2Department of Ophthalmology, Korea University College of Medicine, Seoul, Korea

Purpose: To determine how myopia and peripapillary atrophy (PPA) affect the measurement of retinal nerve fiber layer (RNFL) thickness by optical coherence tomography (OCT) and scanning laser polarimetry (GDx) with variable and enhanced corneal compensation (VCC and ECC).

Methods: We measured RNFL thickness in 20 eyes from 20 subjects without glaucoma and with myopic PPA (PPA group) and 20 eyes from 20 normal subjects without PPA (control group) with various scan circle sizes by OCT, GDx-VCC and GDx-ECC.

Results: On OCT analysis, the individual clock-hour RNFL thickness of the PPA group was significantly less than that of the control group in the nasal, superior and inferior areas, whereas the thickness was similar in the temporal area where PPA was most commonly seen. On GDx-VCC and GDx-ECC analyses, the individual clock-hour RNFL thickness of the PPA group was similar or less in the nasal, superior and inferior areas than that of the control group, whereas the thickness was greater in the PPA group than in the control group in the temporal area. This RNFL thickness pattern seen with both OCT and GDx measurement was consistent for all the scan circle sizes even though the scan circle was large enough that it did not encompass the PPA area.

Conclusions: When measured by OCT and GDx, the thickening of the RNFL in the temporal area was observed in the PPA group. Our results suggest that PPA per se may not be responsible for the temporal thickening of RNFL in myopic eyes with PPA.

Key words: Glaucoma; Myopia; Optical coherence tomography; Retinal nerve fiber layer

Introduction

Glaucoma is a progressive glaucomatous optic neuropathy with a glaucomatous visual field defect. Various conditions, such as myopia, are considered risk factors for glaucoma. It has been postulated that the optic nerve head in a myopic eye is weaker because of the structural changes in the connective tissue. In addition, it is difficult to identify glaucomatous optic disc changes in myopic eyes because of the physiologically large cup, tilting of the disc and peripapillary atrophy (PPA). PPA is observed in eyes with myopia as well as glaucoma. The retina and choroid become thin in the PPA, exposing some of the underlying sclera. The retinal pigment epithelium is absent or irregular in chorioscleral crescent or PPA.

Various methods have been introduced for measuring retinal nerve fiber layer (RNFL) thickness. Among them, optical coherence tomography (OCT), scanning laser polarimetry (GDx) with variable corneal compensation (VCC) and enhanced corneal compensation (ECC) are commonly used. It is possible that PPA can influence the measurement of RNFL thickness by GDx because abnormal birefringence can occur due to diminution of reflectivity from the retinal pigment epithelium, which can produce an augmentation of the polarization signal from deeper retinal structures such as the sclera. Likewise, it may also be possible that PPA can influence the measurement of RNFL.
thickness by OCT because the accuracy of the bottom of the nerve fiber layer of the NFL is arbitrarily defined as a change in the refractive index in the retinal tissue, and the presence of PPA can change the reflection of lights. Measuring RNFL thickness in myopic eyes by GDx has been reported in various studies, which showed abnormal retardation patterns of RNFL on areas with PPA. However, there is a paucity of reports on the clinical results from using OCT to measure RNFL thickness in eyes with myopic PPA.

This study was performed to investigate the influence of myopic PPA on the measurement of RNFL thickness by OCT, GDx-VCC and GDx-ECC. We measured RNFL thickness with various scan circle sizes including a large scan circle that did not include the PPA area. We postulated that if a change in RNFL thickness is still found in the large scan circle not including the PPA area, PPA itself does not affect the RNFL thickness measurement.

### Patients and Methods

In July 2008, we analyzed 20 eyes from 20 enrolled subjects without PPA (control group) and 20 eyes from 20 enrolled subjects with myopic PPA (PPA group). The subjects included hospital staff from the Korea University Guro Hospital and students of the Korea University Medical College. We selected one eye at random from each subject for the analysis. The Institutional Review Board of Korea University Guro Hospital approved our protocol and all procedures adhered to the tenets of the Declaration of Helsinki. All investigations were performed with informed consent. All subjects underwent comprehensive ophthalmic examinations, including refraction, intraocular pressure (IOP) measurement by Goldmann applanation tonometer, slit-lamp biomicroscopy and funduscopic examination. PPA was defined as chorioretinal atrophy with visible large choroidal vessels and sclera around the optic disc. Visual fields were tested by the Humphrey Field Analyzer (Zeiss-Humphrey Systemis, Dublin, CA) using a 30-2 Swedish Interactive Threshold Algorithm. Inclusion criteria were as follows: best corrected visual acuity greater than 20/25, IOP less than 21 mmHg, no visual field defects, no ocular abnormalities except for myopia and no systemic diseases including diabetes and hypertension. We excluded eyes with glaucomatous optic disc changes, visual field abnormalities and retinal diseases including myopic macular degeneration.

OCT measurement was performed by a well-trained examiner with the optic nerve head scan mode of the Stratus OCT 3000 (Carl Zeiss Meditec, Dublin, CA, USA). RNFL thickness around the optic disc was measured for each eye with four different scan circle sizes (3.2, 3.4, 3.6 and 4.0 mm). We included results that had a centered optic disc, were well focused and had a signal strength equal to or greater than 8. GDx-VCC and GDx-ECC (Carl Zeiss Meditec, Dublin, CA, USA, version 5.5.1) measurements were also performed by the same examiner without pupil dilation. Again, we only included images that had a centered optic disc, were well-focused and had a quality score of 8 or more. Each obtained image was analyzed with three different scan circle sizes (small, 2.4 mm; medium, 3.2 mm; and large, 4.0 mm in inner diameter). To analyze individual clock-hour RNFL thickness, raw data for all the eyes were extracted from the GDx device. The horizontal and vertical diameters of the optic discs were obtained from the GDx-ECC measurements.

We analyzed the differences between the two groups in average RNFL thickness and RNFL thickness at each clock hour area as measured by OCT, GDx-VCC and GDx-ECC. All differences in the parameters between the two groups were analyzed by t test. To analyze the correlation between spherical equivalent (SE) and RNFL thickness, we calculated Pearson’s correlation coefficient. A p value less than 0.05 was considered significant.

### Results

The mean ages of the control and PPA groups were 27.00 ± 4.52 (SD) and 27.20 ± 5.13 years old, respectively. The mean SEs of the control and PPA groups were -2.15 ± 2.23, and -5.90 ± 3.33 diopter, respectively. The mean IOPs of the control and PPA groups were 14.88 ± 2.96 and 15.31 ± 2.80 mmHg, respectively, and the horizontal and vertical
optic disc diameter were 1358.00 ± 283.06 and 1606.11 ± 215.18 μm, respectively, for the control group, and 1446.08 ± 277.42 and 1682.15 ± 246.65 μm, respectively, for the PPA group. Age, IOP and optic disc diameters were not significantly different between the two groups (p > 0.05). The eyes of the PPA group were more myopic than those of the control group (p = 0.000) (Table 1).

When identifying the temporal outermost area as 9 o’clock and nasal innermost area as 3 o’clock, the distribution of PPA in the PPA group was as follows: PPA of six eyes (30%) presented between 7 and 11 o’clock, PPA of four eyes (20%) between 7 and 12 o’clock, PPA of three eyes (15%) between 6 and 11 o’clock, PPA of five eyes (25%) between 6 and 12 o’clock, and PPA of two eyes (10%) between 5 and 12 o’clock. Thus, all the eyes (100%) in the PPA group had a PPA between 7 and 11 o’clock (temporal area), 11 eyes (55%) had PPA at 12 o’clock, eight eyes (40%) had PPA at 6 o’clock, and two eyes (10%) had PPA at 5 o’clock.

The relationship between the scan circle size and the distance between the outermost margin of the PPA and the optic disc margin was as follows: the 2.4 mm (small) scan circle was across the PPA area in 17 eyes (85%), the 3.2 mm (medium) scan circle was across the PPA area in 12 eyes (60%), the 3.4 mm scan circle was across the PPA area in nine eyes (45%), the 3.6 mm scan circle was across the PPA area in three eyes (15%), and the 4.0 mm (large) scan circle was across the PPA area in no eyes (0%).

On OCT analysis, the average RNFL thickness of the

Y.H. Hwang, et al : Retinal Nerve Fiber Layer in Myopia

The average RNFL thickness measured by OCT was significantly correlated with the SE for all subjects, showing that the RNFL thickness decreased as the degree of myopia increased (Table 3). The RNFL thicknesses in the clock hour areas without PPA in the PPA group were significantly lower than those in the corresponding clock hour areas in the control group ($p<0.05$). However, RNFL thicknesses in the clock hour areas with PPA (7 to 11 o'clock hour areas) showed no significant differences between the two groups ($p>0.05$). This pattern of RNFL thickness differences between the two groups was consistent for all the four different scan circle sizes (Table 4, Fig. 1).

On GDx analysis, the average RNFL thickness obtained by GDx-VCC in the PPA group was significantly greater than that of the control group ($p<0.05$). However, the average RNFL thickness obtained by GDx-ECC showed no significant difference between the two groups ($p>0.05$) (Table 2). When comparing RNFL thickness measured by GDx-VCC and GDx-ECC between the PPA and control groups at each clock hour area, the RNFL thickness in areas with PPA (temporal area) was greater in the PPA group.

| 12         | 154.72±21.04 | 133.48±27.71 | 0.002    |

PPA = peripapillary atrophy.

*p-value: t-test.
(p < 0.05) than in the control group. However, in areas without PPA (nasal, superior, and inferior areas), the RNFL thickness showed no difference or was less in the PPA group. The pattern of RNFL thickness differences between the two groups was consistent for all three of the different scan circle sizes (Table 5, 6, Fig. 2). The average RNFL thicknesses measured by GDx-VCC and GDx-ECC were not correlated with SE for overall subjects, except for the RNFL thickness measured by the large scan circle of GDx-VCC, which showed a negative correlation between the SE and average RNFL thickness (Table 3).

**Discussion**

An OCT study previously showed that RNFL thickness was less in highly myopic eyes than in eyes with lower myopia, and there was a linear correlation between RNFL thickness and axial length/spherical equivalent.26 Other studies have also shown similar correlations between myopia and RNFL thickness measured by OCT.27-29 A similar difference in RNFL thickness according to the degree of myopia was also found in our own study using OCT. In addition, the RNFL thicknesses at each clock hour measured by OCT with various scan circle sizes were thinner in the PPA group than in the control group, except for the temporal area where PPA most commonly exists. The pattern of RNFL thickness seen in OCT measurement was consistent for all scan circles of various sizes even though the scan circle was large enough that it did not include the PPA.

We found that average RNFL thickness of the PPA group measured by GDx-VCC was higher than that of the control group, although the PPA group had a higher degree of myopia. On the other hand, when analyzing RNFL thickness at each clock hour area, the RNFL thickness of the PPA group was greater in areas with PPA than that of the control group, whereas in areas without PPA, the RNFL thickness of the

PPA = peripapillary atrophy.
*p-value: t-test.
PPA group was not significantly different or less than that of the control group. Therefore, our results suggest that the difference in average RNFL thickness measured by GDx-VCC was primarily caused by the difference in the temporal area where PPA existed. This may be attributed to the high scleral reflectivity, which can cause an increase in the retardation values because of retinal and choroidal atrophy in myopic eyes with PPA. However, even though the size of scan circle was large enough not to include the PPA area, the RNFL thickness was still overestimated using GDx, as it was with OCT.

The average RNFL thickness measured by GDx-ECC did not demonstrate any difference between the two groups, in contrast to the result obtained by GDx-VCC. When RNFL thickness at each clock hour area was analyzed, the RNFL thickness of the PPA group in areas with PPA was greater than that of the control group, whereas the RNFL thickness of the PPA group was not significantly different or less than the control group in areas without PPA. This may suggest that RNFL thickness in the temporal area can be overestimated when measured by GDx-ECC, although the degree of overestimation is less than that with GDx-VCC. Previous studies comparing RNFL thickness measured by GDx-VCC and by GDx-ECC also showed similar results.  

Figure 2. Retinal nerve fiber layer (RNFL) thickness curves of control and peripapillary (PPA) groups obtained by GDx-VCC and GDx-ECC with various scan circle sizes. The RNFL thickness of the PPA group was less than that of control group except for in the temporal area. In the temporal area, the RNFL thickness of the PPA group was greater than that of the control group.
may be due to the fact that measuring by GDx-ECC resulted in an improvement in the typical scan score and reduction in the high retardation values in the area with PPA.

Most of the OCT and GDx studies on myopia have used one scan circle and included myopic eyes that had a small PPA that was not included in the scan circle.\textsuperscript{25,26,28} We wanted to know whether PPA per se has an effect on the measurement of RNFL thickness. Our results revealed that the difference in the pattern of RNFL thickness between the two groups in the temporal area was consistent with all scan circles, regardless of size, even when the scan circle was large enough not to include the PPA area. When the RNFL thickness was measured with a 4.0 mm diameter scan circle, no scan circle included the PPA in the subject eye. However, the RNFL measurement with this large scan circle showed similar results as those with the smaller scan circles. Therefore, the RNFL thickness in the temporal area measured by OCT did not differ between the two groups and the RNFL thickening measured by GDx-VCC and GDx-ECC in the temporal area between the two groups was not affected by PPA.

Abnormal retardation is a possible cause of overestimation of RNFL thickness with GDx. However, it is unclear why the RNFL thickness in the temporal area measured by OCT showed no significant difference, whereas a thinner RNFL was found in the nasal, superior and inferior areas in eyes with myopia. In addition, little is known about the temporal thickening in the area outside the PPA in myopia. Histological studies have demonstrated that the sensory retina becomes thinner in myopic eyes.\textsuperscript{30,31} However, those studies did not address RNFL thickness in each quadrant. Therefore, it remains to be determined whether or not actual thickening is present in the temporal area in myopic eyes. The possibility of overestimating the RNFL thickness in the temporal areas also needs to be considered. For example, optic disc tilting could influence the measurement of the RNFL thickness. Optic disc tilting is frequently seen in myopic eyes,\textsuperscript{9} and errors in RNFL measurements could occur by off-axis scanning. OCT evaluates images presumed to be taken perpendicularly to the longitudinal axis of the eyeball.\textsuperscript{32} However, in myopic eyes, the nasal half of the optic disc is elevated, and the temporal half is depressed.\textsuperscript{30} Therefore, when the OCT scan reflects oblique, there could be a change in the RNFL thickness.

It is known that a larger optic disc can exhibit a thicker RNFL with a fixed scan circle size, because the scan circle is located closer to the optic disc edge in eyes with a larger optic disc.\textsuperscript{35} Therefore, size differences in optic discs may be a confounding factor in this study. However, we found no statistically significant differences between the vertical and horizontal diameters of the optic disc between the two groups.

Although we did not collect data for axial length, it is reasonable to assume that there could be axial length differences between the two groups. Eyes with a higher degree of myopia have longer axial lengths.\textsuperscript{7,30}\textsuperscript{26,27} Studies using OCT determined that the average RNFL thickness decreases with increasing axial length and negative refractive power.\textsuperscript{36,37} Differences in axial lengths between the two groups could affect our results.

In conclusion, the measurement of RNFL thickness of myopic eyes by OCT, GDx-VCC and GDx-ECC in the temporal area where PPA exists produces different patterns that those in the areas where PPA does not exist. However, PPA itself does not appear to influence the measurement of RNFL thickness with these instruments. More attention is needed to evaluate the measurement of RNFL thickness by OCT, GDx-VCC, and GDx-ECC in the temporal area of myopic eyes, regardless of the presence of PPA.
