ABSTRACT

We present spectra taken with the Infrared Spectrograph on Spitzer covering the 5–38 μm region of the 10 ultraluminous infrared galaxies (ULIRGs) found in the IRAS Bright Galaxy Sample (BGS). There is a factor of 50 spread in the rest-frame 5.5–60 μm spectral slopes, and the 9.7 μm silicate optical depths range from at least τ9.7 ≤ 0.4 (Aγ ≤ 78). There is evidence for water ice and hydrocarbon absorption and C2H2 and HCN absorption features in 4 and possibly all 6 of the BGS ULIRGs, indicating shielded molecular clouds and a warm, dense ISM. We have detected [Ne v] emission in 3 of the 10 BGS ULIRGs, at flux levels of 5–18 × 10^{-14} ergs cm^{-2} s^{-1} and [Ne v] 14.3/Ne ii] 12.8 line flux ratios of 0.12–0.85. The remaining BGS ULIRGs have limits on their [Ne v]/[Ne ii] line flux ratios, which range from 0.15 to <0.01. Among the BGS ULIRGs, the AGN fractions implied by either the [Ne v]/[Ne ii] or [O iv]/[Ne ii] line flux ratios (or their upper limits) are significantly lower than implied by the MIR slope or strength of the 6.2 μm PAH EQW feature. There is evidence for hot (T > 300 K) dust in five of the BGS ULIRGs, with the fraction of hot dust to total dust luminosity ranging from ~1% to 23%, before correcting for extinction. When integrated over the IRAC-8, IRS blue peak-up, and MIPS-24 filter bandpasses, the IRS spectra imply very blue colors for some ULIRGs at z ~ 1.3. The large range in diagnostic parameters among the nearest ULIRGs suggests that matching survey results to a small number of templates may lead to biased results about the fraction of luminous dusty starbursts and AGNs at high z.

Subject headings: galaxies: active — galaxies: starburst — infrared: galaxies

1. INTRODUCTION

Ultraluminous Infrared Galaxies (ULIRGs), i.e., those galaxies with infrared luminosity LIR ≥ 10^{12} L_{⊙}, have the power output of quasars, yet emit nearly all of their energy in the mid- and far-infrared part of the spectrum. Most ULIRGs are found in interacting and merging systems (e.g., Armus et al. 1987; Sanders et al. 1988a; Murphy et al. 1996), where the merger has driven gas and dust toward the remnant nucleus, fueling a massive starburst and either creating or fueling a nascent active galactic nucleus (AGN; Mihos & Hernquist 1996). ULIRGs are rare in the local universe, comprising only 3% of the IRAS Bright Galaxy Sample (Soifer et al. 1987), yet at z > 2–3, ULIRGs may account for the bulk of all star formation activity and dominate the far-infrared background (e.g., Blain et al. 2002).

Observations with the Infrared Space Observatory (ISO) satellite greatly expanded our understanding of the mid-infrared spectra of ULIRGs (e.g., Genzel et al. 1998; Lutz et al. 1999; Rigopoulou et al. 1999; Sturm et al. 2002; Tran et al. 2001). Diagnostic diagrams based on fine-structure lines and aromatic emission features allowed some ULIRGs to be classified according to their dominant ionization mechanism. However, the complexities of the ULIRG spectra, the fact that many are likely composite AGN and starburst sources, and the limitations in sensitivity of the ISO spectrometers, left many ULIRGs, even at relatively low redshift, beyond the reach of these methods, until now.

In order to adequately sample the local ULIRG population and to test the range of mid-infrared diagnostic tools for uncovering buried AGNs, we have obtained mid-infrared spectra of a large number (>100) of ULIRGs having redshifts of 0.02 < z < 0.93 with the Infrared Spectrograph (IRS) on Spitzer as part of the IRS team Guaranteed Time program. These sources are chosen primarily from the IRAS 1 Jy (Kim & Sanders 1998), 2 Jy (Strauss et al. 1992), and the FIRST/IRAS radio—far-IR sample of Stanford et al. (2000). In this paper, we present IRS spectra of the 10 ULIRGs in the IRAS Bright Galaxy Sample (Soifer et al. 1987). The Bright Galaxy Sample (BGS) is a flux-limited, complete sample of all 324 galaxies with 60 μm IRAS flux densities greater than 5.4 Jy in the IRS Point Source catalog (IPAC 1985). The 10 ULIRGs in the BGS are IRAS 05189–2524, IRAS 08572+3915, IRAS 09320+6134 (UGC 5101), IRAS 12112+0305, IRAS 12540+5708 (Mrk 231), IRAS 13428+5608 (Mrk 273), IRAS 14348–1447, IRAS 15250+3609, IRAS 15327+2340 (Arp 220), and IRAS 22491–1808. An earlier reduction of the spectra of UGC 5101 was previously presented in Paper I of this series (Armus et al. 2004), and the silicate absorption properties of IRAS 08572+3915 have been discussed in Spoon et al. (2006). The basic properties of the sample are listed in Table 1. Throughout the paper,
we adopt a flat, $\Lambda$-dominated universe ($H_0 = 70 \, \text{km s}^{-1} \, \text{Mpc}^{-1}$, $\Omega_M = 0.3$, $\Omega_\Lambda = 0.7$).

### 2. OBSERVATIONS AND DATA REDUCTION

The ULIRGs were observed in the two low-resolution (64 < $R$ < 128; Short-Low and Long-Low or SL and LL) and the two high-resolution ($R$ ~ 650; Short-High and Long-High or SH and LH) IRS modules, using the Staring Mode Astronomical Observing Template (AOT). The galaxies were placed at the two nod positions for each of the IRS slits. High-accuracy IRS blue peak-ups were performed on nearby 2MASS stars for 7 of the 10 BGS sources before offsetting to the target galaxies. For IRAS 12112+0305, IRAS 14348–1447, and IRAS 22491–1808 we performed high-accuracy IRS blue peak-ups on the nuclei themselves. IRAS 08572+3915, IRAS 12112+0305, and IRAS 14348–1447 have well-resolved double nuclei (see Condon et al. 1990; Evans et al. 2000, 2002). In the case of IRAS 08572+3915, the IRS observations were centered on the northwest nucleus, which dominates the near and mid-infrared emission (Soifer et al. 2000). For IRAS 12112+0305 and IRAS 14348–1447, the slits were centered on the northeast and southwest nuclei, respectively. Details of the observations are given in Table 2. The IRS is fully described in Houck et al. (2004).

All spectra were reduced using the S11 IRS pipeline at the Spitzer Science Center. This reduction includes ramp fitting, dark sky subtraction, droop correction, linearity correction, and wavelength and flux calibration. One-dimensional (1D) spectra were extracted from the IRS data products using the SMART data reduction package (Higdon et al. 2004). For the SH and LH data, we performed full slit extractions. For the SL and LL data, we used an extraction aperture that expanded linearly with wavelength but was set to 4 pixels at the blue end of each order. The SL and LL data have had local background light subtracted by differencing the adjacent subslit position (order) before spectral extraction. The projected extraction apertures in units of kiloparsecs are given in Table 1. While the apertures project to relatively large areas for the more distant systems, the slits are always matched to the Spitzer beam, and therefore, for compact MIR sources such as ULIRGs, the flux we measure is dominated by the central source. Of the three sources with IRS peak-up data, IRAS 22491–1808 is unresolved while IRAS 12112+0305 and IRAS 14348–1447 are marginally resolved at the ~10%–15% level.

### TABLE 1

**BGS ULIRGs**

| Object | $z$ | Distance (Mpc) | log ($L_\text{IR}(L_\odot)$) | SL (kpc) | SH (kpc) | LL (kpc) | LH (kpc) |
|--------|----|---------------|----------------------------|---------|---------|---------|---------|
| IRAS 12540+5708 (Mrk 231) | 0.042 | 183.9 | 12.57 | 3.2 × 6.4 | 4.2 × 10.1 | 9.4 × 18.8 | 9.9 × 19.8 |
| IRAS 15327+2340 (Arp 220) | 0.018 | 77.6 | 12.16 | 1.4 × 2.8 | 1.8 × 4.3 | 4 × 8 | 4.2 × 8.4 |
| IRAS 05189–2524 | 0.042 | 185.7 | 12.16 | 3.2 × 6.4 | 4.2 × 10.1 | 9.5 × 19 | 10 × 20 |
| IRAS 13428+5608 (Mrk 273) | 0.038 | 164.3 | 12.15 | 2.9 × 5.8 | 3.7 × 8.2 | 8.4 × 16.8 | 8.8 × 17.6 |
| IRAS 08572+3915 | 0.058 | 257.6 | 12.14 | 4.5 × 9 | 5.9 × 14.2 | 13.1 × 26.2 | 13.9 × 27.8 |
| IRAS 15250+3609 | 0.055 | 243.9 | 12.05 | 4.3 × 8.6 | 5.6 × 13.4 | 12.4 × 24.8 | 13.1 × 26.2 |
| Arp 220 | 0.039 | 174.3 | 12.00 | 3 × 6 | 4 × 9.6 | 8.9 × 17.8 | 9.4 × 18.8 |
| Mrk 231 | 0.077 | 345.9 | 12.19 | 6 × 12 | 7.9 × 19 | 17.6 × 35.2 | 18.6 × 37.2 |
| IRAS 12112+0305 | 0.073 | 324.2 | 12.33 | 5.7 × 11.4 | 7.4 × 17.8 | 16.5 × 33 | 17.4 × 34.8 |
| IRAS 14348–1445 | 0.083 | 371.7 | 12.35 | 6.5 × 13 | 8.5 × 20.4 | 18.9 × 37.8 | 20 × 40 |

**Table Note.** Basic properties of the BGS ULIRGs. The 8–1000 $\mu$m IR luminosities are derived from the IRS data, using the prescription of Penult (1987). The projected spectral apertures (slit width by effective slit length) are given in kiloparsecs for all sources. For the low-resolution slits, a 4 pixel effective slit length is given, corresponding to the blue end of the extraction aperture that expands with wavelength; see text for details.

### TABLE 2

**IRS Observation Log**

| Object | Date | Peak-up | SL1 | SL2 | LL1 | LL2 | SH | LH |
|--------|------|---------|-----|-----|-----|-----|----|----|

| IRAS 14348–1447 | 2004 Feb 07 | BPU | 1 × 60 | 1 × 60 | 2 × 30 | 2 × 30 | 2 × 120 | 4 × 60 |

**Notes.**—The observation date, IRS peak-up type, and integration times for each IRS slit are given for the 10 BGS ULIRGs. IRS peak-ups for all sources used the blue array and high-accuracy, but were performed on offset stars selected via the Staring Mode AOT for the first seven ULIRGs. In each case, the quantity is cycle × ramp time (s) for a single nod in staring mode. There are always two nod positions per IRS slit.

* The SL and LL observations for UGC 5101 were performed on 2004 March 23, while the SH and LH observations were performed on 2003 November 15.
Fig. 1.—IRS Short-Low and Long-Low spectra of the 10 BGS ULIRGs in order of decreasing 25 μm flux density. Prominent emission features and absorption bands (the latter indicated by horizontal bars) are marked on representative spectra. Not all features are marked on all spectra; see Tables 3 and 4 for measured features. Expanded views of the 5–14 μm regions (Short-Low) of each spectrum are shown at the end.
3. RESULTS

3.1. Continuum and Dust Features

Broad emission features associated with polycyclic aromatic hydrocarbons (PAHs) at 6.2, 7.7, 8.6, 11.3, and 12.7 μm, along

with absorption from amorphous silicates centered at 9.7 and 18 μm, dominate the spectra in nearly all cases (see Fig. 1). We also often detect the weaker PAH emission at 14.2, 16.4, 17.1, and 17.4 μm. The broad 17.1 μm feature sits under both the 16.4 and 17.4 μm PAH features (see Smith et al. 2004) and the H2 S(1) line, which is often prominent in the ULIRG spectra (see below). There is a large range in spectral shape across the IRS wavelength range (5–38 μm) among the sample galaxies. IRAS 05189+2524 and Mrk 231 have relatively flat spectra with weak silicate absorption and weak PAH emission. At the other extreme are sources like UGC 5101 and IRAS 14348+1447, which have very strong PAH emission, deep silicate absorption, and water ice (most easily seen as a strong absorption from 5.5 to 6.5 μm, under the 6.2 μm PAH emission feature). Water ice absorption is also evident in Arp 220, Mrk 273, and IRAS 15250+3609. This absorption, suggested by Spoon et al. (2002) to be indicative of shielded molecular clouds along the line of sight to the nucleus, appears to be common among nearby ULIRGs, appearing in half of the BGS sources. Note that although the 5.5–6.5 μm absorption is dominated by water ice, hydrocarbon absorption at 6.85 and 7.25 μm is often evident redward of the 6.2 μm PAH emission feature (see Spoon et al. 2005). IRAS 08572+3915 has a very interesting spectrum, since it shows extremely strong silicate absorption at both 9.7 and 18 μm, but no PAH emission. For the BGS sample as a whole, the silicate optical depths range from τ9.7 < 0.4 (A_V < 7.9 mag) in IRAS 05189+2524 to τ9.7 = 4.2 (A_V = 78 mag) in IRAS 08572+3915, adopting a smooth continuum anchored at 5.3–5.6 μm, 14 μm (for the PAH-dominated sources), 34 μm, and A_V/τ9.7 = 18.5 from Roche & Aitken (1984). Optical depths measured in this way are always lower limits to the “true” optical depth (see below). The IRS low-resolution spectra of the 10 BGS ULIRG are shown together in

Fig. 1.—Continued
We also detect absorption features from gas-phase interstellar C$_2$H$_2$ and HCN at 13.7 and 14.0 $\mu$m, respectively, in 4 of the 10 BGS ULIRGs, namely Mrk 231, Arp 220, IRAS 08572+3915, and IRAS 15250+3609. Both absorption features are detected in all galaxies, although the HCN line in Mrk 231 is uncertain due to a continuum “jump” just redward of the absorption. These features are labeled in Figure 3. Weak C$_2$H$_2$ absorption may also be present in IRAS 05189–2524 and Mrk 273, but in these galaxies the HCN line is not detected. Fluxes and equivalent widths (EQWs) for the C$_2$H$_2$ absorption-line range from $5 \times 10^{-21}$ W cm$^{-2}$ s$^{-1}$ and 0.002–0.012 $\mu$m, respectively, with IRAS 15250+3609 having the deepest C$_2$H$_2$ absorption and Mrk 231 having the shallowest absorption among the four ULIRGs. Fluxes and EQWs for the HCN line are smaller, in the range $2 \times 6 \times 10^{-21}$ W cm$^{-2}$ s$^{-1}$ and 0.002–0.007 $\mu$m, respectively, again with IRAS 15250+3609 showing the deepest absorption. The strengths of the C$_2$H$_2$ and HCN features, as well as the measured temperature and column density of the gas, can be used to constrain the temperature of the gas and, in some cases, its chemical evolutionary state (e.g., Lahuis & van Dishoeck 2000; Boonman et al. 2003). A detailed analysis of these lines in ULIRGs will be presented in a future paper (Lahuis et al. 2007). However, the positions of the line centroids at 13.7 and 14.0 $\mu$m already suggest that a warm gas component of $\sim 200–400$ K dominates the absorption in Mrk 231, Arp 220, IRAS 08572+3915, and IRAS 15250+3609.

3.2. Emission Lines

The high-resolution (SH and LH) ULIRG spectra are dominated by unresolved atomic fine-structure lines of Ne, O, Si, and S covering a large range in ionization potential (see Figs. 3 and 4 and Tables 3 and 4). Ratios of the fine-structure lines can be used...
to gauge the dominant ionizing source, either hot stars or an active nucleus. Some features, e.g., the [Ne v] lines at 14.3 and 24.3 μm, imply the presence of an AGN by their very detection in a galaxy spectrum, since it takes 97.1 eV to ionize Ne⁵⁺, and this is too large to be produced by O stars. [Ne v] emission is seen in the spectra of individual Galactic planetary nebulae (Bernard-Salas et al. 2001; Pottasch et al. 2001), but not in the integrated nuclear (many kpc) spectrum of a galaxy unless an AGN is present. The same is not true for [O iv], since it takes only 55 eV to ionize O²⁺. The 25.9 μm line has been seen in a number of pure starburst galaxies (e.g., Lutz et al. 1998; Smith et al. 2004; D. Devost et al. 2007, in preparation).

Of the 10 BGS ULIRGs, we have detected [Ne v] emission in 3: IRAS 05189−2524, Mrk 273, and UGC 5101. The detection of [Ne v] in UGC 5101 has been previously reported by Armus et al. (2004). The fluxes in the 14.32 μm lines are 18.36, 12.86, and 5.10 × 10⁻¹⁴ ergs cm⁻² s⁻¹ in IRAS 05189, Mrk 273, and UGC 5101, respectively. In all three galaxies, we detect both the 14.32 and 24.32 μm [Ne v] lines. The 14.32 μm emission line was also seen in the short wavelength spectrometer (SWS) spectrum of Mrk 273 (Genzel et al. 1998) at a level of 8 × 10⁻¹⁴ ergs cm⁻² s⁻¹, about 50% less than our measured flux. For sources undetected in [Ne v] with both the SWS (Genzel et al. 1998) and the IRS, the limits are typically a factor of ~10−20 lower in the IRS data than the SWS data. The nearby, low-ionization [Cl ii] feature at 14.37 μm can easily be mistaken for [Ne v], but the resolution of the IRS and the high signal-to-noise ratio (S/N) of our data allow us to separate out the two lines in all cases. We have detected the [Cl ii] line in 5/10 of the BGS ULIRGs. In some cases (e.g., Mrk 273) both the [Ne v] and the [Cl ii] lines are detected. In others (e.g., Arp 220) only the [Cl ii] line is seen.

The [S iii] 18.71/[S ii] 33.48 line flux ratio can be used as a diagnostic of the density of the ionized gas. For the BGS ULIRGs, this ratio ranges from a lower limit of ≥0.17 in Arp 220 to ~0.65 in IRAS 22491−1808, implying electron densities ranging from the low-density limit (for gas at T = 10⁴ K) to about 200−300 cm⁻³. The average [S iii] 18.71/[S ii] 33.48 line flux ratio for the BGS ULIRGs with both lines detected is 0.51, implying an average electron density of about 100−200 cm⁻³. Our average ratio is consistent with that found for most of the starburst galaxies analyzed by Verma et al. (2003). It is important to note, however, that the [S ii] line fluxes have not been corrected for extinction, so the intrinsic [S iii] 18.71/[S ii] 33.48 line flux ratio and the corresponding densities are likely to be higher than reported here. We do not know the extinction to the ionized gas, but an A_v = 10 mag would cause us to underestimate the [S ii] line flux ratio, and hence the densities, by up to a factor of ~2−3.

In addition to the fine-structure lines, the pure rotational lines of H₂ [e.g., S(3) 9.66, S(2) 12.28, and S(1) 17.03] are often very strong in the BGS ULIRGs. The H₂ lines can be used to determine the temperature and mass of (warm) molecular gas. All 10 BGS ULIRGs can be fit with at least one temperature component, and three galaxies (Arp 220, IRAS 12112+0305, and IRAS 14348−1447) require two components, due to the detection of the S(7) lines, which indicate the presence of a hot (T ~ 1200 K) component. From fits to the S(1) through S(3) lines, the BGS ULIRGs have molecular gas temperatures of about 260−360 K and masses of about 3 × 10⁷ M☉ (IRAS 08572+3915) up to 120 × 10⁷ M☉ (IRAS 12112+0305). This is typically a few percent of the cold molecular gas mass as derived from 12CO observations. The hot (~1200 K) gas that dominates the S(7) emission typically has a mass that is a factor of 50−100 lower than the gas at ~300 K. The state of the warm molecular gas in our larger sample of ULIRGs, including the BGS ULIRGs, is discussed fully in Higdon et al. (2006).
3.3. Diagnostic Diagrams

We present [Ne v] 14.3/[Ne ii] 12.8 and [O iv] 25.9/[Ne ii] 12.8 diagnostic emission line flux ratio diagrams for the ULIRGs in Figures 5 and 6. In both cases the fine-structure line ratio is plotted against the 6.2 $\mu$m PAH equivalent width (EQW) in microns, and a sample of AGNs and starburst galaxies observed with the IRS are shown for comparison (D. Devost et al. 2007, in preparation; Brandl et al. 2006; Weedman et al. 2005; Hao et al. 2005). The AGNs included are I Zw 1, NGC 1275, Mrk 3, PG 0804+761, PG 1119+120, NGC 4151, PG 1211+143, 3C 273, Cen A, Mrk 279, PG 1351+640, Mrk 841, and PG 2130+099. The starbursts included are NGC 660, NGC 1222, IC 342, NGC 1614, NGC 2146, NGC 3256, NGC 3310, NGC 4088, NGC 4385, NGC 4676, NGC 4818, NGC 7252, and NGC 7714. The ULIRGs Mrk 1014, Mrk 463e (Armus et al. 2004), and NGC 6240 (Armus et al. 2006) have been added to the BGS ULIRG spectra in Figures 5 and 6. Since both [Ne v] and [O iv] are much stronger in AGNs than starburst galaxies, while the 6.2 $\mu$m PAH lines are derived from single Gaussian fits to the high-resolution IRS data, except for lines blueward of ~9.6 $\mu$m, which are only measured in the low-resolution spectra. Uncertainties in the fluxes and equivalent widths are listed in parentheses, and are the larger of either the Gaussian fit, or the difference in the two nod positions. Upper limits (3 $\sigma$) are given for undetected, key diagnostic features.

| Line | Flux ($10^{-14}$ ergs cm$^{-2}$ s$^{-1}$) | Rest-frame Equivalent Width ($10^{-3}$ $\mu$m) |
|------|--------------------------------|----------------------------------|
|      | Mrk 231 | Arp 220 | IRAS 05189–2524 | Mrk 273 | IRAS 08572+3915 |
| PAH 6.2 | 78.6 (±29.6) | 225 (±16) | 72.2 (±5.1) | 149 (±22) | <36.2 |
| PAH 7.7 | 10.9 (±4.2) | 253.3 (±17.2) | 34.5 (±0.8) | 171.0 (±31.1) | <12.3 |

**Notes.**—Fine-structure lines, H$_2$ emission lines, and PAH emission features in the BGS ULIRG spectra. The flux and the rest-frame equivalent width are given for each line. The equivalent widths are listed directly below the fluxes for each emission line. In most cases, the fluxes and equivalent widths of the fine-structure and H$_2$ lines are derived from single Gaussian fits to the high-resolution IRS data, except for lines blueward of ~9.6 $\mu$m, which are only measured in the low-resolution spectra. Uncertainties in the fluxes and equivalent widths are listed in parentheses, and are the larger of either the Gaussian fit, or the difference in the two nod positions. Upper limits (3 $\sigma$) are given for undetected, key diagnostic features.

Notes.—Spectral features in the remaining five BGS ULIRG spectra. Fine-structure lines, H₂ emission lines, and PAH emission features in the BGS ULIRG spectra. The flux and the rest-frame equivalent width are given for each line. The equivalent widths are listed directly below the fluxes for each emission line. In most cases, the fluxes and equivalent widths of the fine-structure and H₂ lines are derived from single Gaussian fits to the high-resolution IRS data, except for lines blueward of ~9.6 μm, which are only measured in the low-resolution spectra. Uncertainties in the fluxes and equivalent widths are listed in parentheses, and are the larger of either the Gaussian fit, or the difference in the two nod positions. Upper limits (3σ) are given for undetected, key diagnostic features.

In the simplest interpretation of Figures 5 and 6, ULIRGs scatter between the location of pure AGNs (detected [Ne v], little or no PAH emission) and pure starbursts (strong PAH emission, no [Ne v], and weak or absent [O iv]). Hot dust reduces the apparent strength of the 6.2 μm PAH EQW, even if vigorous star formation is present. In both the [Ne v] and [O iv] diagrams, we also indicate simple, linear mixing lines (i.e., Sturm et al. 2002) along both axes that are meant to roughly indicate the percentage of AGNs and starbursts contributing to the emission in a particular object. The vertical red lines (along the [Ne v]/[Ne ii] or [O iv]/[Ne ii] axes) indicate the percentage of the emission that is being generated by an AGN. In both cases the 100% level is taken to be the average of the line ratio in the AGN with detected emission. As the fractional contribution from the AGN decreases (or equivalently the fractional contribution from a starburst increases), the [Ne v]/[Ne ii] and [O iv]/[Ne ii] line flux ratios drop. The horizontal green lines (along the 6.2 μm axes) indicate the percentage of the emission that is being generated by a starburst. As the fractional contribution from the starburst drops (or equivalently the fractional contribution from an AGN increases), the PAH EQW gets smaller. Here, the 100% level is taken to be the average of the 6.2 μm EQW in the pure starburst galaxies. The drop in
6.2 μm EQW with decreasing starburst (increasing AGN) fraction is probably due to both a decrease in the PAH emission and an increase in the amount of hot dust continuum (see below). There is significant scatter in the [Ne v]/[Ne ii] and [O iv]/[Ne ii] line flux ratios among the AGNs, some of which may be due to circumnuclear star formation (although they generally have very low 6.2 μm PAH EQWs) and some of which is likely to be intrinsic. Ionization models (Voit 1992) suggest a large scatter in the line flux ratios due to variations in ionization parameter and spectral index.

There is a large range in [Ne v]/[Ne ii] (0.015 to 1.58), [O iv]/[Ne ii] (0.051 to 6.23), and 6.2 PAH EQW (0.006 to 0.517 μm) among the 13 ULIRGs depicted in Figures 5 and 6. In both plots, Mrk 463e (IRAS 12112+0305) has the largest (smallest) line flux ratio, although strictly speaking IRAS 12112+0305 has only the most stringent upper limit, since it is undetected in both [Ne v] and [O iv]. IRAS 22491−1808 has the largest 6.2 PAH EQW, 0.59 μm, among the sample ULIRGs. In both the [Ne v]/[Ne ii] and [O iv]/[Ne ii] excitation diagrams, the ULIRGs scatter between the AGNs and the starburst galaxies. The objects that
would be considered pure AGNs, and for which the active nucleus dominates the bolometric luminosity, generally have [Ne \text{v}] / [Ne \text{ii}] line flux ratios of 1–3 and 6.2 \mu m equivalent widths less than 0.005–0.02 \mu m. The starburst galaxies have [Ne \text{v}] / [Ne \text{ii}] ratios (6.2 \mu m PAH EQWs) that are generally a factor of 50–100 smaller (larger) than the pure AGN values. The linear mixing lines suggest that the ULIRGs Mrk 463e, IRAS 05189–2524, and Mrk 1014 are dominated by central AGNs, since they have AGN contributions above 50% in [Ne \text{v}] / [Ne \text{ii}], perhaps not surprising since all are optically classified as Seyfert galaxies. While IRAS 05189–2524 and Mrk 1014 have PAH emission, it is at least an order of magnitude weaker than in the starburst galaxies, and therefore young stars likely contribute less than 10% of the power in these ULIRGs. The [O \text{iv}] / [Ne \text{ii}] ratio in IRAS 05189–2524 suggests an AGN contribution a bit lower than does the [Ne \text{v}] / [Ne \text{ii}] ratio (~30% versus 60%), but given the uncertainties and the extremely weak 6.2 \mu m PAH emission, the AGN dominating the energetics is likely in this source.

Conversely, ULIRGs such as IRAS 12112+0305 and IRAS 22491–1808, which have large 6.2 \mu m EQWs (0.52 and 0.59 \mu m, respectively), comparable to the starburst galaxies, and no [Ne \text{v}] detections, are likely to have their bolometric luminosities dominated by young stars. The same is true for both IRAS 14348–1447 and Arp 220, since both have very stringent limits on [Ne \text{v}], although their 6.2 \mu m PAH EQWs are about half that seen in the majority of the pure starburst galaxies. IRAS 12112+0305, IRAS 14348–1447, and Arp 220 are all characterized as starbursts from their L-band spectra, since they have relatively strong 3.3 \mu m PAH emission (Imanishi et al. 2006). Both Mrk 273 and UGC 5101 have [Ne \text{v}], [O \text{iv}], and 6.2 \mu m PAH EQWs that fall in between pure starbursts and AGNs, suggesting that a central engine and young stars contribute measurably to their luminosity. Both galaxies have relatively weak 6.2 \mu m emission (after correcting for water ice absorption, which is very strong in UGC 5101), suggesting that star formation contributes about 30% of the luminosity. However, their [Ne \text{v}] and [O \text{iv}] line...
fluxes are also low (especially the [O iv] line flux in UGC 5101), implying that the AGN contribution is only about 20%–40% in Mrk 273 and less than 10% in UGC 5101. Mrk 273 is listed as AGN-dominated in Imanishi et al. (2006), based on its L-band spectrum.

Finally, there are three BGS ULIRGs, Mrk 231, IRAS 08572+3915, and IRAS 15250+3609, with seemingly inconsistent positions in Figures 5 and 6. These ULIRGs have very weak 6.2 μm PAH EQWs, at least a factor of 40–50 below that seen in pure starburst galaxies, yet none have any detectable [Ne v] or [O iv] emission. It is certainly true that the limits on [Ne v] emission in these galaxies are not nearly as stringent as other ULIRGs in our sample (e.g., IRAS 12112+0305), but their [Ne v]/[Ne ii] emission line flux ratios are still at least a factor of 5–10 below those seen in the pure AGNs. Mrk 231 is an optically classified broad-line AGN, whereas IRAS 08572+3915 and IRAS 15250+3609 are LINERs. While IRAS 15250+3609 has no published L-band spectra, both Mrk 231 and IRAS 08572+3915 are classified as AGN-dominated based on extremely weak 3.3 μm emission (Imanishi, Dudley & Maloney 2006). Along with Mrk 220, both IRAS 08572+3915 and IRAS 15250+3609 have strong molecular absorption features (see Table 5) which may indicate deeply embedded star formation (Lahuis et al. 2007).

The same general trend of the ULIRGs scattering between pure AGNs and pure starburst galaxies can be seen in Figure 7, where we plot the ratio of the [Ne v] 14.3 μm and IR flux, both uncorrected for reddening, against the IRAS far-infrared 25/60 μm flux density ratio. Here, the 8–1000 μm IR flux is derived from the IRAS data, using the prescription of Perault (1987). The 25/60 μm ratio has often been used to separate ULIRGs that are “warm” (25/60 μm > 0.2) and possibly AGN-dominated from those that are “cold” (25/60 μm ≤ 0.2) and likely to be dominated by star formation (de Grijp et al. 1985; Sanders et al. 1988b). In general, ULIRGs with warmer colors have larger [Ne v]/FIR, ranging from a low of less than about 0.02 × 10⁻¹⁷ in Arp 220 to a high of nearly 5 × 10⁻¹⁴ in Mrk 463e. Since the extinction to the [Ne v]-emitting region is unknown (see below), part of the scatter in Figure 7 may be due to the fact that we have not corrected the [Ne v] flux. However, the extremely large range in the [Ne v]/FIR ratios among AGN-dominated ULIRGs (Mrk 1014, Mrk 231, Mrk 463, and IRAS 05189+2524) and the AGN population itself suggest that extinction is not the only factor. Also notice that sources with very weak [Ne v] emission (e.g., NGC 6240 and UGC 5101) have larger [Ne v]/FIR ratios than Mrk 231, even though the lines of sight to the nuclei in the former two ULIRGs are heavily obscured.

Another way to probe the presence of an active nucleus is to trace the presence of an AGN torus directly, via the thermal emission from hot dust. It is known both from theoretical models (e.g., Pier & Krolik 1992; Granato et al. 1997) and direct observations (e.g., Alsonso-Herrero et al. 2001) that the AGN radiation field can heat dust up to temperatures of ~1000 K for silicate and ~1500 K for graphite grains. As a result, the dust continuum emission becomes prominent at short infrared wavelengths (3–6 μm).

Such a diagnostic method was proposed by Laurent et al. (2000), based on spectral data from the Infrared Space Observatory. Here, we apply this approach to our Spitzer/IRS data, making only minor modifications. As discussed in detail in Laurent et al. (2000), the diagnostic assumes that the integrated mid-IR emission can be represented by a sum of contributions from (1) regions where the dust is predominantly heated by an AGN and (2) regions where star formation is the main source of energy. Both AGNs and extreme starbursts contribute to the destruction of PAHs, as well as to the transient heating of the very small grains, leading to a strong continuum at 14–15 μm. One can select three template spectra—one of a dominant AGN source, one of a typical H II region, and one of a PAH-dominated photodissociation region (PDR)—and attempt to identify the relative contribution of each template to any measured spectrum. If we use the ratio of the 6.2 μm PAH flux to the underlying continuum flux at 5.5 μm as a tracer of the contribution of the quiescent star formation and PDRs to the integrated galaxy flux, then both AGN and H II regions will display a very low value. Similarly, the ratio of the 5.5 to the 15 μm flux will be low for starbursts, since they lack the extreme radiation field that heats up the dust (presumably in a torus) to high temperatures. In Figure 8, we present a revised version of the Laurent et al. (2000) diagram using the 15 to 5.5 μm flux ratio (15/5.5 μm) versus the 6.2 PAH over 5.5 μm continuum ratio (6.2/5.5 μm). Here, 3C 273 (Hao et al. 2005) is chosen to represent the “pure” AGN (although this object only has an upper limit on the measured 6.2 μm PAH flux), while M17 and NGC 7023 are chosen to define the H II region and PDR vertices, respectively. ISO SWS data are used for M17 and NGC 7023 (Peeters et al. 2004). As in Figures 5 and 6, AGNs, starbursts, and ULIRGs measured with the IRS are overplotted for comparison. Simple linear mixing lines are indicated between each vertex on the plot. For any position, one can then estimate the relative fraction of AGNs and young stars to the dust heating. Just as in the excitation diagrams based on the [Ne v] and [O iv] emission lines, the ULIRGs scatter between pure AGNs and pure starbursts in Figure 8. However, in this diagram, the ULIRGs appear on average to have much larger AGN fractions due to their low 15/5.5 and 6.2/5.5 μm flux ratios. Note, however, that the pure starburst galaxies also have low 15/5.5 μm flux ratios as compared to H II regions, and at least five ULIRGs have 15/5.5 μm flux ratios consistent with the range defined by the starbursts, which themselves have 15/5.5 μm about 1/10 as large as the H II regions. Most of the separation between AGNs and starburst galaxies in Figure 8 occurs in the 6.2/5.5 μm axis, where Mrk 463, Mrk 231, IRAS 08572+3915, IRAS 05189+2524, IRAS 15250+3609, and Mrk 1014 are at least 90% AGNs.

### 3.4. Spectral Energy Distribution Fitting

To estimate the effect of dust emission at different temperatures on the ULIRG spectral energy distributions (SEDs) and to measure the strengths of the PAH emission features against the underlying, silicate-absorbed continuum, we have fit the spectra with a multicomponent model that includes 2–3 graphite and silicate dust grain components, PAH emission features (fit with Drude profiles), a 3500 K blackbody stellar component, and unresolved

**TABLE 5**

| Object     | 15/5.5 | 6.2/5.5 | C2H2   | HCN    |

**Notes.**—Absorption features in the BGS ULIRG data. Col. (2): Silicate optical depth. Cols. (3) and (4): EQW (in units of 10⁻³ μm) of the C₂H₂ and HCN features at 13.7 μm and 14.0 μm, respectively.
Gaussian emission lines (for the fine-structure and H$_2$ lines). The basic steps in the fitting method are (1) the creation of a PAH and continuum spectrum by subtracting a first estimate of the emission lines from the observed spectrum; (2) a first fit to the continuum and PAHs followed by a subtraction of the continuum, plus the estimated lines from the observed spectrum; (3) a fit to the resulting PAH spectrum followed by a subtraction of the PAH and continuum fit to create an observed emission line spectrum; (4) a fit to the resulting spectrum to produce the next estimate of the line strengths; and finally (5) a repeat of the process if the reduced $\chi^2$ is improved by more than 1%. The initial PAH template is derived from the IRS spectrum of the starburst galaxy NGC 7714 (Brandl et al. 2004). We assume that the PAH emission is unextinguished, yet the PAH feature ratios are free to vary. For a full description of the fitting procedure, see Marshall et al. (2006). To extend the SEDs, we have added near-infrared and far-infrared data from Scoville et al. (2000), Moshir et al. (1990), Klaas et al. (2001), and Benford (1999) to the IRS low-resolution spectra, where available. The results of the fitting are presented in Table 6 and Figure 9. While this sort of multicomponent fitting over such a large range in wavelength does not necessarily produce a “unique” fit to the data, the extremely high signal-to-noise ratio IRS spectra of the BGS ULIRGs do provide valuable constraints over the critical 2–38 $\mu$m rest-frame range, where warm dust is important. In all cases we determine the best fit by reducing the $\chi^2$ residuals over the entire spectral range.

In most cases the fit is extremely good. In some cases, e.g., IRAS 08572+3915 and IRAS 15250+3609, the detailed absorption profiles (silicate, water ice, and hydrocarbon) are not matched. For the water ice and hydrocarbon absorptions that are evident between 5.5–6.5 $\mu$m, we have used a template profile based on the spectrum of UGC 5101 to fit all the ULIRGs, and clearly there is substructure in the profiles among the ULIRGs that is not accounted for by this method. In the case of the silicate

![Fig. 7.—Observed [Ne v] 14.3 $\mu$m line flux, scaled to total infrared (8–1000 $\mu$m) flux vs. the IRAS 25/60 $\mu$m flux density ratio for the same sources as in Fig. 5. The vertical axis is in units of 10$^{-4}$. The upper panel shows the ULIRGs alone, while the lower panel shows the ULIRGs together with the AGNs and starburst galaxies. The dotted vertical line indicates the dividing line between “cold” (25/60 $\mu$m < 0.2) and “warm” (25/60 $\mu$m > 0.2) IRAS sources.](image-url)
absorption (dominating the continuum at 9.7 and 18 μm), some of the profile mismatches may be due to the presence of crystalline silicates. The observed crystalline to amorphous silicate fraction is known to vary among ULIRGs (Spoon et al. 2006). Our simple model includes only amorphous silicates, and thus we expect some profile mismatches in the most heavily obscured sources.

For the BGS ULIRGs and the four comparison sources listed in Table 6 (Mrk 1014, Mrk 463e, NGC 6240 and NGC 7714; Armus et al. 2006; Marshall et al. 2006; Brandl et al. 2004), we are asking a simple question: does the IRS data, when coupled with the NIR and FIR data from the literature, provide evidence for a component of hot dust in the continuum, and if so, what is the fractional contribution of this hot dust to the bolometric luminosity of the source? We define a “hot” dust component as one with a characteristic blackbody temperature of \(T_H \geq 300\) K. A spectral component with \(T = 300\) K represents grains with temperatures up to about 600 K, which is the temperature expected for a graphite grain in thermal equilibrium at a distance of about 10 pc from an AGN source with \(L = 10^{12} L_{\odot}\), near the upper envelope usually estimated for the inner radius of a dusty torus surrounding an AGN of this luminosity. Although individual Galactic star-forming regions can produce very hot dust (e.g., van der Tak et al.)
The mid-infrared nuclear spectra of pure starburst galaxies do not have measurable quantities of dust at this temperature (Marshall et al. 2006; Brandl et al. 2006), so detection of hot dust in a nuclear spectrum provides indirect evidence for a buried AGN. Dust with $T_D > 700$ K implies the existence of significant numbers of grains at the sublimation temperature of graphite (about 1200 K), which would emit at radii of about 1 pc from a central source of $10^{12} L_\odot$.

We find evidence for a hot dust component in 5 out of the 10 BGS ULIRGs, namely Mrk 231, Arp 220, IRAS 05189$-$2524, IRAS 08572$+$3915, and UGC 5101. The best-fit temperature of the hot component ranges from $\sim 450$--$850$ K among these five sources. The ratio of the luminosity in the hot component to the total luminosity (uncorrected for extinction) ranges from less than 1% in Arp 220 to 23% in IRAS 08572$+$3915. While the extinction to the hot dust component is fit in the modeling, the correction is highly uncertain, ranging from a factor of about 1.5 in IRAS 05189$-$2524 to a factor of 5 in UGC 5101. Corrected values of $L_H/L_{IR}$ are generally accurate to only 20%--30%, and should never exceed 1.0 (see col. [7] of Table 6). The extremely large correction tabulated for IRAS 08572$+$3915 in Table 6 (more than a factor of 10) is probably an overestimate, brought on by a poor fit to the silicate absorption profile (see Fig. 9), which may be (in part) caused by the presence of crystalline silicates (Spoon et al. 2006). The remaining five BGS sources (Mrk 273, IRAS 15250$+$3609, IRAS 22491$-$1808, IRAS 12112$+$0305, and IRAS 14348$-$1447) have no compelling evidence for a measurable hot dust component. While the addition of another dust component does indeed lower the reduced $\chi^2$ of the fit, the temperature of this component is always below 250 K, and in most cases the “hot” and “warm” dust components overlap significantly when we impose this third dust component on the fit. In addition to the BGS sources, Mrk 1014, Mrk 463e, and NGC 6240 are also well fit with a hot dust component, and these are included in Table 6, as well as the fit to the starburst galaxy NGC 7714 (which has no hot dust emission).

As a way to measure the total “hot” plus “warm” dust luminosity in the ULIRGs, which is less subject to the definition of precise temperature of the components, we calculate the 1--40 $\mu$m dust luminosity as a function of the total infrared luminosity for all sources in Table 6 (col. [8]). The ratios range from a low of 19% in Arp 220 to a high of 81% in Mrk 463e, before any corrections for extinction. This ratio generally measures the flatness of the spectrum, taking care to exclude the prominent emission features (PAH and fine-structure lines) and stellar emission in the NIR. As expected, the flattest BGS ULIRG spectra, namely Mrk 231, IRAS 05189$-$2524, and IRAS 08572$+$3915, have the largest $L_{1.4-24}/L_{IR}$ luminosity ratios. These are also the sources with the largest hot dust luminosity ratios. The corrected values are generally very high (35%--100%), but again these corrections are most uncertain in the galaxies with very deep 9.7 $\mu$m absorption features whose profiles are poorly fit.

Finally, we tabulate the PAH to total luminosity ratio for the BGS ULIRGs and comparison sources in column (9) of Table 6. These ratios are uncorrected for extinction. The largest ratio (4.4%) is found in NGC 7714, while the smallest is seen in Arp 220 and Mrk 463e (0.4%). The extremely small $L_{PAH}/L_{IR}$ ratio for Arp 220 has been noted before (e.g., Spoon et al. 2004). Although Arp 220 is usually referred to as the “prototypical” ULIRG, the relative PAH strength is actually quite low among ULIRGs as a class, especially those optically classified as starbursts.

### 4. DISCUSSION

#### 4.1. AGN and Starburst Diagnostics

The greatly increased sensitivity of the IRS and Spitzer, coupled with the narrower slits of the IRS, provide better isolation of the nucleus against the galactic disk than was possible with the ISO spectrographs, increasing our ability to detect the signatures of weak (or obscured) AGNs in the mid-infrared. Our regularly achieved flux limits after very short integration times and the
detection of previously unseen AGN signatures in some ULIRGs and starburst galaxies (Armus et al. 2004, 2006; D. Devost et al. 2007, in preparation) attest to this advancement. However, among the brightest ULIRGs (the 60 μm selected BGS sample), we have detected high-ionization lines in only 3 out of 10 galaxies, namely UGC 5101, Mrk 273, and IRAS 05189+2524. Of these three, one (Mrk 273) had a previous [Ne v] detection with the SWS (Genzel et al. 1998) and two are optically classified as Seyfert 2 galaxies (Mrk 273 and IRAS 05189+2524). Fitting the SEDs, we see evidence for hot \( T > 300 \) K dust in 5/10 of the BGS ULIRGs, namely UGC 5101, IRAS 05189+2524, Mrk 231, IRAS 08572+3915, and Arp 220. The temperature of this hot dust is highest in UGC 5101 and Arp 220, but also the fraction of the total luminosity is low in these sources, especially in Arp 220 where it is \(<1\%\). Although Mrk 273 has high-ionization emission lines, the spectral shape is relatively steep, and the addition of a hot dust
component does not significantly improve the fit. If we add the three nearby, bright ULIRGs from Armus et al. (2004, 2006), Mrk 1014, Mrk 463e, and NGC 6240, all of which have high-ionization lines and hot dust, we have 6/13 with \([\text{Ne} \text{v}]\) emission and 8/13 with hot dust.

In Table 7 we have assembled classifications for the optical/near-infrared, mid-infrared (IRS), and X-ray for the 10 BGS ULIRGs along Mrk 1014, Mrk 463e, and NGC 6240. The IRS classifications are based on the presence and strength of \([\text{Ne} \text{v}]\) and \([\text{O} \text{iv}]\) emission, the MIR spectral shape, the 6.2 \(\mu\text{m}\), and total PAH emission. In general the \([\text{Ne} \text{v}]\) and \([\text{O} \text{iv}]\) based AGN fractions agree within a factor of two. In IRAS 05189–2524 the \([\text{Ne} \text{v}]\) line seems unusually strong (with respect to \([\text{O} \text{iv}]\)) and in Mrk 273 and NGC 6240 the opposite is true (\([\text{Ne} \text{v}]\) appears weaker). In most cases the AGN fraction estimated from the high-ionization lines is much lower than that estimated from the strength of the PAH emission or the MIR slope. While some ULIRGs have very small AGN fractions, as evidenced by a lack of \([\text{Ne} \text{v}]\), weak \([\text{O} \text{iv}]\), and strong PAH emission (e.g., IRAS 22491–1808), many sources, including those with obvious AGN signatures in the optical or near-infrared (e.g., Mrk 231, Mrk 273, and Mrk 1014) have weaker \([\text{Ne} \text{v}]\) and/or \([\text{O} \text{iv}]\) emission than expected given their measured PAH strength. This is also true for some of the ULIRGs classified as LINERs (e.g., UGC 5101 and NGC 6240), for which we have detected very weak \([\text{Ne} \text{v}]\) emission (from a buried AGN) and PAH emission that is weaker than in pure starburst galaxies. The high-ionization tracers never suggest a larger AGN fraction than is indicated by the strength of the PAH emission or the MIR slope.

Like Mrk 231 and IRAS 08572+3915, IRAS 15250+3609 has very weak PAH emission, but no detectable \([\text{Ne} \text{v}]\). In IRAS 15250+3609 the presence of water ice and hydrocarbon absorption makes an accurate estimate of the 6.2 \(\mu\text{m}\) PAH emission very difficult, and there is a possibility that we have underestimated the strength of this feature. Like the extreme example of Arp 220, most of the activity in IRAS 15250+3609 is probably deeply buried, even when observed in the mid-infrared. It is not surprising that this system also has the strongest C2H2 and HCN absorption bands of the BGS sample.

An important caveat to using the \([\text{Ne} \text{v}]/\text{[Ne} \text{ii}]\) line flux ratio to quantitatively estimate the AGN fraction in any particular source is that the line ratio is not independent of extinction, even though the \([\text{Ne} \text{v}]\) and \([\text{Ne} \text{ii}]\) lines are very close in wavelength. The \([\text{Ne} \text{v}]\) emission comes from a region of hot, tenuous gas surrounding the central source, known as the coronal line region (CLR). The \([\text{Ne} \text{ii}]\), on the other hand, can have a significant contribution from an extended, foreground starburst. This may partly explain the extremely low \([\text{Ne} \text{v}])/\text{[Ne} \text{ii}]\) levels in UGC 5101 and NGC 6240. In both of these ULIRGs the PAH emission suggests a much larger AGN fraction than is apparent from the \([\text{Ne} \text{v}]\) emission. Even correcting the observed \([\text{Ne} \text{v}]\) emission for the extinction implied by the silicate optical depths, \(\tau \sim 1.2\) (or \(A_V \geq 22\) mag) for NGC 6240 and \(\tau \sim 1.6\) (or \(A_V \geq 31\) mag) for UGC 5101, while substantial, moves neither galaxy into the pure AGN area.
of Figure 5, nor increases the [Ne v] enough to make the AGN fractions comparable to those estimated from the PAH emission—and this is assuming that all the correction is made to [Ne v] and that none of the [Ne ii] is obscured, which is highly unlikely. So, while extinction may be a factor in the measured [Ne v]/[Ne ii] flux ratios and the true AGN fractions may be higher than those listed in Table 7, for the ULIRGs with extremely weak yet detected [Ne v] emission (like UGC 5101 and NGC 6240), the apparent silicate optical depths are not large enough to derive corrected ratios, which implies a significant AGN contribution to the total power budget.

Of course, the apparent silicate optical depths, derived from smooth fits to the continuum, are always lower limits to the extinction, since they do not take into account foreground continuum, PAH, or, most importantly, silicate emission. As discussed in Armus et al. (2006) in the context of NGC 6240, the $\tau_{\text{PAH}}$ list in Table 6, which can be very large, may be a more accurate estimate of the optical depth at 10 $\mu$m, since it does explicitly correct for silicate emission. For UGC 5101 and NGC 6240, using the $\tau_{\text{PAH}}$ estimates to correct the measured [Ne v] emission effectively increases the estimated AGN fraction to ~80% and ~20%, respectively, making both much more consistent with the estimates derived from the PAH emission and MIR slopes.

Hard X-ray observations of NGC 6240 and UGC 5101 suggest a significant AGN contribution, after correction for extremely large H i columns of $1-2 \times 10^{24}$ cm$^{-2}$ (Vignati et al. 1999; Imanishi et al. 2003). In fact, NGC 6240 has the largest $L_{\text{X}}/L_{\text{IR}}$ ratio of any ULIRG observed to date, ~250$-740 \times 10^{-4}$, comparable to those found for Seyfert galaxies and quasars (Ptak et al. 2003), suggesting that the central AGN contributes as much as 50%–100% of the bolometric luminosity (see also Lutz et al. 2003). The large uncertainty in the extinction-corrected hard X-ray flux is due to an uncertain correction for reflected light. Seyfert 2 galaxies generally have values of 50–500, while Seyfert 1 galaxies have values of 200–2000 (Ptak et al. 2003). The third column of Table 7 gives the hard X-ray to infrared luminosity ratios for the 13 ULIRGs discussed here. Although there is a large spread, in all cases the ULIRGs with significant AGN contributions (as measured either in the optical/NIR or MIR spectra) have $L_{\text{X}}/L_{\text{IR}} > 10-20 \times 10^{-4}$. The IR starburst-like ULIRGs, including some with LINER-like optical spectra, all have $L_{\text{X}}/L_{\text{IR}} < 1 \times 10^{-4}$. The ULIRG with the largest [Ne v]/[Ne ii] line flux ratio, Mrk 463e, has a relatively low $L_{\text{X}}/L_{\text{IR}}$ ratio, for AGNs. While the CLR is relatively unobscured in this Seyfert 2 ULIRG, apparently the accretion disk is visible only behind significant H i; in this case, a column of about $2 \times 10^{23}$ cm$^{-2}$ (Bassani et al. 1999).

While there are sources with both high-ionization lines and hot dust, the groups do not completely overlap, even though these are both tracers of a (buried) AGN. This can be explained by realizing that the [Ne v] and the hot dust are being generated in two different regions. The hot dust comes from either a shell at a radius of 1–10 pc or the inner edge of an obscuring torus at a similar radius. If the dust is in a torus that is nearly edge-on, the coronal-line region, which gives rise to the [Ne v] emission, may actually be easier to observe in the mid-infrared if it has a scale height that is larger than the thickness of the torus. Evidence for relatively large CLRs (tens of parsecs) in some nearby Seyfert galaxies has indeed been found (e.g., Maiolino et al. 2000; Almudena Prieto et al. 2005). On the other hand, if the torus is slightly tilted, affording us a view of the hot, far-side inner edge, both the [Ne v] and the hot dust would be observable. However, an underlying uncertainty in the detectability of the CLR is that both the

extinction toward and the covering factor of the [Ne v]-emitting clouds (i.e., what fraction of the ionizing radiation the clouds intercept) are neither known nor constant from source to source.

Three of the ULIRGs (Mrk 231, Arp 220, and IRAS 08572+3915) have evidence for hot dust, but no detected [Ne v]. One source, Mrk 231, is anomalous. It has an optically detected broad-line region, a flat mid-infrared spectrum (indicating hot dust), and yet no detected [Ne v] emission. While the broad lines are polarized, and probably contain a significant scattered component (Hines et al. 2001), it is unlikely that the absence of [Ne v] can be explained by extinction toward the CLR, since hot dust is observed, as evidenced by the shape of the mid-infrared spectrum, and this dust is likely to be only a parsec or so from the central source. In Mrk 231, the covering factor of the nucleus by the coronal-line clouds may be very small, resulting in an unusually small or weak coronal-line region (compared to other dusty AGNs, like Mrk 1014 or Mrk 463). Alternatively, the hot dust may be coming from a warped disk just outside of the coronal-line region, effectively blocking the [Ne v] emission from our line of sight. The second source, Arp 220, is less surprising. Spoon et al. (2004) suggest that much of the power source remains hidden along our line of sight, even in the mid-infrared. We have fit the SED with a hot dust component, but the contribution of this component to the total infrared luminosity is very small, and therefore this detection remains uncertain. We can obtain a poorer fit to the data by removing the hot dust and allowing the stellar emission to be obscured by $A_V \sim 12$ mag, but since the hot dust contribution is so small, either fit is still viable. The third source with evidence for hot dust but no detectable [Ne v] emission is IRAS 08572+3915. This has perhaps the strongest mid-infrared spectrum of the local ULIRGs. IRAS 08572+3915 has the largest silicate absorption and yet the flattest mid-infrared spectrum (when normalized at rest-frame 60 or 25 μm) of the BGS ULIRGs. The silicate profile suggests crystalline silicates (Spoon et al. 2006), with an $A_V$ of at least 78 mag. Clearly there is an enormous amount of extinction toward the nucleus, and yet a large amount of hot dust emission escapes without being “downgraded” into the far-infrared. The $L$-band spectroscopy of this source also shows strong absorption by dust, with little or no 3.3 μm PAH emission (Imanishi et al. 2006). Ground-based 10 and 20 μm spectrophotometry first led Dudley & Wynn-Williams (1997) to suggest that IRAS 08572+3915 harbored a buried AGN. ULIRGs like IRAS 08572+3915 may be rare, representing a population of buried AGNs, which are not readily detectable by means other than their unusual mid-infrared colors (see below).

4.2. Mid-Infrared Colors

Local galaxies display a wide range of mid-infrared spectral shapes due to the presence of dust in emission and absorption. In particular, the PAH emission features at 6.2, 7.7, 8.6, 11.3, and 12.7 μm, and the silicate absorption bands at 9.7 and 18 μm dominate the spectra of dusty galaxies over a large range in luminosity. Since these features are strong and very broad, they can be detected in broadband photometry and serve as crude redshift indicators for sources that are highly obscured in the optical and even too faint for mid-infrared spectroscopy with the IRS. Recent studies of mid-infrared selected galaxies have shown that low-resolution IRS spectra can be used to obtain redshifts of $z = 2–3$ ULIRGs with 24 μm flux densities $f_{24} \geq 0.7$ mJy and optical magnitudes of $R \geq 24–25$ mag (Houck et al. 2005; Yan et al. 2005). Since the silicate absorption at 9.7 μm can often be the strongest feature in the mid-infrared spectrum of a highly obscured galaxy, such as a ULIRG, a combination of IRS blue peak-up filter 16 μm imaging together with IRAC 8 μm and MIPS 24 μm data can easily pinpoint the most obscured systems. In particular, the 16/24 and 8/24 μm flux density ratios, when compared to local templates, can be used to select obscured galaxies at $z = 1–2$. Highly obscured systems will exhibit a sharp increase in the 8/24 and 16/24 μm flux density ratios as the 9.7 μm silicate absorption passes through the MIPS 24 μm filter bandpass (Takagi & Pearson 2005).

As a way to “calibrate” searches for $z \sim 1.5$ ULIRGs, we present the 8/24 and 16/24 μm color ratios for the BGS ULIRGs in Figures 10 and 11. We also include the nearby starburst galaxy NGC 7714 (Brandl et al. 2004) for comparison. In all cases, the synthetic color ratio has been calculated using the observed IRS spectra, the published IRS blue peak-up, MIPS 24 μm filter functions, and, for the case of the 8/24 μm plot, the ground-based NIR photometry used in the SED fitting. The latter is required because the blue edge of the IRAC 8 μm filter bandpass moves below the short-wavelength cutoff of the IRS SL second-order spectrum for $z > 0.3$. The ULIRGs in both plots show qualitatively similar behavior, namely a peak in the flux ratios at $z \sim 0.3$ and $\sim 1.3$ caused by the silicate absorption bands entering the MIPS 24 μm filter. However, the extremely blue colors predicted for some ULIRGs at $z \sim 1.3$ in the 16/24 μm flux ratio plot are striking. The galaxy with the strongest signal (bluest colors) in Figure 11, IRAS 08572+3915, has the deep silicate absorption at 9.7 μm and a relatively flat (warm) mid-infrared SED. Starburst-like ULIRGs, even those with strong silicate absorption, typically have 16/24 μm colors of 1–2 at $z = 1.3$. AGN-like ULIRGs with little absorption are even redder. IRAS 08572+3915 and, to a lesser extent, IRAS 15250+3609 have extreme colors, well above 16/24 μm $= 3$. Galaxies such as IRAS 08572+3915, while rare, may be found in dedicated IRS blue peak-up and MIPS 24 μm observations.
imaging surveys. Both Takagi & Pearson (2005) and Kasiwai et al. (2005) estimate that there may be up to a few hundred “silicate dropouts,” per square degree, based on model predictions and the results of early Spitzer surveys. It is the combination of a relatively flat, mid-infrared spectrum (indicating significant amounts of hot dust) and deep silicate absorption that give IRAS 08572+3915 its extreme mid-infrared colors.

5. SUMMARY

In this paper we have presented mid-infrared 5–40 μm spectra of the ULIRGs in the IRAS Bright Galaxy Sample, taken with the IRS on Spitzer. Among this small sample there is a very large range in mid-infrared spectral properties (slope, absorption lines, emission lines) reflective of a variety of excitation conditions and ISM densities. We find

1. A factor of 50 spread in the spectral slope from 60 to 5.5 μm in the rest frame. IRAS 08572+3915 is the flattest (bluest) while Arp 220 is the steepest (reddest) among the BGS ULIRGs.

2. The 9.7 μm silicate optical depths range from τ_{9.7} ≤ 0.4 in IRAS 05189–2524 to τ_{9.7} ≥ 4.2 in IRAS 08572+3915, implying line-of-sight (apparent) extinctions of A_{9.7} ≥ 7.9 mag to more than A_{9.7} ≥ 78 mag. IRAS 08572+3915 has both the flattest spectral slope and the deepest silicate absorption of the BGS ULIRG sample.

3. Evidence for water ice and hydrocarbon absorption (from 5.5–6.5 μm) in 7/10 BGS ULIRGs, as well as absorption features of C_{2}H_{3} and HCN, in 4 and possibly 6 of the 10 BGS ULIRGs, indicating shielded molecular clouds and a warm, dense ISM in these objects.

4. The presence of [Ne v] emission at 14.3 and 24.3 μm in 3 out of the 10 BGS ULIRGs: IRAS 05189–2524, Mrk 273, and UGC 5101, with 14.3 μm line fluxes of 18.36, 12.86, and 5.10 × 10^{-14} ergs cm^{-2} s^{-1}, and [Ne v] 14.3 / [Ne ii] 12.8 line flux ratios of 0.85, 0.24, and 0.12, respectively. The remaining seven BGS ULIRGs have upper limits on their [Ne v] / [Ne ii] line flux ratios that range from ~0.01 to 0.15.

5. Fitting the SEDs, we see evidence for hot (T > 300 K) dust in 5/10 of the BGS ULIRGs, namely UGC 5101, IRAS 05189–2524, Mrk 231, Arp 220, and IRAS 08572+3915. The fraction of hot dust to total dust luminosity is highest in IRAS 08572+3915 (~23%, before correcting for considerable extinction) and lowest in Arp 220 (≤1%). The temperature of this hot dust component ranges from ~450–850 K. Mrk 463e, Mrk 1014, and NGC 6240 also show evidence for hot dust in their spectra.

6. Constructing excitation diagrams from the [Ne v] / [Ne ii], [O iv] / [Ne ii], and 6.2 μm PAH equivalent width (EQW) suggests that Mrk 463e, Mrk 1014, and IRAS 05189–2524 are AGN-dominated, while IRAS 12112+0305, IRAS 14348–1447, IRAS 22491–1808, and Arp 220 are starburst-dominated. Mrk 273 appears to have a significant starburst contribution (30%–50%) to its total luminosity. Mrk 231, IRAS 08572+3915, and IRAS 15250+3609 show very weak 6.2 μm PAH emission and yet are undetected in [Ne v] or [O iv], even though they are optically classified as a Seyfert 1 (Mrk 231) and LINERs (IRAS 08572+3915 and IRAS 15250+3609), respectively. Since both Mrk 231 and IRAS 08572+3915 have significant hot dust emission, it is likely that the coronal-line regions in these sources are unusually weak or absent. In the case of IRAS 15250+3609, the power source remains buried, even in the mid-IR. Two sources, UGC 5101 and NGC 6240, have very weak [Ne v] and hot dust emission, indicative of buried AGNs. This is supported by the fact that both of these sources have significant hard X-ray emission behind extremely large columns of H i (1–2 × 10^{24} cm^{-2}). In all ULIRGs in this study, except for Mrk 463 and Mrk 1014, the AGN fractions implied by either the [Ne v] / [Ne ii] or [O iv] / [Ne ii] line flux ratios (or their upper limits) are significantly lower than implied by the MIR slope or strength of the 6.2 μm PAH EQW feature.

7. Flux ratios between the IRS blue peak-up and MIPS 24 μm filters, constructed from the IRS spectra as a function of redshift for the BGS ULIRGs, imply significantly blue colors (large 16/24 μm flux ratios) at z = 1–2, peaking at z = 1.3, as previously suggested by Takagi & Pearson (2005). The one BGS ULIRG not observed with the ISO satellite, IRAS 08572+3915, has the most extreme colors of any local ULIRG (z ≤ 0.1), due to a combination of extremely deep silicate absorption and a flat SED in the mid-infrared. Extreme 16/24 μm colors are also predicted for IRAS F00183–7111 (Spoon et al. 2004; Takagi & Pearson 2005). Although the BGS sample of ULIRGs is small, this suggests that perhaps up to 10% of ULIRGs may have unusual colors indicative of deeply buried AGNs. These sources should be found from their IRS blue and MIPS 24 μm colors in Spitzer imaging surveys now planned or underway.

Even among the nearest, brightest ULIRGs there is a startlingly large range in PAH equivalent width, high-ionization emission line flux ratios, and spectral slope. We find evidence for AGNs in the mid-infrared spectra of ULIRGs with optical/ NIR Seyfert or LINER classifications. We do not find evidence for buried AGNs in ULIRGs classified optically as starburst-like among the BGS sample. However, the AGN fractions implied by the [Ne v] / [Ne ii] or [O iv] / [Ne ii] line flux ratios are often significantly lower than suggested by either the mid-infrared slope or the
strength of the 6.2 μm PAH feature. Although we have yet to analyze the full IRS ULIRG sample, the idea of a “typical” ULIRG mid-infrared spectrum appears to be much less useful in light of the results of this survey thus far.

We would like to thank Bruce Draine, Aaron Evans, Dean Hines, David Hollenbach, Mark Lacy, Els Peeters, and Jason Surace for many helpful discussions. Support for this work was provided by NASA through an award issued by JPL/Caltech.
