M,\nu}$ and the Dirichlet boundary $\Gamma_{M,\sigma}$, such that the following definitions hold:

\[ \Gamma_M = \Gamma_{M,\nu} \cup \Gamma_{M,\sigma}, \]
\[ \Gamma_{M,\sigma} \cap \Gamma_{M,\nu} = \emptyset. \]
The principle of virtual work reads as:

$$\delta W_M = \int_{\Omega_M} \sigma_M : \delta \varepsilon_M \, d\Omega - \int_{\Omega_M} b_M \cdot \delta u_M \, d\Omega - \int_{\Gamma_M} t_M \cdot \delta u_M \, d\Gamma = 0,$$

(3)

where $\delta W_M$, $b_M$ and $t_M$ denote the macroscopic virtual work, macroscopic body force and macroscopic traction, and $\delta \varepsilon_M$ and $\delta u_M$ the macroscopic virtual strain and macroscopic virtual displacement. No assumptions are introduced regarding $\sigma_M$. Instead, it is obtained directly from the micro-scale computations as explained in Subsections 2.4 and 2.5.

2.2. Macro-to-micro transition

The microscopic displacement field inside the RVE can be decomposed into two parts:

$$u_m(x) = u_M + \hat{u}(x),$$

(4)

where $\hat{u}(x)$ are micro-fluctuations. The current macroscopic state enters the RVE computations via the boundary conditions. In this work periodic boundary conditions are chosen because they give better estimates for the effective stiffness in comparison with the uniform displacement or uniform traction boundary conditions [Coenen et al., 2012]. The periodic boundary conditions are defined as follows:

$$u_{m,i} = (F_M - 1)x_{m,i} \quad \text{for } i = 1, 2, 3, 4$$

(5a)

$$u_{\Gamma_{m,12}} = u_{\Gamma_{m,12}} + u_{m,4} - u_{m,1}$$

(5b)

$$u_{\Gamma_{m,23}} = u_{\Gamma_{m,14}} + u_{m,2} - u_{m,1}$$

(5c)

where $F_M$ denotes the deformation gradient at the corresponding macroscopic material point, $u_{m,i}$ is the displacement of the corner node $i$, and $\Gamma_{m,12}$, $\Gamma_{m,23}$, $\Gamma_{m,34}$ and $\Gamma_{m,14}$ are the boundaries of the RVE (see Fig. 3). While the terms $[u_{m,4} - u_{m,1}]$ and $[u_{m,2} - u_{m,1}]$ represent the macroscopic component of displacement, $u_{\Gamma_{m,12}}$ and $u_{\Gamma_{m,14}}$ are the periodic micro-fluctuations at the boundary pairs ($\Gamma_{m,12}$ and $\Gamma_{m,34}$) and ($\Gamma_{m,14}$ and $\Gamma_{m,23}$), correspondingly.

2.3. ASR meso-scale problem

The ASR meso-scale model presented here is purely mechanical. The hydration and diffusion processes, which govern the evolution of the chemical reaction, are not
modelled. The effect of temperature is taken into account through the ASR-product expansion law, which is discussed further. In the following, we summarise the basic equations and assumptions constituting the ASR meso-scale model.

We now consider the two-dimensional domain $\Omega_m$ with closure $\Gamma_m$, which represents an ASR-affected RVE as shown in Fig. 3. Three mutually exclusive phases constitute $\Omega_m$: the mortar $\Omega_{m,C}$, which includes the cement paste and the sand, the aggregates $\Omega_{m,A}$, and the ASR sites $\Omega_{m,G}$. An isotropic eigenstrain field $\varepsilon_{m,eig}$ is imposed at each ASR site to account for the expansion. The eigenstrain is linked to the elastic strain $\varepsilon_{m,el}$ via the following equation:

$$\varepsilon_m = \varepsilon_{m,el} + \varepsilon_{m,eig},$$  \hspace{1cm} (6)$$

where $\varepsilon_m$ is the infinitesimal strain tensor $\varepsilon_m = \nabla \mathbf{u}_m = \frac{1}{2} \left( \nabla \mathbf{u}_m + \nabla \mathbf{u}_m^T \right)$. Note that the Cauchy stress $\sigma_m$ depends only on the elastic part of the strain, i.e. $\sigma_m = \sigma_m(\varepsilon_{m,el})$.

The volume increase of the ASR product is approximated by increasing the imposed eigenstrain in every step of the simulation. In this study, we assume that the strain imposed to an ASR site $\varepsilon_{m,eig}$ is proportional to the total amount of the generated ASR product which in turn is proportional to the chemical reaction extent $\xi$. Dependence of alkali-silica reaction kinetics on the temperature and the relative humidity was experimentally studied by Larive [1998]. A first-order kinetic law in isothermal conditions results in the explicit equation for the chemical reaction extent $\xi$:

$$\xi(t, T) = \frac{1 - \exp[-t/\tau_{ch}(T)]}{1 + \exp[-t/\tau_{ch}(T) + \tau_{lat}(T)/\tau_{ch}(T)]},$$  \hspace{1cm} (7)$$

8
where $t$ and $T$ are the current time and temperature, and $\tau_{lat}$ and $\tau_{ch}$ are latency and characteristic times respectively. Therefore, the ASR expansion law reads:

$$
\varepsilon_{\text{eig}}(t, T) = \varepsilon(\infty) \left( 1 - \frac{\exp[-t/\tau_{ch}(T)]}{1 + \exp[-t/\tau_{ch}(T) + \tau_{lat}(T)/\tau_{ch}(T) \times I]} \right),
$$

where $I$ is the identity matrix and $\varepsilon(\infty)$ is the asymptotic volumetric expansion strain in the stress-free experiment [Larive, 1998, Ulm et al., 2000]. The latency time $\tau_{lat}$, the characteristic time $\tau_{ch}$ and the asymptotic strain $\varepsilon(\infty)$ are the calibration parameters of the model. Given a homogeneous temperature of a specimen, the proposed law results in the same expansion values at all ASR sites.

Quasi-static conditions are assumed because the ASR degradation process is slow and hence the expression for the virtual work is obtained:

$$
\delta W_m = \int_{\Omega_m} C_m \left( \varepsilon_m - \varepsilon_{m,eig} \right) : \varepsilon_m \, d\Omega - \int_{\Omega_m} b_m \delta u_m \, d\Omega - \int_{\Gamma_m} t_m \delta u_m \, d\Gamma = 0,
$$

In this ASR meso-scale model the aggregates and the mortar are assumed to be quasi-brittle materials and the ASR product is modelled as linear elastic. Its expansion causes high stresses in the surrounding material. Compressive and tensile stresses are acting in radial and tangential direction respectively, as illustrated in Fig. 4. Because the tensile strength of the aggregates and the mortar is significantly lower than their compressive strength, it is valid to assume that the material fails locally always under tension with subsequent linear softening. The failure criterion and the constitutive law are depicted in Fig. 5. Material behaviour at the meso-scale is detailed in Section 3.

The computation of failure in brittle and quasi-brittle materials by means of the classical non-linear finite element method is often prone to numerical instabilities.
In particular, for problems characterised by the simultaneous propagation of multiple cracks, as in the case of ASR, the solution of the system is likely to diverge and hence a completely different approach becomes necessary. Cuba Ramos et al. [2018] have shown that the use of the sequentially linear analysis (SLA, Rots [2001], Rots and Invernizzi [2004], DeJong et al. [2008], Rots et al. [2008]), allows to capture the complex crack networks inside the aggregates and the mortar. The idea of this method is to choose the load increments in such a way that for each imposed load increment, exactly one integration point undergoes softening and all other integration points remain below their failure criterion. The development of this method has been inspired by lattice models, in which the continuum is replaced by a lattice of beams. In lattice models, divergence problems do not occur because the solution is obtained from a sequence of linear analyses. In every step of the analysis, the beam with the highest load is detected and subsequently removed. The SLA transfers this approach to the continuum modelling. Consequently, in every step, the integration point with the highest load is detected, and if the damage criterion is satisfied, the stiffness and strength at this integration point are reduced according to the current damage value $d_i$, which is defined as

$$d_i = 1 - \frac{1}{a^i},$$  

where the empirical reduction constant $a$, is brought to the power $i$, which is the number of the reduction step. In the following simulations, $a = 2$ and $i = 10$. After reach-
ing this limit, the damage is brought to its maximum value (0.9999 in this case) and its update is stopped. Having a non-unity value of the maximum damage is necessary to avoid the stiffness matrix singularity. After each damaging event, the mechanical properties referred to the damaged integration point are updated as follows:

\[
E_i = E(1 - d_i), \quad v_i = v(1 - d_i), \quad \mu_i = \mu(1 - d_i),
\]

where the index denotes the reduction step. The tensile strength is reduced as

\[
f_{ij} = \varepsilon_u E_i \frac{E_i}{E_i + E_t}.
\]

with

\[
E_t = \frac{f_t}{\varepsilon_u - (f_t/E_t)}.
\]

Due to the discrete reduction of stiffness and strength, the stress-strain curve obtained with the SLA differs from the original softening curve, as illustrated in Fig. 6a. In order to ensure that the dissipated energy equals the theoretical value, different regularisation techniques can be applied [Rots and Invernizzi, 2004]. In this work, the combined regularisation technique, where the tensile strength \(f_t\) and the ultimate strain \(\varepsilon_u\) are simultaneously adjusted, is chosen and the resulting stress-strain curve is shown in Fig. 6b. Details on this technique can also be found in [Cuba Ramos et al., 2018]. Compared to lattice models, the advantage of the SLA is that the concept of strength, elasticity and fracture energy remain meaningful at the macro-scale. Because the use of the tangent stiffness is avoided in the SLA, numerical instabilities do not arise and,
during the analysis, the equilibrium path of the material degradation is always followed. Another advantage is that due to the controlled increase of damage, jumps over the structural response do not occur. However, the major drawback of this method is its high computational cost. This cost results from the fact that integration points cannot be damaged simultaneously and a new solution has to be computed after each damage event. Consequently, the total number of computations of solutions is significantly larger than in a non-linear finite element approach. A more detailed description of the application of SLA to the meso-scale ASR problem can be found in Cuba Ramos [2017].

2.4. Micro-to-macro transition

The stress distribution inside the RVE is obtained through the solution of the meso-scale boundary value problem. For the macro-scale, the average stress response of the RVE needs to be determined. This can be done using the Hill-Mandel macro-homogeneity condition [Hill, 1963]

\[
\frac{1}{\Omega_m} \int_{\Omega_m} \sigma_m : \varepsilon_m \, d\Omega_m = \sigma_M : \varepsilon_M. \tag{14}
\]

Note that \(\sigma_m\) and \(\varepsilon_m\) are coupled to their macroscopic counterparts via the following equations:

\[
\sigma_m = \sigma_M + \hat{\sigma}, \tag{15}
\]
\[
\varepsilon_m = \varepsilon_M + \hat{\varepsilon}. \tag{16}
\]

where \(\hat{\sigma}\) and \(\hat{\varepsilon}\) are the micro-fluctuations of the stress and the strain fields, respectively. The Hill-Mandel macro-homogeneity condition implies that the work of the stress fluctuations \(\hat{\sigma}\) on the strain fluctuations \(\hat{\varepsilon}\) vanishes, i.e.

\[
\frac{1}{\Omega_m} \int_{\Omega_m} \hat{\sigma} : \hat{\varepsilon} \, d\Omega_m = 0. \tag{17}
\]

Therefore, \(\hat{\sigma}\) and \(\hat{\varepsilon}\) must be orthogonal to each other. The macroscopic stress can be expressed in terms of traction along the boundaries of the RVE:

\[
\sigma_M = \int_{\Gamma_m} t_m \otimes x_m \, d\Gamma_m. \tag{18}
\]

It was shown in Suquet [1985] that the boundary conditions presented in Subsection 2.2 fulfill the Hill-Mandel condition and yield equivalence between the macroscopic stress
and volume average of the microscopic stresses inside the RVE:

$$\sigma_M = \int_{\Gamma_m} t_m \otimes x_m \, d\Gamma_m = \frac{1}{\Omega_m} \int_{\Omega_m} \sigma_m \, d\Omega_m.$$  \hfill (19)

The above equation is used for the stress homogenisation at the meso-scale.

For the macroscale analysis, a tangent stiffness tensor is required at each integration point. The effective stiffness tensor is defined by the effective stress-strain relation

$$\sigma_M = C_M \varepsilon_M.$$  \hfill (20)

Both, $\sigma_M$ and $\varepsilon_M$ are symmetric second-order tensors with three independent components in 2D. There are multiple methods of stiffness homogenisation available in the literature. The one proposed by Kouznetsova et al. [2001] comprises rearrangement of the full RVE stiffness tensor and its condensation with the help of position vectors of the fixed corner nodes. Miehe [1996] has suggested a method based on a forward difference approximation. In the present work, we adopt the virtual tests approach, the mathematical formulation of which is thoroughly described by Fritzen [2011]. In the scope of this method, the results of three virtual loading tests, linearly independent from each other, are required to determine the symmetric fourth-order tensor $C_M$.

For a specimen with isotropic stiffness reduction in cracks and no contact upon their closure, tensile and compressive loading tests would result in the same tensor $C_M$. However, a material with orthotropic damage and stiffness recovery will behave differently under tension than under compression. While pulling a specimen would only open the cracks perpendicular to the load, its compression will close them and cause stresses in the bulk. This is however a simplification of a problem. In reality, cracks could be oriented in different directions, and the opening of one crack could be accompanied by the closure of another. That is why even the tensile test of an orthotropic material with contact is expected to produce a higher stiffness than the similar test of an isotropic material without contact. In general, stiffness obtained via compression is higher than the one computed by tension. The effect of the test type on the stiffness reduction is demonstrated in Section 4.

Since the homogenised stiffness is used to solve the macro-scale problem for displacements, the better it approximates the stiffness of the meso-scale structure, the faster the multi-scale scheme converges. Providing low tensile stiffness for an element which undergoes compression would result in an underestimation of its stress level and thus a slow convergence of the iterative scheme. Similarly, providing high compressive
stiffness for the stretched element will result in the same issue. In order to avoid this nonconformity, the direction of the stiffness homogenisation tests is decided based on the homogenised stress value. For this, the hydrostatic part is extracted from the averaged microscopic RVE stresses, and its value is used to judge on the stress state of the macroscopic element. If the hydrostatic stress is positive, then two uniaxial tensile tests are done, if it is negative - two compression tests. The uniaxial tests are performed in the horizontal and vertical direction. Additionally to the uniaxial tests, one pure shear test is done.

2.5. Nested multi-scale approach

As discussed in Subsection 2.2, the boundary conditions for the RVEs are prescribed in terms of the macroscopic deformation gradient. The macroscopic displacements, however, are not known a priori and depend on the deformation process inside the RVEs. In the multi-scale approach adopted here, deformation-driven iterative procedures are applied, where an initial macroscopic deformation is imposed and a series of solve steps are performed until reaching convergence. Subsequently, both the macroscopic and mesoscopic loads can be incremented, and the next iteration starts.

The homogenised microscopic stress passed to the macro-scale serves both to judge on the convergence of iterations and also to update the displacements at the macro-scale. The overall macroscopic stiffness tensor, composed of the homogenised stiffness tensors of the underlying RVEs, is used at the macro-scale to compute the increment of displacements. The algorithm for the current multi-scale implementation, executed
by every processor, is detailed in Algorithm 1.

**Algorithm 1: Multi-scale algorithm for ASR-affected concrete**

```plaintext
for every integration point at the macro-scale do
  Generate an RVE;
for every time step i do
  Apply boundary conditions at the macro-scale;
  for every RVE do

```

2.6. Parallel implementation

The current ASR multi-scale model was implemented into the open-source finite-element library Akantu [Computational Solid Mechanics Laboratory at Ecole Polytechnique Federale de Lausanne 2016, Richart and Molinari 2015, Cuba Ramos 2017]. The coding developments were carried out under the premise that the meso-scale computations for a single RVE are executed in serial. Therefore, the FE meshes of the RVEs must be small in size. This is the case for two-dimensional numerical concrete samples,
3. Material behaviour at the meso-scale

It was previously reported that models with isotropic damage law without stiffness recovery in compression fail to reproduce loaded ASR experiments [Dunant and Scriven 2012b]. Because the final goal of this study is to model a macro-structure with a mainly compressive stress state, such a capacity is crucial. For that reason, we have adopted the fixed crack concept with stiffness recovery upon crack closure [Blaauwendraad 1989]. In this approach one models continuum as an elastic-brittle orthotropic material with elastic properties degraded in a single direction. This direction is chosen at the first damaging event and kept fixed for the rest of the simulation (see Fig. 8). When a previously opened crack closes, it can again transmit stresses in the perpendicular direction. This capacity is important for complex stress states that develop in time. The direction of the crack is decided based on the principal stress
Figure 8: Fixed crack model. Orientation axes of a crack $n_1$ and $n_2$ are turned with respect to the global coordinate system by an angle $\alpha$.

criteria:

$$\sigma_i \leq f_t, \text{ with } i = 1, 2, 3,$$

where $\sigma_i$ is the $i$th principal stress. If the stress $\sigma_i$ at any integration point violates Eq. [21], the plane perpendicular to the direction of $\sigma_i$ becomes the crack plane.

Having a single crack passing through an element allows a simple energy accounting, in a way proposed by Bazant and Oh [1983]. The essence of this model is to smear out existing micro-cracks over the fracture process zone of width $w_c$, taken equal to the average element size. The area under the stress-strain curve in Fig. [5] equals the fracture energy $G_c$ divided by the crack band width $w_c$:

$$\frac{G_c}{w_c} = \int_0^{\infty} \sigma \, d\epsilon' = \frac{1}{2} f_t^2 \left( \frac{1}{E} - \frac{1}{E_t} \right),$$

where $\epsilon'$ is the fracturing strain, $E$ is the initial material stiffness in the direction perpendicular to the crack, $E_t$ is the tangent to the tensile stress-strain softening curve. In all meso-scale simulations, the crack band width, $w_c$, is taken equal to the element size of 0.5 mm. The ultimate strain $\epsilon_u$ becomes a function of the fracture energy, the crack band width, and the material strength in tension $f_t$:

$$\epsilon_u = \frac{2G_c}{w_c f_t}. \quad (23)$$

The stress-strain relation for the orthotropic material in a compact matrix form is

$$\sigma = C(\epsilon - \alpha \Delta T), \quad (24)$$

with $C$ being the stiffness matrix in the coordinate system associated with the global problem, $\alpha$, and $\Delta T$ the temperature increase. Multiple works studied thermal stress
in the vicinity of a crack [Kit et al., 1977, Atkinson and Clements, 1977, Da Yu Tzou, 1990]. Among other findings, they have shown that the temperature gradient can cause crack propagation. Factors that play a role in this process include material properties, boundary conditions (both mechanical and thermal), crack shape, its dimension and the level of insulation. Considering the complexity of the problem, its finer scale and the lack of knowledge of material and crack properties, currently, we ignore the thermo-mechanical aspects of crack growth and discard the second term on the rhs of Eq. 24. This is however a simplification that should be addressed in future work.

An orthotropic material has three perpendicular symmetry planes. Basis vectors of this material are perpendicular to the symmetry planes. These vectors could differ from the basis vectors of the global coordinate system. In such a case, the transformation from the coordinate system associated with the material symmetry planes to the global coordinate system in matrix form can be expressed as

\[
C = Q \cdot C^{(p)} \cdot Q^T,
\]

where \(Q\) is the transformation matrix and \(C^{(p)}\) is the orthotropic stiffness matrix in the direction of the basis vectors. In the scope of the crack model, matrix \(Q\) accounts for the angle \(\alpha\) between the global coordinate system and the crack plane shown in Fig. 8. The stiffness matrix takes the form [Bower, 2009]:

\[
C^{(p)} = \begin{bmatrix}
    c_{11} & c_{12} & c_{13} & 0 & 0 & 0 \\
    c_{22} & c_{23} & 0 & 0 & 0 & 0 \\
    c_{33} & 0 & 0 & 0 \\
    \text{sym} & c_{44} & 0 & 0 & 0 \\
    c_{55} & 0 \\
    c_{66}
\end{bmatrix},
\]

(26)

Its components are related to the elastic constants:

\[
c_{11} = E_1(1 - \nu_{23}\nu_{32})\gamma \quad c_{22} = E_2(1 - \nu_{13}\nu_{31})\gamma \quad c_{33} = E_3(1 - \nu_{12}\nu_{21})\gamma \\
c_{12} = E_1(\nu_{21} + \nu_{31}\nu_{23})\gamma \quad c_{13} = E_1(\nu_{31} + \nu_{21}\nu_{32})\gamma \quad c_{23} = E_2(\nu_{23} + \nu_{13}\nu_{32})\gamma \\
c_{44} = \mu_{23} \quad c_{55} = \mu_{13} \quad c_{66} = \mu_{12} \quad \gamma = 1/(1 - \nu_{12}\nu_{21} - \nu_{23}\nu_{32} - \nu_{31}\nu_{13} - 2\nu_{21}\nu_{32}\nu_{13})
\]

where \(E_k\) is the Young’s modulus in the direction of the basis vector \(n_k\), \(\nu_{kl}\) and \(\mu_{kl}\) are the Poisson’s ratio and the shear modulus between directions \(n_k\) and \(n_l\). Symmetry of
the stiffness matrix is ensured by satisfying the following equality:

\[ \frac{\nu_{kl}}{E_k} = \frac{\nu_{lk}}{E_l} \quad \text{for} \quad k, l = 1, 2, 3 \quad \text{and} \quad k \neq l \quad \text{(no sums)}. \quad (27) \]

For the undamaged material, all the elastic properties equal the initial isotropic values:

\[ E_k = E, \quad \nu_{kl} = \nu, \quad \mu_{kl} = \mu. \quad (28) \]

If a crack starts growing along the plane \( n_2 n_3 \), as shown in Fig. 8, the material properties for the perpendicular direction \( n_1 \) are reduced according to:

\[ E_1 = E(1 - d), \quad \nu_{12} = \nu_{13} = \nu(1 - d), \quad \mu_{12} = \mu_{13} = \mu(1 - d), \quad (29) \]

where \( d \) is a damage parameter that will be defined further. Material properties in the undamaged directions stay unchanged and equal to the initial isotropic value.

Modelling orthotropic damage facilitates the efficiency of accounting for stiffness recovery upon crack closure. Initially, the principal stress in the direction perpendicular to the crack is controlled. A negative value indicates that the crack segment is closed and its stiffness has to be recovered. In this study, we adopt frictionless crack approach and fully recover Young’s moduli and Poisson’s ratios while keeping the values of shear moduli reduced:

\[ E_k = E, \quad \nu_{kl} = \nu, \quad \mu_{kl} = \mu(1 - d). \]

4. Meso-scale model calibration

While the elastic and fracture properties of concrete are available in the literature, the parameters of the ASR expansion law (Eq. 8) require calibration with experiments. Values to be calibrated are the number of ASR sites, the proportionality factor \( \alpha \), and the latency, \( \tau_{lat} \), and characteristic, \( \tau_{char} \), times. Calibration is done based on the experimental results of Multon and Toutlemonde [2006], who studied the effect of loading on the macroscopic behaviour of ASR-affected concrete. For this purpose, cylindrical specimens of concrete with ASR were either free to expand or loaded longitudinally and radially. Control cylinders without ASR were set under the same conditions. Their deformations were taken out from similar measurements of the ASR specimens. It allowed separating the ASR-caused strain values from the concrete shrinkage and creep.

The algorithm proposed by Wriggers and Moftah [2006] is used to generate the geometrical models of the concrete specimens and RVEs. In this algorithm, a circular
shape is assumed for all aggregates and the Fuller curve is used as a grading curve for the generation of aggregates. Subsequently, the geometrical models are discretised with Gmsh [Geuzaine and Remacle 2009] into finite-element meshes of linear triangular elements with a uniform average element size $h = 0.5$ mm. The resulting numerical concrete samples have a size of $70 \times 70$ mm$^2$, and contain aggregates of circular shape with diameters in the range $1 - 16$ mm (see Fig. 9). Concrete specimens were generated with an aggregate packing density of 70%.

Mechanics of the ASR product accounts for different phenomena taking place in a range of scales varying from nanometre to millimetre, and not yet fully understood. These processes include the growth of ASR product (either amorphous or crystalline), the opening of micro-cracks due to that, possible transport of product into pores and fissures, change of its properties with time and the surrounding environment. Leemann et al. [Leemann et al. 2016, Leemann and Munch 2019] have shown that the primary ASR product starts to accumulate between mineral grains within reactive concrete aggregates. Therefore, a typical size of an ASR inclusion is few nanometres. In the current numerical study, the size of an element is 0.5 mm. Thus, the expansion that we apply at a single finite element to represent the effect of ASR, should be seen as a homogenised expansion of an aggregate surrounding a single pocket of the ASR product, rather than the expansion of the product itself. In order to reproduce the ASR sites, a certain number of finite elements are randomly chosen inside the aggregates and assigned the mechanical properties of the ASR product. The components of concrete specimens have the material properties listed in Tab. 1. Shear modulus $\mu$ is computed as $\mu = E/[2(1 + \nu)]$.

|                | $E$ [GPa] | $\mu$ [GPa] | $\nu$ [-] | $G_c$ [J/m$^2$] | $f_t$ [MPa] |
|----------------|-----------|-------------|--------|----------------|-------------|
| Aggregates     | 59$^1$    | 22.6        | 0.3$^1$ | 160$^1$        | 10$^2$      |
| Mortar         | 12$^1$    | 4.6         | 0.3$^1$ | 60$^3$         | 3$^1$       |
| ASR product    | 11$^4$    | 4.7         | 0.18$^4$| -              | -           |

Table 1: Material properties.
The boundary conditions for the calibration tests are shown in Fig. 9. Two simulations are performed, with the first one being the ASR-induced free expansion and the second one the loaded ASR-expansion of concrete. In the first test, only the internal load coming from the expanding ASR-sites is present. In the second test, a vertical compression load of 10 MPa is additionally applied on top. Similar to the experiments, both simulations last 450 days. The time step is taken to be equal to 0.5 days. This value provides a good time resolution and allows to capture the gradual evolution of the crack network.

![Concrete microstructure and boundary conditions for the calibration tests. Specimens are composed of aggregates (in blue) surround by mortar (in grey). The load is applied on top of the specimen during the compression test only.](image)

Figure 9: Concrete microstructure and boundary conditions for the calibration tests. Specimens are composed of aggregates (in blue) surround by mortar (in grey). The load is applied on top of the specimen during the compression test only.

The parameters of the ASR-expansion law and the density of the ASR sites were calibrated on the free expansion experiment and kept the same for the loaded case and the simulations presented in the following section. They are listed in Tab. 2.

1 Taken from Dunant and Scrivener 2012b.
2 Taken from Ben Haha 2006.
3 Taken from Xu and Zhu 2009.
4 Taken from Leemann and Lura 2013.
Table 2: Parameters of the ASR-expansion law.

| Parameter                                           | Value     |
|-----------------------------------------------------|-----------|
| Ratio of the ASR sites area to the aggregates area  | 0.1 %     |
| Asymptotic strain $\varepsilon(\infty)$            | 6.5 %     |
| Latency time $\tau_{lat}$                          | 30 days   |
| Characteristic time $\tau_{ch}$                     | 60 days   |

Results of the calibration tests and the experimental expansion values are plotted in Fig. 10. Macroscopic expansion curves of the numerical specimens are compared to the experimental ones. The latter represent the average expansion values over multiple tested specimens. The range of the observed values is marked by the error bars. Both experimental and numerical curves account only for the ASR-caused expansion: deformation of concrete due to its shrinkage and the load application were previously taken out. In Fig. 10(a) both the numerical and the experimental specimens show different strain values depending on the direction. While for the simulation the difference is insignificant, the experimental results show more pronounced separation. In the free-expansion simulation, cracks are overall randomly oriented, however they may have a slight orientation bias due to the aggregates positioning or the ASR-sites placement (see Fig. 11a). In the real concrete, the difference in expansions may also be caused by the casting directions, the effect of the self-weight, specific boundary conditions, rock anisotropy, etc [Larive 1998, Ben Haha 2006, Gautam and Panesar 2016].
Macroscopic strain curves for both free expansion and loaded conditions have a typical S-shape, as a result of the similar shape of the ASR-product expansion curve. It is important to mention, that in the field conditions, the ASR-affected dams experience continuous swelling during decades [Mauris et al., 2015]. The difference in long-term behaviour of the laboratory specimens with ASR and the full-scale structures is subject of debate. One of the possible cause of the expansion halt is the alkalis concentration drop due to its leaching from specimens.

The numerical prediction of the loaded specimen shows also similar trends as the experimental one (see Fig. 10b). Both in the experiment and in the simulation, application of 10 MPa load reduces significantly the concrete expansion along the loading direction. While the experimental average longitudinal expansion is almost null, the numerical curve has its maximum value equal to 0.0097%. The experimental strain in the stress-free direction is slightly bigger than the average values of the free expansion case, which is also reproduced by the numerical model. However, the numerical prediction overestimates this increase in the lateral expansion. This is due to the effect of the concrete microstructure, the material properties variation, and the specific distribution of the ASR sites. Using the real concrete tomography to build a numerical model and then comparing two sets of results could improve the model’s accuracy. Another source of difference could be that the shear resistance of cracks is simply modelled by reduced shear modulus. Nonetheless, the clear advantage of this model is its ability to have positive longitudinal expansion under loaded conditions due to the orthotropic damage model with stiffness recovery, which was not the case in the previous model of Dunant and Scrivener [2012a].

The damage patterns within the free and the loaded concrete specimens are shown in Fig. 11. The response of the microstructure to the load application shows cracks alignment with the load direction. This damage pattern explains why the expansion in the horizontal direction is higher than in the vertical one (Fig. 10b). Since multiple coalesced vertical cracks are widely opened in the horizontal direction, the corresponding macroscopic strain $\varepsilon_{\text{num}}^{\text{lat}}$ is larger than the strain in the direction of the load $\varepsilon_{\text{num}}^{\text{long}}$.

Fig. 12 plots the damage ratio, $D$, which is the ratio between the damaged area of a phase and its total area. To compute this parameter, the area of each damaged element from a specific phase is multiplied by its damage value $d$, summed together and divided by the total area of this phase. For both simulations, we can observe less damage in
Figure 11: Damage patterns within concrete specimens affected by ASR under (a) free expansion conditions, (b) uniaxial compression loading of 10 MPa. While the freely expanding concrete block develops randomly oriented cracks, the compressed block has them mostly aligned with the load direction. Previous studies on the effect of creep on ASR show that it helps to accommodate larger strains in the cement paste without damaging it [Giorla et al., 2015]. The presented model does not include visco-elasticity, thus overestimates the damage amount in the mortar. It, however, could be easily extended to model visco-elastic mortar at the meso-scale [Rezakhani et al., 2020].

Figure 12: Damage ratio within aggregates and mortar for the free expansion and the loaded ASR simulations. The free specimen has larger cracks extent both in aggregates and mortar due to their random orientation.

It is interesting to compare the stiffness loss estimated via compressive and tensile
The relative stiffness, expressed in per cent, is computed by applying either compressing or extending displacements on one specimen’s surfaces. After solving for a new displacement field, internal forces at the nodes along this surface are integrated into a scalar. The ratio between the current value of this integral and its initial value serves as an estimator of the specimen’s stiffness. Pulling or squeezing a sound piece of concrete would give rise to high reaction forces, whereas in a severely damaged specimen the applied load will only open cracks.

From both tests, we see the relative stiffness estimated in tension being lower than the compressive one. This is due to the stiffness recovery of cracks brought in contact. Although this phenomenon could still happen while applying tension, its effect is more pronounced during the compression test. Another interesting observation concerns the ratio between stiffness values into two directions. In the free expansion case the stiffness is almost equally reduced in both directions, whereas the loaded case shows larger stiffness loss in the x-direction. This anisotropy is equally pronounced in both tensile and compressive estimates and is linked to the vertical cracks percolation. The difference between stiffness values estimated via tensile and compressive tests justifies adaptive homogenisation procedure, where the loading type of tests is chosen based on the stress state of the macroscopic element. In Fig. 13a, the grey shaded area denotes the limiting values of stiffness in the accelerated free expansion experiments of Ben Haha [2006]. The results of the current model show stiffness reduction of $10^{-20\%}$, which is very close to the experimental values. As Cuba Ramos et al. [2018] have previously suggested, adding the crack interlock and closure effects indeed increases the load-bearing capacity of the numerical sample. This realistic meso-scale concrete behaviour permits integrating the proposed model into the multi-scale numerical model.

5. Multi-scale model verification

With a calibrated meso-scale ASR model, the multi-scale model can now be tested. To the best of these authors’ knowledge, there are no sets of laboratory experiments and long-term field data on the same ASR-affected concrete available in the literature. To overcome this issue, we propose using the same laboratory experiments by Multon and Toutlemonde [2006] as a macro-scale structure to test the ASR multi-scale model and to provide the proof of concept for the method. Although the separation of scales
Figure 13: Estimation of the stiffness loss via compressive and tensile tests under (a) free expansion conditions, (b) uniaxial loading of 10 MPa. The grey shaded area corresponds to the range of experimental values reported by Ben Haha [2006].

concept does not hold anymore, this choice allows a direct comparison between the results of the FE\textsuperscript{2}-simulation and the experimental measurements. Another advantage of this set up is its simple stress state, which is not a case for a large operating structure such as a dam or a bridge pier. By applying a load at the macro-scale, we can directly observe how it is balanced by the internal forces at the meso-scale. Fig. 14 shows

Figure 14: Meshes used for the multi-scale simulation. Each of 16 macroscopic finite elements has a square concrete RVE at the meso-scale.

Figure 15: Mesh for the detailed macro-scale simulation used for the comparison with FE\textsuperscript{2}.
the multi-scale set up used for the validation test. The size of the numerical macro-
scale specimen is 140 × 280 mm, while the RVE size is kept the same as the one
used previously (70 × 70 mm). In the present case, each finite element at the macro-
scale is linked to an underlying RVE, which represents the heterogeneous structure of
concrete at the meso-scale. The total number of RVEs corresponds to the number of
finite elements in the macroscopic FE mesh because each macroscopic finite element
contains only one integration point.

Laboratory experiments were performed at 38°C temperature \cite{Multon2004}. Since
the temperature field is homogeneous within the specimen, a constant single value $T_M$
is passed to all RVEs during all time steps.

For comparison, fully detailed simulations of the macro-scale structure were per-
formed. The mesh for these simulations is shown in Fig. 15. In both models, the den-
sity of the ASR sites and the parameters of the ASR product expansion law from the
calibration tests is used (see Tab. 2). The two following tests were performed: free ex-
ansion and uniaxial compression with 10 MPa. This proposed stress range is chosen
to simulate possible stress variations within a massive concrete structure undergoing
ASR.

Expansion curves from the multi-scale simulations are plotted in Fig. 16 next to the
ones coming from the fully detailed macro-scale simulations. Expansion values were
obtained by averaging the strain values at the macro-level. We see a good match be-
tween these two sets of curves in both simulations. Naturally some di-

ffe-

erences remain
between multi-scale and detailed macro-scale simulations. Similar to the calibration
simulations, there is a gap between the numerical lateral expansion value and its ex-
perimental counterpart. All these variations are because of the specific microstructure
of the detailed macro-scale model, which is not exactly reproduced by the multi-scale
model. Comparison between the outcome of Monte Carlo simulations of the detailed
model with the multi-scale results would be fairer in this sense. For the proof of con-
cept, we, however, limit ourselves to a single realisation of the macro-structure.

The average damage ratio for the multi-scale simulations is plotted in Fig. 17. Since
at the macro-scale the damage is homogeneous, averaging was done over all RVEs.
The FE$^2$ simulation of the 10 MPa compression has the lowest amount of damage both
in aggregates and mortar (5% and 29% correspondingly). It is followed by the free
expansion experiment with 7% of aggregates and 42% of mortar being damaged. As
Figure 16: Expansion curves of the macroscopic specimen obtained by multi-scale and detailed macro-scale simulations: (a) free expansion experiment; (b) uniaxial compression by 10 MPa. The average values of the experimental expansion curves are plotted for comparison. The two sets of numerical results are in a good agreement and are also close to the experimental values.

previously discussed in Section 3 these numbers do not represent the percentage of the damaged material area, but the area of finite elements containing thin cracks.

Figure 17: Average damage ratio for the (a) free and (b) loaded multi-scale simulation

Crack patterns within RVEs are shown in Fig. 18a-b. For comparison, images of the damage in the detailed macro-scale specimens are given in Fig. 18c-d. A similar amount of damage and orientation of cracks in each pair of simulations is evident. The difference in damage amount between the two loading cases is somehow expected. Compressive load pushes the stress state of each finite element further from the tensile failure envelop. In such a case, cracks are strongly localised and follow the direction perpendicular to the maximum principal stress. In case of a free expansion experiment,
the stress state is closer to the limits, therefore cracks appear earlier and grow longer. Periodic boundary conditions applied at the RVEs cause cracks continuity across the borders. Artificial cracks perpendicularity to the periodic borders is a well-known issue, which also brings bias into the homogenised stiffness tensor. A possible solution was proposed in Coenen et al. [2012], where the boundaries align with the evolving localisation bands, enabling crack bands to grow slantwise to the boundaries directions. Potentially, this method could be adopted in the current model and enhance crack patterns and stiffness estimation.

6. Conclusions

A multi-scale finite-element method for simulating the mechanical consequences of ASR in large concrete structures has been presented. The multi-scale approach is advantageous because the material behaviour in the simulation is governed by the underlying physical phenomena of ASR. Consequently, no drastic assumptions on how the mesoscopic damage evolution affects the effective stiffness of the concrete are required. To our knowledge, this is the first multi-scale model for ASR, which couples the macroscopic concrete degradation to the advancement of ASR in the fully resolved meso-scale model and explicitly models the ASR sites. The multi-scale model has been implemented in the parallel open-source library Akantu. Meso-scale laboratory experiments of Multon and Toutlemonde [2006] are numerically simulated as proof of concept. The model is able to simultaneously account for the loading due to the boundary conditions on the macro-scale and for the loading due to the ASR expansion at the meso-scale. The results, furthermore, demonstrate that the macroscopic stress state influences the orientation of damage inside the underlying RVEs. The effective stiffness becomes anisotropic, in cases where damage is aligned inside the RVE. Comparison of the multi-scale and the fully detailed macro-scale model shows a fair agreement of results both for free and loaded expansion tests. Although the evolution of the percolated crack bands within RVEs is evident, their diffused patterns make the classical homogenisation concept still applicable.

Another important development introduced in this model is the mesoscopic material law, which allows for the orthotropic reduction of elastic properties upon crack nucleation and their recovery upon crack closure. It was shown that this constitutive law better reproduces trends in macroscopic expansion and stiffness loss observed in
Figure 18: Damage patterns within typical RVEs under (a) free expansion conditions and (b) a uniaxial compression stress of 10 MPa. Damage distribution within the full macro-scale models under (c) free expansion conditions and (d) a uniaxial compression stress of 10 MPa. Crack patterns and amount of damage are in fair agreement between the two sets of simulations.
the laboratory experiments than the isotropic damage without contact.

The performed validation of the multi-scale model suggests its applicability for detailed studies of real concrete structures affected by ASR. Such a study of a dam is planned in future work, including accounting for a different reaction extent for each RVE due to a non-uniform thermal field in the dam. Combining the link between the temperature and the microscopic eigenstrain with the temperature gradients at the macro-scale due to variable boundary conditions [Comi et al. 2012] would result in a non-uniform internal loading within each RVE. This is expected to emphasize the anisotropy of the ASR-affected concrete, which in the first place is triggered by the boundary conditions.
