Abstract
Biomarker targeted two-stage adaptive design is used increasingly in early-stage clinical trials in a variety of therapeutic areas including oncology, where the sample size of the trial is re-estimated based on the first stage data. In such trials often the sample size is moderate, and so incorporating prior information and using robust methods are desirable. In this article, to improve upon existing methods using parametric normal models, we propose a nonparametric Bayesian approach for designing such adaptive trials in a phase IIb/IIIa setting comparing a treatment vs. a control. Extensive simulation studies are conducted to evaluate the performance of the proposed method and compare it with the existing normal parametric model. Our results indicate that with good prior information, more reasonable and robust inference than with existing parametric methods can be obtained.

Keywords
Adaptive design, Biomarker targeted design, Maximum likelihood estimate, Non-parametric Bayes model, Sample size, Two-stage clinical trial

Introduction
Biomarker targeted design is an important step towards precision medicine, which can improve efficiency of randomized clinical trial [1,2]. Zhou, et al. [3] and Lee, et al. [4] proposed Bayesian approach and Wang, et al. [5] applied this design in therapeutic trials, Freidlin, et al. [6] discussed issues with this design, Tang and Zhou [7] proposed a general framework. The two or three stage designs are commonly used in recent phase IIb-IIIa trials comparing treatment vs. control. Such sequential monitoring has become an integral part of clinical trial. It allows for early stopping of the trial for extreme results observed in interim stage(s) [8-11].

More recently, Gao, Roy, and Tan [12,13] proposed a two-stage adaptive design for biomarker targeted population where only biomarker positive subjects enter the trial study. However, the test is imperfect subject to false positive and false negative errors. Thus a mixture normal model is used for the biomarker positive subjects. The final sample size re-estimation is based on the positive predict value (PPV), the proportion of true positives among test positives, estimated from the first stage data, deviates slight from a more common adaptive designs [14-16]. Proschan [17] and Xiong, Tan and Boyett [18] discussed sample size re-estimation in clinical trials. Since for early-stage clinical trial, often the sample size is relatively small, and so incorporating valuable prior information, if available, and using a robust method would be desirable. For the first goal a Bayesian model is preferable, while for robustness the nonparametric method is more suitable. Thus, we propose a nonparametric Bayesian method to achieve both goals.

The rest of this article is organized as follows. Section 2 introduces the problem, then develops the proposed nonparametric Bayesian method, and compares with the frequentist parametric method, the two-stage sequential test, and sample size re-estimation. In Section 3, extensive simulation studies are conducted to evaluate the performance of the proposed method, compared it with the existing normal parametric model. We leave the technical details in the Appendix.
Background and the Proposed Method

Background and review of the existing methods

We first introduce the setting by briefly reviewing the related targeted design in Gao, Roy, and Tan [13]. Consider a two-stage clinical trial with continuous or response endpoint comparing two groups, control and treatment, to assess the effect of a new treatment. The observed data at stage $k$ is

$$D_n = \{x_{ij} : i = 1, \ldots, n_{k1}, j = 1, \ldots, n_{k2}\}$$

from independent biomarker test positive individuals ($k = 1, 2$), $x_{ij}$ is response from the $i$-th individual in the control group, and $x_{ij}$ is from that from the control group. By convention, the sample size $n_{c1}$ and $n_{c2}$ include $n_{c1}$ and $n_{c2}$; $n_1 = n_{c1} + n_{c2}$ is the planned sample size for stage I; and $n_2 = n_{c1} + n_{c2}$ is the total sample size at end of the trial, which is subject to updating based on parameters estimates from stage I data. Let $\mu_c$ be the mean response of the control group, $\mu_t$ be that for the treatment group, and $\theta = \mu_t - \mu_c$ be the treatment difference in the overall study population. The objective of the trial is to test whether there is treatment difference between the two arms, i.e. to test $H_0 : \theta = 0$ versus $H_1 : \theta \neq 0$, with pre-specified significance level $\alpha$ and power $\beta$, and determine the total sample size $n_2$.

Since only biomarker test positive patients enter the trial, and a proportion $\omega$ of them are truly positive. Hence the trial population consists of true biomarker enrichment group (E) and the non-enrichment (NE) group. Let $\mu_{cE}$ and $\mu_{cNE}$ be the mean response for NE and E portion in the treatment arm respectively, and $\mu_{tE}$ and $\mu_{tNE}$ be those of the control and treatment group at end of stage I, $\mu_{tE}$ and $\mu_{tNE}$ include $\mu_{t1}$ and $\mu_{t2}$ respectively, and $\mu_c$ and $\mu_t$ be those of the control and treatment groups. Then

$$\mu_c = (1 - \omega) \mu_{cE} + \omega \mu_{cNE} \quad \text{and} \quad \mu_t = (1 - \omega) \mu_{tE} + \omega \mu_{tNE}.$$  

In Gao, Roy and Tan [13], the following normal mixture model are used

$$X_{i1} \sim (1 - B)N(\mu_{c1}, \sigma^2) + B N(\mu_{c2}, \sigma^2) \sim N(\mu_c, \sigma^2), \quad (i = 1, \ldots, n_c),$$

$$X_{i2} \sim (1 - B)N(\mu_{t1}, \sigma^2) + B N(\mu_{t2}, \sigma^2) \sim N(\mu_t, \sigma^2), \quad (i = 1, \ldots, n_t),$$

where $B \sim \text{Bernoulli}(\omega)$.

Let $\bar{X}_{c1}^{(1)}$ and $\bar{X}_{c2}^{(1)}$ be the sample means of the control and treatment group at end of stage I, $\bar{X}_{c1}^{(1)} = x_{c1}^{(1)} / \omega$, $\bar{X}_{c2}^{(1)} = x_{c2}^{(1)} / \omega$, $\sigma_{c1}^2 = \frac{1}{n_{c1} - 1} \sum (x_{c1}^{(1)} - \bar{X}_{c1}^{(1)})^2$, $\sigma_{c2}^2 = \frac{1}{n_{c2} - 1} \sum (x_{c2}^{(1)} - \bar{X}_{c2}^{(1)})^2$.

Then the total sample size $n_2$ needed for the whole trial is estimated as

$$n_2 = \frac{(Z_{\alpha/2} + Z_{\beta/2})^2 \sigma_{c1}^2}{\omega (\mu_{c1} - \mu_{c2})^2},$$

where $\mu_{c1} = (1 - \omega)(\mu_{cE} - \mu_{cNE}) + \omega (\mu_{c1} - \mu_{cNE})$ and $\sigma_{c1}^2 = \sigma^2 + (1 - \omega)(\mu_{c1} - \mu_{cNE})^2$.

Maximum likelihood estimation (MLE) for mixture model is more conveniently obtained by the EM algorithm, given in the Appendix.

The proposed method

For early-stage clinical trial often the sample size is relatively small, and in some cases there is prior knowledge about the data distribution. A subjectively specified parametric model however may not be able to describe the distribution, so a nonparametric prior is preferred. Thus we adopt a nonparametric Bayesian model for this problem.

Let $F_c$ and $F_t$ be the distribution function of the control and treatment arm respectively. Often there are prior information for them. Let $\pi(F_c)$ and $\pi(F_t)$ be their priors, we assume $\pi(F_c) - \mathcal{D}(P_c(\cdot))$ and $\pi(F_t) - \mathcal{D}(P_t(\cdot))$, where $\mathcal{D}(P_c(\cdot))$ is the Dirichlet process with parameter $P_c(\cdot)$; similarly for $\mathcal{D}(P_t(\cdot))$. The distribution $P_c$ is the prior knowledge about $F_c$, and similarly for $P_t$.

We adopt the following assumptions assumed in Gao, Roy and Tan [13].

1. $\mu_{c1} = \mu_{cE} = \mu_{cNE} = \mu_{c2}$
2. $\text{Var}(X_{c1}) = \text{Var}(X_{c2}) = \text{Var}(X_{t1}) = \text{Var}(X_{t2}) = \sigma^2$.

The reason for A1) is that a predictive biomarker is associated with response or lack of response to a particular therapy. Ideally, a predictive biomarker positive patient receiving therapy is expected to show a substantially higher response than negatively-biomarker patients receiving the therapy as well as those in the control group regardless of the marker status. Therefore, A1) with the treatment potentially making $\mu_{t1}$ different from $\mu_{c1}$ and $\mu_{c2}$. Thus, the treatment effect, if any, is assumed to be a result of differential response to the treatment in the positively-biomarker group. A2) is a reasonable assumption to reduce model complexity.

For notational brevity, we will just write $n_i$ for $n_{c1}$ and $n_i$ for $n_{c2}$, etc. At end of stage I, using the non-parametric Bayesian formula for mean [19], in our case we have for $\mu_c$ and $\mu_t$,

$$\bar{X}_{c1}^{(1)} = \frac{1}{n_c} \mu_{PC} + \frac{n_c}{n_c + 1} \bar{X}_{c1}^{(1)},$$

$$\bar{X}_{c2}^{(1)} = \frac{1}{n_t} \mu_{PT} + \frac{n_t}{n_t + 1} \bar{X}_{c2}^{(1)},$$

where $\mu_{PC}$ and $\mu_{PT}$ are the prior means of $P_c$ and $P_t$. We have the estimates for means of the two distributions

$$\hat{\mu}_c = \bar{X}_{c1}^{(1)} = \frac{\bar{X}_{c1}^{(1)} - (1 - \omega_b) \bar{X}_{c2}^{(1)}}{\omega_b}.$$  

Also, using the non-parametric Bayesian formula for variance [19], we have $\hat{\sigma}_c^2$ of $\text{Var}(X_{c1})$ and $\hat{\sigma}_t^2$ of $\text{Var}(X_{c2})$ in our case as

$$\hat{\sigma}_c^2 = \frac{\mu_{2,PC} + \sum_{i=1}^{n_c} x_{c1,i}^2}{n_c + 2} - \frac{(\mu_{PC} + \sum_{i=1}^{n_c} x_{c1,i})^2}{(n_c + 1)(n_c + 2)},$$

$$\hat{\sigma}_t^2 = \frac{\mu_{2,PT} + \sum_{i=1}^{n_t} x_{c2,i}^2}{n_t + 2} - \frac{(\mu_{PT} + \sum_{i=1}^{n_t} x_{c2,i})^2}{(n_t + 1)(n_t + 2)}.$$
which is determined can be obtained using the formula be

where \( \mu_{j} = \int x^2 dP_{\xi}(x) \) is the prior second moment, similarly for \( \mu_{j}. \)

To update the estimation of PPV \( \omega \), let \( S^{(j)} = n_{c} \bar{x}_{c}^{(j)} + n_{j} \bar{x}_{j}^{(j)} \) be the total responses at end of stage \( j \). Since \( E[S^{(j)}] = n_{c} \omega \mu_{c} + n_{j} \omega (1 - \omega) \mu_{j} \), we substitute means and total responses to estimate \( \omega \) as

\[
\hat{\omega} = \frac{n_{c} \bar{x}_{c}^{(j)} - n_{j} \bar{x}_{j}^{(j)}}{n_{c} \mu_{c} - n_{j} \mu_{j}}.
\]

**The two-stage sequential test**

For given significance level \( \alpha \) and power \( \beta \), the decision boundaries are determined to satisfy type I error no greater than \( \alpha \) and with power at least \( \beta \). Consider test statistics \( T_{j} \) at stage \( j \) \((j = 1, \ldots, k)\), the flexible class of boundaries proposed by Wang and Tsiatis [20] are, for some \((c, y)\) to be determined,

\[
b \leq cy^{0.5}.
\]

Under \( H_{0} \) \((T_{1}, \ldots, T_{k})\) is multivariate normal distributed with zero mean vector. The sequential test will reject the null hypothesis at stage \( j \) if \( |T_{j}| \geq b_{j} \). Then we have equation

\[
P_{H_{0}} \left\{ \bigcap_{j=1}^{k} |T_{j}| < cy^{j-0.5} \right\} = 1 - \alpha.
\]

Here we adopt O’Brien-Fleming boundaries having shape parameter \( \gamma = 0 \). In our case, \( k = 2, \alpha = 0.05, c = 2.7967 \). The corresponding threshold of p-value at stage I is approximately 0.0054.

**Sample size re-estimation**

If the null hypothesis is not rejected at stage I, the sample size for the next stage need be determined by considering the required global power. Recall that \( n_{1} \) and \( n_{2} \) are the sample sizes at the end of stage I and II respectively. For simplicity we assume \( n_{r} = n_{c} = n_{j}/2 \). Then under \( H_{0} \),

\[
T_{j} = \sqrt{n_{j}} \frac{\bar{x}_{j}^{(j)} - \bar{x}_{c}^{(j)}}{2\sigma} \sim N(0, 1), \quad (j = 1, 2).
\]

Under \( H_{1} \),

\[
(T_{1}, T_{2})^{T} \sim N(\mu, \Omega),
\]

\[
\mu = \begin{bmatrix} \sqrt{\frac{n_{c} \omega (\mu_{c} - \mu_{j})}{2\sigma}} \\ \sqrt{\frac{n_{j} \omega (\mu_{j} - \mu_{c})}{2\sigma}} \end{bmatrix},
\]

\[
\Omega = \left( 1 + \frac{\omega (1 - \omega) (\mu_{c} - \mu_{j})^{2}}{2\sigma^{2}} \right) \begin{bmatrix} 1 & \frac{n_{1}}{\sqrt{n_{2}}} \\ \frac{n_{2}}{\sqrt{n_{1}}} & 1 \end{bmatrix},
\]

with family-wise power function

\[
\beta = P_{H_{1}} \left( |T_{1}| \geq b_{1} \right) + P_{H_{1}} \left( |T_{2}| \geq \frac{b_{2}}{\sqrt{2}} \left| T_{1} \right| < b_{1} \right),
\]

\[
= P_{H_{1}} \left( |T_{1}| \geq b_{1} \right) + \frac{P_{H_{1}} \left( |T_{2}| < b_{2} / \sqrt{2} \left| T_{1} \right| < b_{1} \right)}{P_{H_{1}} \left( |T_{1}| < b_{1} \right)}.
\]

Denote \( p_{1} = P_{H_{1}} \left( |T_{1}| \geq b_{1} \right) \) and

\[
p(n_{j}) = P_{H_{1}} \left( |T_{2}| < b_{2} / \sqrt{2} \left| T_{1} \right| < b_{1} \right),
\]

which is determined by \( n_{j} \) given other parameters. Then \( n_{j} \) is determined by the least integer satisfies

\[
p_{1} + 1 - \frac{p(n_{j})}{1 - p_{1}} \geq 1 - \beta, \quad \text{or} \quad (p_{1} + \beta)(1 - p_{1}) \geq p(n_{j}).
\]

**Simulation Study**

Extensive simulation studies are conducted to compare three methods, the method of Gao, Roy and Tan [13], the proposed nonparametric Bayesian method, and the parametric maximum likelihood (MLE) based method. We considered both truncated normal and skewed normal (with skewness parameter \( \alpha \)). The reason for the first is that the treatment effects should be negative values; the latter represent departure from the normality assumption. For the sequential test, we assume \( n_{1} = n_{j}/2 \), i.e., the sample sizes are the same for the two stages. If the re-estimated sample size is less than \( n_{j} \), we will keep the original design. Moreover, the estimation of \( \hat{\sigma}^{2} \) can be obtained using the formula below

\[
\hat{\sigma}^{2} = \frac{\hat{\sigma}^{2} + \omega_{b} (1 - \omega_{b}) (\hat{\mu}_{r} - \hat{\mu}_{c})^{2}}{\hat{\omega}}
\]

which is the formula we actually used in the simulation study.

The results are displayed in Table 1, Table 2, Table 3, Table 4 and Table 5, with different parameter settings and sample sizes, with estimated treatment effects \( \mu_{r} \), \( \mu_{j} \), their difference \( \hat{\theta} \), test result, and estimated sample size \( \hat{n}_{z} \), (if the null hypothesis is not rejected in stage I), the probability of reject \( H_{0} \) (so not continue the trial to stage II). In all the tables, results from the method of Gao, Roy and Tan [13] is named `empirical`; the proposed method, named `NP Bayes`, and the MLE with EM-algorithm, named `MLE(EM)`, are compared. The sample size estimate \( n_{j} \) depends on the estimated PPV is not stable. So we display the mean, median and trimmed mean (with trim proportion 10% on both sides) from all three methods, with 500 repetitions. Also, the corresponding disease prevalence (prev), sensitivity (sen), specificity (spec), the true \( \omega_{b} \) and the effect size (EF, \( \left| \text{mean} \right| /s.d \)) used in the simulation are given at the top of each Table.

To reflect the effects on estimated sample size of the skewness of the skewed normal and of EF, Figure 1, Figure 2, Figure 3 and Figure 4 are shown for the mean and trimmed mean estimation methods below. We see that the empirical Bayesian estimate seems more rea-
From the Tables, the empirical and non-parametric Bayesian estimates are close to each other when the sample size is relatively large, which is consistent with reasonable, the empirical methods tend to over-estimate the sample size, and the MLE tends to under estimate it, and that the trimed mean method is much more stable. For comparison, we altered settings for parameters and kept EF the same for each graph.

From the Tables, the empirical and non-parametric Bayesian estimates are close to each other when the sample size is relatively large, which is consistent with

formed the best in the proposed adaptive design since they are more robust and require weak assumption on prior. They utilize the prior information but are not too dependent on prior selection. In smaller scales, it could reduce the unexpected variance, which may lead to large sample size increase in the next stage. In addition, they asymptotically converged to empirical estimators, indicating unbiasedness with large sample sizes.

**Concluding Remarks**

We have proposed a nonparametric Bayesian method for the two-stage adaptive biomarker-targeted clin-
clinical trial design. Compared with the existing parametric model, it has the advantage of incorporating prior information into the design, and being robust to model assumption. Extensive simulation studies are conducted to evaluate the performance of the proposed method, and compare with the commonly used methods for this problem. In our simulation studies, we considered the non-skewed and skewed, to reflect correct and incorrect model specifications. It was found that the skewness will influence the estimation accuracy in this design. The estimate is most accurate with left-skewed distributions, least accurate with right-skewed distributions, and modest with truncated normal distributions. Cases gave moderate results, and would be the hardest to estimate. Moreover, the more left-skewed, the more accurate for the estimations.

Appendix

EM Formula Derivation.

Denote $\phi_1$ for the pdf of $N(\mu_T, \sigma^2)$, $\phi_2$ for that of $N(\mu_C, \sigma^2)$. Under the normal model assumption, the likelihood is the following mixture

$$f_X(X | D_{ni}) = \prod_{i=1}^{n_T} \left[ \omega \phi_1(X_{iT}) + (1-\omega) \phi_2(X_{iT}) \right] \times \prod_{j=1}^{n_C} \phi_2(X_{iC})$$

It is known that parameter estimation in mixture model is not easy, and often the EM algorithm is used for such computation. For this, let $z_i$ be the treatment latent indicator of the $i$-th observation, i.e., $z_i = 1$ as belonging to the treatment group (with pdf $\phi_1$) and $z_i = 0$ for the control group (with pdf $\phi_2$), and denote $Z = (z_1, z_2, \ldots, z_n)$.

Then based on the `complete' data $(X, Z)$, the likelihood is

$$f_X(X | D_{ni}, Z) = \prod_{i=1}^{n_T} \left[ (\omega \phi_1(X_{iT}))^{z_i} ((1-\omega) \phi_2(X_{iT}))^{1-z_i} \right] \times \prod_{j=1}^{n_C} \phi_2(X_{iC})$$

and the corresponding log-likelihood is

$$\ell(\beta | D_{ni}, Z) = \sum_{i=1}^{n_T} \left\{ z_i [\log(\omega) + \log \phi_1(X_{iT})] + (1-z_i)[\log(1-\omega) + \log \phi_2(X_{iT})] \right\} + \sum_{j=1}^{n_C} \log \phi_2(X_{iC})$$

Given the $k$-th iteration value $\beta^{(k)} = (\mu_T^{(k)}, \mu_C^{(k)}, \sigma_T^{(k)}, \omega^{(k)})$, in the E-step we compute

$$z_i^{(k)} = E(z_i | \beta^{(k-1)}, Z^{(k-1)}) = P(z_i = 1 | \beta^{(k-1)}, Z^{(k-1)})$$

$$= \frac{\omega^{(k-1)} \phi_1(x_iT | \mu_T^{(k-1)}, \sigma_T^{(k-1)})}{\omega^{(k-1)} \phi_1(x_iT | \mu_T^{(k-1)}, \sigma_T^{(k-1)}) + (1-\omega^{(k-1)}) \phi_2(x_iC | \mu_C^{(k-1)}, \sigma_C^{(k-1)})}$$

In the M-step, we set

$$\frac{\partial \ell}{\partial \omega} = 0, \quad \frac{\partial \ell}{\partial \mu_T} = 0, \quad \frac{\partial \ell}{\partial \mu_C} = 0, \quad \frac{\partial \ell}{\partial \sigma_T} = 0$$

to get the following equations (Unrelated terms omitted):

$$\sum_{i=1}^{n_T} \left( \frac{1}{\sigma_T^{(k)}} z_i^{(k)} - \frac{1}{1-\omega^{(k)}} \sum_{i=1}^{n_T} (1-z_i^{(k)}) \right) = 0,$n_T \sum_{i=1}^{n_T} z_i^{(k)} (x_{iT} - \mu_T^{(k)}) = 0,$$

$$\sum_{i=1}^{n_T} (1-z_i^{(k)}) (x_{iT} - \mu_C^{(k)}) + \sum_{i=1}^{n_C} (x_{iC} - \mu_C^{(k)}) = 0,$$

$$\sum_{i=1}^{n_T} \left( (1-z_i^{(k)}) \left[ -\frac{1}{2\sigma_T^{(k)}} + \frac{(x_{iT} - \mu_T^{(k)})^2}{2\sigma_T^{(k)}} \right] + z_i^{(k)} \left[ -\frac{1}{2\sigma_T^{(k)}} + \frac{(x_{iT} - \mu_C^{(k)})^2}{2\sigma_C^{(k)}} \right] \right) + \sum_{i=1}^{n_C} \left[ -\frac{1}{2\sigma_C^{(k)}} + \frac{(x_{iC} - \mu_C^{(k)})^2}{2\sigma_C^{(k)}} \right] = 0.$$

Then we have

$$\omega^{(k)} = \frac{1}{n_T} \sum_{i=1}^{n_T} z_i^{(k)}, \quad \mu_T^{(k)} = \frac{\sum_{i=1}^{n_T} x_{iT} z_i^{(k)}}{\sum_{i=1}^{n_T} z_i^{(k)}},$$

$$\mu_C^{(k)} = \frac{\sum_{i=1}^{n_C} x_{iC} + \sum_{i=1}^{n_T} (1-z_i^{(k)}) x_{iT}}{n_C + \sum_{i=1}^{n_T} (1-z_i^{(k)})},$$

$$\sigma_T^{(k)} = \frac{\sum_{i=1}^{n_T} \left[ (1-z_i^{(k)}) (x_{iT} - \mu_T^{(k)})^2 + z_i^{(k)} (x_{iT} - \mu_C^{(k)})^2 \right] + \sum_{i=1}^{n_C} (x_{iC} - \mu_C^{(k)})^2}{n_T + n_C}.$$
